The comments on the paper come from engineers representing the interests that are bringing about the noteworthy advances in the art of sewage disposal. The discussion includes remarks by consulting and sanitary engineers, a research investigator, an experienced plant operator, and a representative from a firm supplying appliances used in sewage disposal. It is gratifying to realize that the improvements in sewage disposal methods are being followed so closely by people representing so many different points of view, and to know how each group recognizes its dependence one upon the other.

Mr. Eddy has traced the development of sewage disposal, and has pointed out the trend toward more elaborate and costly plants. He has described certain of the difficulties that this trend involves. Many of the plants now being constructed require highly technical supervision in their operation. The fact that it is difficult to secure operators with adequate training may perhaps be classified as a "growing pain" which may soon be overcome. The various sewage works associations, with the co-operation of some of the State boards of health and the educational institutions, are now making determined efforts to increase the technical knowledge and ability of sewage plant operators. Mr. Donohue makes the argument in this connection that, if equipment requiring expert supervision is installed, the necessary supervision will be supplied and the operation of the plant as a whole will benefit thereby.

It is to be expected that the cost of disposal works will be higher than was formerly necessary. In many cases the necessity for sewage disposal depends on the concentration of population, where means for the assimilation of sewage in the natural bodies of water are limited. The increase of population creates increased land values and may make it impossible to secure isolated sites,

\* "Fortschritte in der Ausfäulung von Abwasserschläm," von Dr. Ing. Max Prüss, 1928.

† Chf. Engr., Ward's Island Sewage Treatment Works, New York, N. Y.

where some of the cruder methods of disposal might be practiced. The trend is, therefore, toward the construction of plants on a limited area capable of bringing about a high degree of purification, and doing this without the production of objectionable odors that will lower adjacent property values.

The demands made in many cases require a more or less complicated plant, and the amounts invested certainly warrant highly trained technical supervision. It would be false economy indeed, to withhold proper compensation for such service. After all, the fact that complete disposal of sewage can usually be secured at a cost of about \$1 or \$2 per capita per year, permits little criticism of such an expenditure for so important a necessity.

The discussions by Mr. Besselievre and Mr. Allen bring out some of the differences of opinion that are common in sewage disposal practice. Mr. Allen thinks there may be some advantage in digestion in separate stages, and points out the disadvantage of mechanical stirring, in that some of the fresher sludge is discharged with the more thoroughly digested material. It seems that more data are necessary to establish definitely the fact that there are practical advantages in several separate digestion stages.

The action in a digestion tank, as described by Dr. Rudolfs, where the solids in a state of gasification are constantly rising and falling, depending on whether or not bubbles of gas are attached to the particles, does, in effect, tend to separate the digestion processes to a certain extent; that is, the particles undergoing active gasification tend to remain in the upper part of the tank, while those which have become inert work their way toward the bottom.

It would be interesting to compare the effectiveness of the gentle stirring caused by a mechanical contrivance, with the stirring action of these rising gases of digestion. It will be recalled that many years ago, Dr. Imhoff used this argument among others, in advocating the use of deep tanks, when, as in this case, there would be better stirring action owing to the increased amount of gas produced per square foot of area.

The speculation of engineers, the researches of scientists, and the mechanical ingenuity of manufacturers are extremely valuable; but, after all, the results secured in operation are the most important. So it is that concrete results of operation, such as that given by Mr. Downes, are especially welcome.

### STUDIES OF SHEAR IN REINFORCED CONCRETE BEAMS\*

By T. D. MYLREA,† M. AM. Soc. C. E.

WITH DISCUSSION BY MESSRS. EDWARD GODFREY, C. A. P. TURNER, H. E. ECKLES,  
JACOB FELD, HARDY CROSS, P. WILHELM WERNER, AND T. D. MYLREA.

#### SYNOPSIS

Although much has already been written on the subject of shear in reinforced concrete and although design practice has become almost uniformly standardized, there still remain a number of unsettled problems in reinforced concrete design. Standardization, however many its advantages, may easily become synonymous with stagnation. In many respects it can be said that, in the interest of getting structures built, unsettled points have simply been allowed to drop. "This apparently works all right" has been answer enough. Recently, both structural steel and reinforced concrete have begun to feel the benumbing effects of standardization, and some rather drastic revisions have been made in structural standards. Whenever such revisions are made it is of prime importance to re-examine the basis of structural theory to check the assumptions on which it is founded, and to weigh carefully the supporting evidence of experiment.

The writer has attempted to do this in the case of shear in reinforced concrete. In so doing he does not wish to be regarded as a reactionary, but merely as one taking an inventory of stock, for he is satisfied that careful study will show that no serious consequences will follow the raising of certain allowable unit stresses on condition that such increases are not haphazard and that adequate provision is made for all details. In fact, many of the suggestions are in the nature of a survey of the possibilities of the future. It is necessary first to consider briefly the derivation of the usual formulas in order to take up a detailed discussion.

## NOTATION

The following notation is used throughout the paper:

- $n$  = the ratio of the moduli of elasticity,  $E_s$  and  $E_c$ .
- $E_s$  = the modulus of elasticity of steel.
- $E_c$  = the modulus of elasticity of concrete.
- $N$  = the number of reinforcing bars in a distance,  $B$ .
- $B$  = the length of a tension crack measured perpendicular to the bent of bars, assuming that it were possible for the crack to extend to the center of compression (which it never can do).
- $j$  = the ratio of the lever arm of the resisting couple to the depth,  $d$ .
- $d$  = the effective depth of a reinforced concrete beam.
- $s$  = the horizontal distance between stirrups or points at which reinforcing bars are bent up.
- $V'$  = an external shear resisted by reinforcing steel.
- $P$  = the average pull per stirrup.
- $a$  = the bent bar spacing, perpendicular to their direction.
- $\alpha$  = the angle of slope of the bent-up bars.
- $A$  = the length of the tension crack, assuming the direction of the crack to be at  $45^\circ$  and that it extends to the center of compression.
- $v$  = unit shear.
- $b$  = width of beam.
- $v_a$  = average unit shear.
- $v_m$  = maximum unit shear.
- $c$  = diagonal compression.
- $T$  = tension in a bar.
- $u$  = unit bond stress.
- $\Sigma o$  = the total perimeter of the reinforcing bars.
- $c_h$  = horizontal component of  $c$ .
- $c_v$  = vertical component of  $c$ .
- $w$  = uniformly distributed load.
- $k$  = ratio of depth of neutral axis to effective depth.

## STRESSES INDUCED IN WEB REINFORCEMENT

Just as longitudinal reinforcement is provided where longitudinal tension occurs in a reinforced concrete beam so, in the web, reinforcement should be provided to resist diagonal tension. The two phenomena are in no wise different from each other, the curve of tension being continuous along a stress trajectory. Yet confusion has often obscured this point, diagonal tension being regarded as a phenomenon of mysterious origin and much to be feared. If reinforcement is properly placed so that it can neither slip nor crush the concrete, and is provided in sufficient quantity, tension in a diagonal direction is no more to be feared than tension in any other direction. Such reinforcement may be either inclined or vertical and each requires special consideration.

Let Fig. 1 (a) represent a beam in which the web reinforcement consists of stirrups. Before cracking occurs, the displacement of the stirrups due to

flexure only will be as shown in Fig. 1 (b). At the top they will be closer together and at the bottom they will be farther apart, but there will be no change in total length. Due to shear only the detrusion of the concrete permits a movement of one stirrup vertically with respect to its neighbor, but still there is no change in length. (See Fig. 1 (c).) Therefore, before cracking takes place, neither flexure nor shear will cause any stress in vertical stirrups. This is confirmed in the experiments\* of A. N. Talbot, Past-President, Am. Soc. C. E., in some of which there even seemed to be evidence of slight compression in the stirrups when a low load was first applied. In other tests investigators have apparently detected slight tension from the very start. Much unfruitful argument has resulted concerning this point. Before cracking, a reinforced concrete beam behaves much as any other homogeneous beam. Since the shear is not uniformly distributed from top to bottom in such a beam, it is possible that below the neutral axis a vertical compression might exist, while above this axis there might be a slight tension. An embedded foreign body, such as a vertical stirrup, might thus register either tension or compression to a slight degree, depending on whether the measurement was made above or below this axis. The important feature, however, is what happens after the concrete cracks.

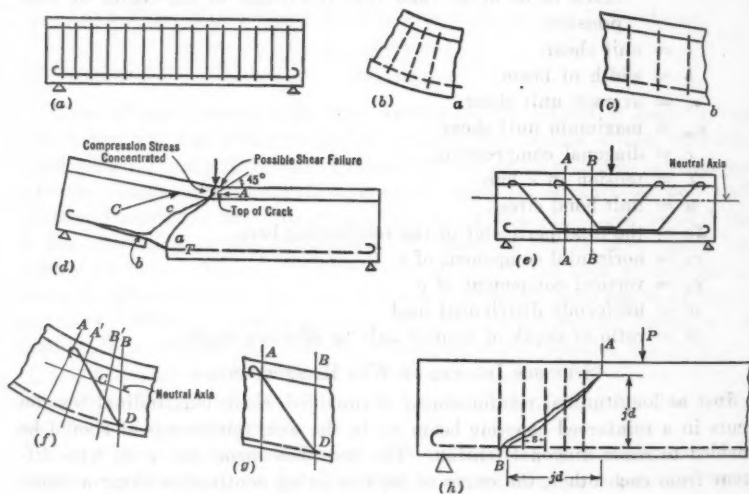

FIG. 1.—ELEMENTS OF VARIOUS REINFORCED CONCRETE BEAMS.

In a beam that is once cracked, diagonal tension failure, unresisted, would soon follow, as shown in Fig. 1 (d); but if the projecting lower cantilever, *a*, and the reinforcement at *b* were secured to the part marked *c*, failure would be greatly delayed. This is the function of vertical stirrups.

Consider the diagonal web reinforcement shown in Fig. 1 (e). Before cracking occurs, and under flexure alone, Sections *A* and *B* are moved rel-

\* Bulletin No. 28, Univ. of Illinois Eng. Experiment Station, p. 24.

ative to each other, as shown in Fig. 1 (f). Above the neutral axis there would be compression in the diagonal bar, due to the shortening of the length,  $AC$ , while tension would be found below in the length,  $CD$ . Due to shear alone (see Fig. 1 (g)), Section  $B$  being moved vertically in relation to Section  $A$ , the whole length,  $AD$ , is increased. Thus, as a result of the combined action of flexure and shear, tensile stress might be present in diagonal reinforcement, below the neutral axis at least, before any cracks appear, and such reinforcement would serve to toughen a beam under low loads better than vertical stirrups. Since adhesion may be considered perfect before cracks appear, the stress in the steel would not be greater than  $n$  times the stress in the surrounding concrete, in which,  $n = \frac{E_s}{E_c}$ . After the beam has cracked, the bars extending diagonally across the crack serve the same function in delaying failure as the vertical stirrups (see Fig. 1 (a)).

#### FORMULAS FOR WEB REINFORCEMENT

Let Fig. 1 (h) represent a half length of a beam subjected to that part of a constant external shear,  $V'$ , not "taken by the concrete". It is assumed that a crack will take place at an angle of  $45^\circ$ , as shown, even though it cannot extend to the center of compression. Let a section,  $A-B$ , be passed along the crack. Then, in performing their part of the duty of maintaining, as nearly as possible, the homogeneity of the beam, the stirrups merely suspend the right side of the beam from the left. The load,  $V'$ , is divided between  $N$ -stirrups, and (from Fig. 1 (h)):

$$N = \frac{j d}{s} \dots \dots \dots (1)$$

Therefore, if  $P$  is the average pull per stirrup,

$$P = \frac{V'}{N} = \frac{V' s}{j d} \dots \dots \dots (2)$$

In Fig. 2 (a), the web reinforcement consists of diagonal bars. Here, the load,  $V'$ , is carried by the vertical components of  $N$ -bars. From Fig. 2 (a):

$$a = s \sin \alpha \dots \dots \dots (3)$$

$$A = \frac{j d}{\cos 45^\circ} \dots \dots \dots (4)$$

$$B = A \cos (45^\circ - \alpha) \dots \dots \dots (5)$$

and,

$$N = \frac{B}{a} \dots \dots \dots (6)$$

The vertical component of one bar =  $P \sin \alpha$ . Therefore:

$$V' = N P \sin \alpha \dots \dots \dots (7)$$

Substituting in Equation (7) the values of  $N$ ,  $A$ , and  $B$  (from Equations (3), (4), (5), and (6)), and reducing,

$$V' = \frac{P j d (\cos \alpha + \sin \alpha)}{s} \dots \dots \dots (8)^*$$

\* For another proof, see *Technologic Papers No. 314*, U. S. Bureau of Standards, p. 392, by Messrs. W. A. Slater, A. R. Lord, and R. R. Zippredt.

Equations (2) and (8) may be transposed, to suit the requirements, so as to give (1) the vertical external shear that may be carried by the reinforcement in a beam of depth,  $d$ ; (2) the pull per stirrup or bent bar; and (3) the

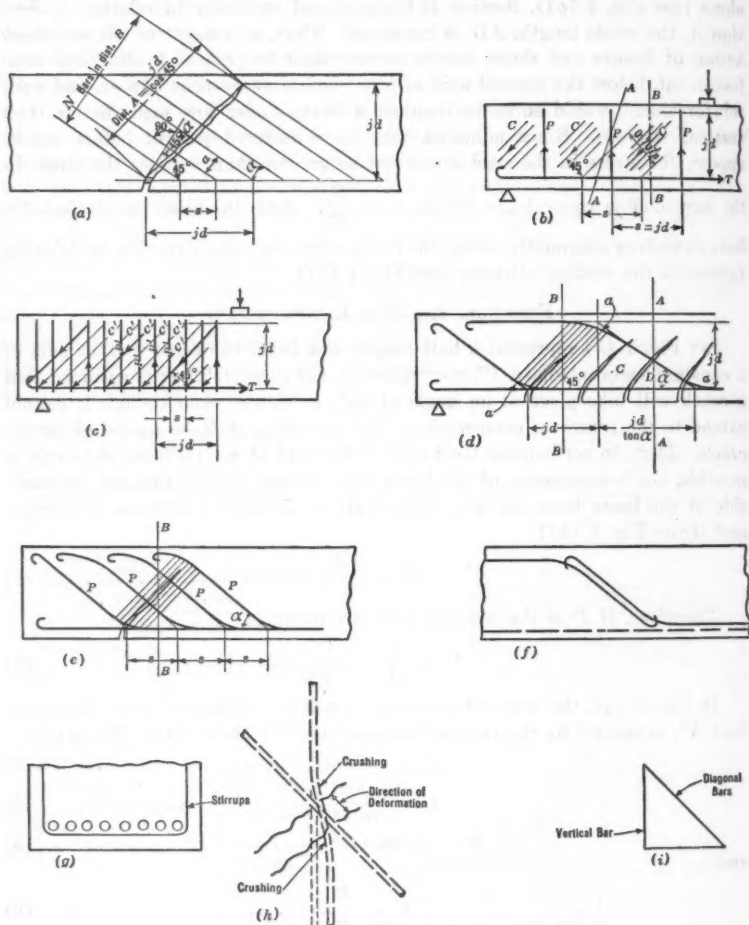

FIG. 2.—WEB REINFORCEMENT DETAILS.

required spacing. For the special case in which the slope of the reinforcement is  $45^\circ$ , Equation (8) becomes:

$$V' = 1.414 P j \frac{d}{s} \dots \dots \dots (9)$$

$$P = 0.707 \frac{V' s}{j d} \dots \dots \dots (10)$$

or,

$$s = \frac{1.414 P j d}{V'} \dots \dots \dots (11)$$

A comparison of Equation (11) with the value of  $s$  obtained by Equation (2), shows that, all other conditions being equal, bars of the same size spaced the same distances apart horizontally will resist 1.4 times as much shear when inclined at  $45^\circ$  as when they are vertical. Expressed in a slightly different way, to carry the same shear, bars at  $45^\circ$  might be spaced 1.4 times as far apart as vertical stirrups of the same cross-sectional area. Since, however, such bars are 1.4 times as long as vertical bars there is no saving in weight. In Equations (1) to (11), a uniform load may be provided for by using the average shear in the length,  $j d$ .

#### TRUSS ANALOGY

In Europe it is common practice to conceive the web reinforcement as the tension web members of a truss, the concrete acting in lieu of compression members inclined at 45 degrees. With vertical stirrups the imaginary truss would thus be of the Howe type, while with diagonal reinforcement it would be of the Warren type. If the bars are closely spaced the trusses are of the multiple-intersection Howe or Warren type, respectively, the compression being assumed always to act at an angle of 45 degrees.

In Fig. 2 (b), the stirrups are spaced at distances equal to the effective depth of the beam. By passing Section A-A it is seen that  $P = V'$ . If intermediate stirrups are inserted, as in Fig. 2 (c), the load,  $P$ , is divided among them in the ratio of  $\frac{s}{j d}$ . Then,  $P = V' \frac{s}{j d}$ , the formula developed for the member considered as a beam. (See Equation (2).)

In Fig. 2 (d), the distance between successive bends is  $j d + \frac{j d}{\tan \alpha}$ . Again, passing a section, A-A, and analyzing as a truss, the stress in any bent bar is:

$$P = \frac{V'}{\sin \alpha} \dots \dots \dots (12)$$

If intermediate bent bars are used at equal spaces,  $s$ , as shown in Fig. 2 (e), the total stress,  $\frac{V'}{\sin \alpha}$ , is divided among  $N$ -bars, and,

$$N = \frac{j d + \frac{j d}{\tan \alpha}}{s} \dots \dots \dots (13)$$

The stress in any one bar is, therefore:

$$P = \frac{\frac{V'}{\sin \alpha}}{\frac{j d + \frac{j d}{\tan \alpha}}{s}} = \frac{V' s}{j d \sin \alpha \left(1 + \frac{1}{\tan \alpha}\right)} = \frac{V' s}{j d (\sin \alpha + \cos \alpha)} \dots \dots \dots (14)$$

which is the same as Equation (8). It makes no difference, therefore, whether the member is conceived as a beam or as a truss, the resulting formulas for the

web reinforcement are the same. To be sure, in the truss analogy, bond between the longitudinal steel and Blocks *C* and *D* (Fig. 2 (*d*)) is neglected, but this factor is probably over-estimated, particularly at higher loads.

The truss analogy, however, makes evident a number of tendencies requiring caution in design. For example, unless the concrete is to be dangerously over-stressed at Points *a* (Fig. 2 (*d*)), long bends are seen to be imperative. At the same time it is evident from this analogy how careful the designer should be to extend the upper part of the bar back into the concrete far enough to provide an effective anchorage. It shows, too, that such a splice as that indicated in Fig. 2 (*f*) might be questionable, especially when the splitting effects of the hooks are taken into consideration. It shows how necessary it is to anchor the web reinforcement at both top and bottom strongly enough to develop its full tensile strength. No one familiar with structural steel design would think of providing web members of sufficient area to take the stress, and then only partly fastening them at the ends. Unless web members are fully developed above the cracks they are ineffective.

Furthermore, since a web member comes into play only after a beam has cracked, and since the diagonal compression (see Fig. 2 (*b*) and Fig. 2 (*c*)) is considered uniform through the whole thickness of the web, the vertical component must be taken up at frequent intervals across the web. Vertical stirrups, therefore, enclosing a large number of bars, as shown in Fig. 2 (*g*), are practically useless. The flexible lower reach of the stirrup can never prevent the inner bars from tearing out through the bottom of the beams at high loads, nor even prevent the loosening of the bond on the longitudinal bars at low loads. (See Fig. 1 (*d*) at Point *b*.)

#### COMBINATIONS OF BENT BARS AND STIRRUPS

Quite commonly there are not enough bars available for bending to resist shear, and vertical stirrups are introduced to assist. Generally, the same unit tensile stress is used in computing both bent bars and stirrups. Such a procedure, however, is not warranted.

It was shown that diagonal bars are stressed from the beginning. In concrete with an assumed tensile strength of 300 lb. per sq. in., and  $n = 10$ , this steel will be subject to a tension of  $300 \times 10 = 3\,000$  lb. per sq. in., before the crack occurs. Careful observations of cracks will show the deformations to be as depicted in Fig. 2 (*h*). The relative extension of diagonal and vertical bars, therefore, would be somewhat as shown in Fig. 2 (*i*), producing relatively higher stresses in the diagonal bars than in the stirrups. This ratio would be 1.4 to 1 if it were not for the tendency of the stirrups to crush into the concrete (see Fig. 2 (*h*)). Neglecting this crushing and assuming the maximum allowable steel stress to be 16 000 lb. per sq. in., the stress in the vertical

steel is only  $\frac{16\,000 - 3\,000}{1.4} = 9\,300$  lb. per sq. in. when the stress in the

diagonal steel is 16 000 lb. per sq. in. The unit stress developed in the stirrups being only 9 300 lb. per sq. in., they will have to resist their part of the shear at a unit stress not exceeding this value when the bent bars are stressed simultaneously to 16 000 lb. per sq. in. This, of course, becomes of much

more importance when dealing with the high stresses that can reasonably be anticipated to be the common practice of the near future.

It has frequently been observed that a beam with web reinforcement consisting of a combination of bent bars and stirrups usually develops somewhat higher shear strength than one reinforced with either bent bars or stirrups alone. In the beam thus reinforced the stirrups probably restrain the bent bars from breaking out through the sides of the beams under heavy loads.

From these considerations it may be expected that, in a beam subjected to an increasing load, the web reinforcement would act somewhat as follows: The diagonal bars would be stressed from the beginning. Simultaneously with the occurrence of a crack they would receive a large increment of stress, and the vertical stirrups would also come into action; but the stress in the diagonal bars would be greater than that in the stirrups. If the conditions are such that both bent bars and stirrups can be fully developed, the stresses in both will increase, but at a more rapid rate in the diagonals than in the stirrups. After the diagonals reach the elastic limit, they will deform without much increase in stress for a time, after which the stress will again increase, but at a slower rate. Meanwhile, the stress in the verticals will increase rapidly until in them, too, the elastic limit is reached. Therefore, until their usefulness is ended, the stress in the stirrups will always lag behind that in the bent bars. Such a lag was observed in the tests of the Emergency Fleet Corporation.\*

#### COMPARATIVE DEFLECTIONS

The deflection of beams with different web reinforcement might also be expected to vary. Since it requires a greater vertical movement at a crack to cause a given stress in vertical stirrups than in bent bars, then for a given steel stress a greater deflection will result in a beam reinforced with stirrups than in one of equal web strength reinforced with bent bars. If both bent bars and stirrups are used, an intermediate deflection will result, its magnitude depending on the proportion of each type of reinforcement. Thus, beams of equal strength may deflect differently. This is of no practical importance until great deflections occur, when the added increment of deflections permitted by the stirrups may result in earlier compression failure due to the concentration of compression stress near the top of the beam.

Some work has been done in an attempt to predict deflections. Turneaure and Maurer† have developed an analytical treatment of the subject and G. A. Maney, M. Am. Soc. C. E., has made an interesting study of test data.‡ It is rare that deflections need to be known in advance, and, except when limited to deflection under loads producing comparatively low stresses, attempts to predict them usually fail. In addition to the influence of the type of web reinforcement this uncertainty is probably due, in a large degree, to the fact that slip of any of the reinforcement strongly influences the results, and, as has been shown,§ slip occurs early in the load history of most beams. An attempt to

\* *Technologic Paper No. 314*, U. S. Bureau of Standards.

† "Principles of Reinforced Concrete Construction," Third Edition, 1919, Chapter VI.

‡ *Proceedings*, Am. Soc. for Testing Materials, 1914, p. 310.

§ "Bond and Anchorage in Reinforced Concrete," *Journal*, Western Soc. of Engrs., January, 1926.

treat, analytically, an action so dependent on the approximate homogeneity of the constituent parts cannot but fail when an unknown element of slip occurs.

A careful study of tests in which end slip as well as deflections has been observed, such as the tests of Bach,\* seems to indicate that until end slip begins, like beams, reinforced alike, will deflect alike. It may be anticipated that when design reaches the stage where such uncertain elements as end slip are eliminated, deflections can be predicted accurately.

#### PROPORTION OF THE SHEAR "NOT TAKEN BY WEB STEEL"

It was found early that, if the total external shear,  $V$ , were used in Equation (2), the computed stress in stirrups often exceeded the known ultimate strength of the steel, from which it was concluded that other influences were at work in resisting shear. It was suggested† that part of the shear is carried by the uncracked concrete at the top of the beam, and that,

"The actual proportion taken by the stirrups has not been established, but it seems that the stress cannot be more than two-thirds or three-fourths of the amount obtained by the formula."

It then became common practice to use only two-thirds of the total vertical shear in computing web reinforcement. Later, it was discovered that when the loading was such as to produce a greater shear at one end of a beam than at the other, the two-thirds rule gave apparently anomalous results, and practice has largely shifted to allowing a fixed value for the percentage of shear "taken by the concrete" (that is, shear not discernible in the steel). A value is generally taken that is a definite proportion of the ultimate compressive strength of the concrete cylinders when tested at the age of 28 days. In recent practice this proportion has been made to depend on the end anchorage of bars.

Confirmatory test data bearing on this phase are not plentiful. Some measurements have been made at the University of Wisconsin.‡ More recently, the results obtained by the Emergency Fleet Corporation§ have been published, and the University of Illinois Engineering Experiment Station has completed experiments|| extending over a period of years, which add much to the available data.

From other tests made at the University of Illinois,¶ it appears that, even up to the ultimate load, the ratio of measured to computed stress in stirrups does not exceed 65 or 70%, whereas in the longitudinal steel in the same beams the ratio was 85%, or more. Of course, on a bar encased in concrete, an extensometer does not measure the maximum unit deformation at a crack, but only the average between two points, and along a large part of the gauge length the steel stress is decreased by the concrete; but if this average is less in one set of like measurements than it is in another, it is only fair to assume that the maximum is also less in the first set. From this it may be concluded

\* *Deutscher Ausschuss für Eisenbeton*, Heft 38, 1917, by Dr. C. Bach and Prof. O. Graf.

¶ Master's thesis, by S. Uchlmera, Univ. of Illinois, 1922.

that, if the total vertical shear is used in solving Equation (2), the actual stress in stirrups in beams as ordinarily designed is less than the computed stress.

It is uncertain just to what extent other factors enter, but concrete capable of resisting compression should also be capable of resisting shear. Therefore, all the concrete above the crack (see Fig. 1 (*d*) and 1 (*h*), and Fig. 2 (*a*) to 2 (*d*)), undoubtedly offers considerable resistance to vertical shear, and, hence, under the usual design stresses an allowance for this effect is permissible.

The amount of the allowable reduction is still problematical. The deformation of a cracked beam is equivalent to a rotation about some point, *A* (Fig. 1 (*d*)), and the stirrup nearest the bottom of the crack would be strained and, consequently, stressed more than stirrups crossing the crack nearer the center of rotation. Nevertheless, the experiments quoted show that even in the stirrup that is stressed most the computed tension is more than the actual; and hence it would seem quite justifiable in ordinary work to assume that, if all the shear resisted by the concrete above the cracks were conceived as being uniformly spread over the whole cross-section of the beam, the average intensity thus found could be represented by some such value as one-fiftieth of the cylinder strength of the concrete. In the day when high shear values will be allowed this reduction will not be of great consequence, and it will be better to neglect it entirely. In fact, it will then be quite possible that, owing to the gradual time yield in shear of the concrete above the crack, the full shear,  $V$ , must be taken by the web reinforcement, and will be more nearly divided equally among the web bars crossing the crack.

#### SHEAR "TAKEN BY THE CONCRETE"

The phrase, "the shear taken by the concrete", has been confusing to many engineers. The preceding explanation is the one generally accepted. The laws of statics show, however, that the concrete may take all the shear, or only a part of it, depending on the form and distribution of the web reinforcement. For example, it is evident that on Section *B-B*, in Fig. 3 (*a*), the concrete resists all the vertical shear, and this capacity to resist shear is shared by the concrete both above and below the crack. A designer working in materials other than reinforced concrete would not hesitate to use two diagonal struts to carry a given diagonal compression, and he would not worry about a crack between them, providing neither strut could fail by buckling. Diagonal cracks, therefore, do not interfere with the capacity of the concrete in a beam to resist diagonal compression or vertical shear.

At the upper and lower surfaces of the beam, as well as at the upper and lower surfaces of the crack, the intensity of the shear will be zero, with a maximum between, as shown in Fig. 3 (*a*). The only requirement of statics is that the sum of the areas, *A* and *B*, at any section, *A* or *B*, shall equal the total vertical shear,  $V$ . The opinion is sometimes expressed, too, that the concrete below the neutral axis cannot resist horizontal shear because of the cracks. A consideration of Fig. 3 (*b*) shows that this is not true. It is evident that between cracks the stirrups do not resist horizontal shear, and across the crack they act vertically in tension only. Between cracks (Fig. 3 (*b*)), the concrete must resist all the horizontal shear occasioned by

any difference in tension in the longitudinal reinforcement. Since close to the reinforcement this shear is directly dependent on bond, its distribution is similar to that of the bond stress, as shown at *C*, Fig. 3 (b),\* while farther up it assumes more nearly the parabolic distribution shown at *D*. If the bond should break down entirely, the stress in the horizontal steel would be the same at both cracks, there would be neither horizontal nor vertical shear in the block of concrete between cracks, and all the vertical shear on Section *B* would be carried by the concrete above the top of the crack, as at *E*.

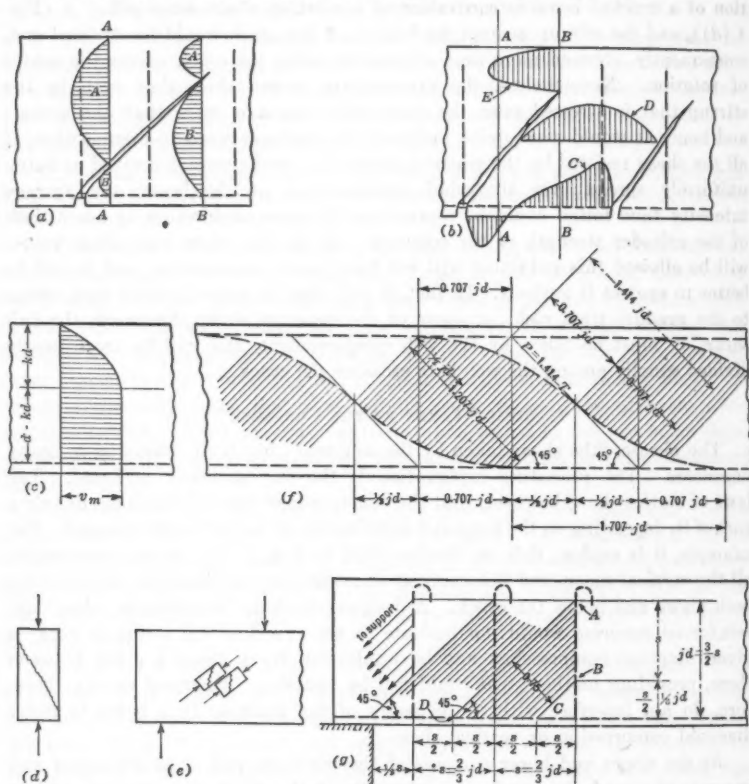

FIG. 3.—STRESS DIAGRAMS.

While it is evident that when stirrups alone are used the concrete will have to resist the total vertical shear,  $V$ , on any vertical section, it is easily shown that when the web reinforcement consists of bent bars, the concrete may resist all or only part of the shear on the section. For example, at Section *B*, Fig. 2 (d), the concrete resists all the vertical shear, while on Section *A*, owing to the sharpness of the bends and to the long distance between

\* Journal, Western Soc. of Engrs., January, 1926, p. 11.

bends, the truss analogy would indicate that the blocks, *C* and *D*, carry but little diagonal compression, and, hence, the external shear is resisted almost entirely by the vertical component of the tension in the steel. If, however, the bars of Fig. 2 (*d*) were spaced more closely together, as in Fig. 2 (*e*), and a vertical section were then passed, it will be seen that the shear on Section *B* would be divided between the vertical component of the tension in the steel and the vertical component of the diagonal compression.

Because of this division of the shear on a vertical section between the vertical component of the diagonal compression and the closely spaced diagonal web reinforcement, it has sometimes been presumed that the value of *V'* in Equations (8) to (11), might be much reduced. This is not the case, however. The usual formulas, Equations (8) to (11), developed for the critical section along a crack sloping at 45°, are quite consistent with the analysis on a vertical section.

In Fig. 2 (*d*), at Section *B*, the truss analogy would indicate that for a distance, *j d*, the whole vertical shear is resisted by the concrete, whereas at Section *A*, for a distance,  $\frac{j d}{\tan \alpha}$ , it is resisted entirely by the vertical component of the steel stress. When  $\alpha = 45^\circ$ , then  $\frac{j d}{\tan \alpha} = j d$ . If the bent bar could be entirely developed, and if the diagonal compression could be carried trusswise down a single line from bend to bend, the bends might be spaced at distances  $2 j d$  apart. This result, however, may also be obtained from Equation (11), if *V'* is made equal to  $0.707 P$ .

Thus, it is seen that in a beam reinforced with stirrups, the concrete resists all the shear on any vertical section, while in a beam with web reinforcement sloping at 45° and spaced not more than *j d* apart, the concrete resists one-half the shear on any vertical section, and that this condition is quite consistent with the usual analysis based on a section passing diagonally along a crack. This statement will not confuse any one familiar with the usual method of analyzing double intersection Warren trusses. It will be seen, too, that the ordinary shear formulas include the "indirect inclined compressions" mentioned by Dr. Faber.\*

#### NOMINAL DISTRIBUTION OF THE SHEAR

From Fig. 3 (*a*) and Fig. 3 (*b*), the shear distribution is seen to be very complicated, and it is impossible to state with exactness either the location or magnitude of its maximum value. Still, it is desirable to have some knowledge of relative shear intensities, and this can best be obtained in terms of the average shear on the section. Then:

$$v_a = \frac{V}{b d} \dots \dots \dots (15)$$

The attempt is often made to find an expression for *v<sub>m</sub>*, as follows: If a rectangular beam is assumed to be made of a concrete capable of taking shear but not tension, then between the neutral axis and the longitudinal steel the horizontal shear will be constant. Above the neutral axis the curve of shear

\* "Reinforced Concrete Beams in Bending and Shear," by Dr. Oscar Faber.

intensity will follow a parabolic arc, as shown in Fig. 3 (c). The total shaded area must equal  $V$ , hence,

$$V = v_m (1 - k) b d + \frac{2}{3} v_m b k d = v_m \left(1 - \frac{1}{3} k\right) b d = v_m b j d \dots (16)$$

Since  $j$  is greater in T-beams than in rectangular beams, this formula automatically takes cognizance of the small shear carried to the support by the overhanging parts of the flange. It is obviously impossible, however, for the shear distribution to be as shown in Fig. 3 (c), where the concrete is cracked, and, in the region where no cracks exist, it must be in the form of the full parabolic arc. Except that it fits in with theory based on the usual assumptions, Equation (16) seems to have no special advantage over Equation (15), which is certainly easier to use and conveys as much to the mind.

#### DIAGONAL COMPRESSION

Considering the member subjected to flexure to act as a homogeneous beam, two sets of stress trajectories, intersecting at right angles, may be traced on the side, one of which delineates diagonal tension and the other diagonal compression. At corresponding points the magnitude of these stresses is equal. Considering the member as a trussed system, Fig. 2 (b) to Fig. 2 (e) plainly indicates the diagonal compression, and it remains to determine the magnitude of this stress.

When vertical stirrups are used, spaced a distance,  $s = j d$ , apart (see Fig. 2 (b)), the vertical component of the diagonal compression is equal to the pull,  $P$ , on the stirrups. The magnitude of the diagonal compression,  $C$ , is, therefore,  $1.4 P$ ; and acting on a width of  $0.707 s$ , its intensity is:

$$p = \frac{1.4 P}{0.7 s b} = \frac{2 P}{s b} = \frac{2 V' s}{j d s b} = \frac{2 v b j d s}{j d b s} = 2 v \dots \dots \dots (17)$$

Similarly, when the stirrups are more closely spaced, and  $P' = V' \frac{s}{j d}$ , the increment of diagonal compression,  $c'$ , Fig 2 (c) contributed by each stirrup, is equal to  $1.4 V' \frac{s}{j d}$ . Acting on a width,  $0.707 s$ , the intensity of the diagonal compression is, again,

$$p = \frac{1.4 V' s}{j d 0.707 b s} = 2 v$$

That is, when vertical stirrups alone are used the intensity of the diagonal compression is equal to twice the average vertical shear at the section under consideration.

Again, when only diagonal web reinforcement (see Fig. 2 (e)) is used, with such a spacing,  $s$ , that adjoining diagonal compression bands just touch along their edges, the vertical component of the diagonal compression equals  $P \sin \alpha$ . The magnitude of the diagonal compression is, therefore,  $1.4 P \sin \alpha$ . Acting on a width,  $0.707 s$ , the resultant intensity is:

$$p = \frac{1.4 P \sin \alpha}{0.7 s b} = \frac{1.4 \times 0.7 V' s \sin \alpha}{0.7 s b j d} = \frac{1.4 v b j d \sin \alpha}{b j d} = 1.4 v b \sin \alpha \dots (18)$$

When  $\alpha = 45^\circ$ , this expression becomes:

$$p = 1.4 v \times 0.7 = v \dots \dots \dots (19)$$

That is, when bent bars are used, the intensity of the diagonal compression is only one-half as great as when vertical stirrups alone are used; and when these bars are bent at  $45^\circ$ , the intensity is equal to the average vertical shear.\* Thus, while the practice of placing a limit on the unit vertical shear as a means of controlling the diagonal tension is unnecessary, if sufficient completely developed steel is used to resist the diagonal tension, such a limit may very properly be used to prevent the occurrence of excessive diagonal compression stresses.

It has already been stated that, in concrete, failure by pure shear is difficult to produce. "Compression" failure of a brittle prismatic specimen, however, is really shear failure (see Fig. 3 (d)), and allowable unit compression values are usually determined by dividing the ultimate unit "compressive" strength of prismatic test specimens by a factor of safety. In the case of diagonal compression in a beam (see Fig. 3 (e)), the condition is analogous to that in a prismatic specimen, and if the allowable diagonal compression stress is limited by values determined from prismatic test specimens, a failure in pure shear cannot occur. The very fact that compression is inclined is due to the inclusion of shear as a factor. Thus, if the diagonal tension and diagonal compression are effectively taken care of, shear need be given no further consideration, its principal use being simply as a measure of the diagonal compression. (See Fig. 2 (b) and Fig. 2 (d).)

#### SPACING OF THE BENDS IN WEB STEEL

The writer has stated that if bars bent at an angle of  $45^\circ$  could be entirely developed, and if the diagonal compression could be carried "trusswise" down a single line from bend to bend, the bends might be spaced at distances of  $2jd$  apart. Under such circumstances there are parts of the concrete not used in resisting diagonal compression, and the beam is not developing its full capacity in shear. Some modification of spacing, therefore, is required. Fig. 3 (f) shows the arrangement and bending of bent bars giving the maximum spacing when utilizing all the concrete under the bars in diagonal compression, the slope of the diagonal compression being assumed to be  $45^\circ$ . From the geometry of Fig. 3 (f), this spacing is seen to be  $1.707jd$ , and since from Equation (10):

$$P = 0.707 \frac{V' s}{jd} = \frac{V' 0.707 \times 1.707 jd}{jd} = 1.207 V' \dots \dots \dots (20)$$

the unit diagonal compression is seen to be (see Equation (19)):

$$\frac{1.207 V'}{1.207 b jd} = \frac{V'}{b jd} = v \dots \dots \dots (21)$$

For any closer spacing the unit diagonal compression will remain equal to  $v$ .

With this arrangement of steel, however, and with the truss conditions assumed, if the tension in the top and bottom horizontal parts of the bar is  $T$ , then, in the inclined part, the tension would be  $1.414 T$ . Obviously, if the steel

\* See, also, *Technologic Paper No. 314*, pp. 392 and 429.

stress in the inclined part of the bar is not to exceed that in the horizontal parts, and since  $P$  is directly proportional to  $s$ , the spacing must be decreased to:

$$s = \frac{1}{1.414} \times 1.707 j d = 1.207 j d \dots \dots \dots (22)$$

This is the maximum allowable spacing of bars bent at  $45^\circ$  when it is desired to utilize both web steel and concrete to their utmost capacity in resisting shear. Sharp bends are taboo. As before stated, the intensity of the diagonal compression will remain equal to  $v$ .

At first glance it may seem impossible that, in an actual beam, a tension as great as  $T$  will exist in either the sloping part of the bar or in the upper horizontal portion. Under a moderate load, in a beam reinforced with bars small in comparison with the size of the beam, and which are bent to the largest possible radius, the measured deformation is greatest at the lower horizontal section of the bar, becoming less around the bend and up along the sloping part. As the load is increased, the stress in the sloping part increases more rapidly, and stress is soon found in the upper horizontal part. Soon after the stress in the lower part reaches the elastic limit of the steel, the deformation in the sloping and upper horizontal sections approaches that in the lower horizontal portion. This condition of approaching equality continues until the end, and is especially noticeable when high elastic limit steel is used. Under such circumstances bond, as a dependable factor in design, has been virtually destroyed. In the consideration of proper working stresses the conditions after the elastic limit is passed should always be taken into account. From this, it is evident that in order to make certain of security against diagonal tension failure, particularly when high "shearing" stresses and high tension values are permitted in high elastic limit steel, the ends of all bars should be 100% anchored.

When vertical stirrups are used, without being anchored at the top, the spacing should not be greater than  $\frac{3}{4} j d$ , as is clearly shown by the geometry of Fig. 3 (*g*), and their value may be limited to a less value than this by bond either on the upper part of the stirrup or on the horizontal reinforcement. Even if cracks extend no higher than  $\frac{1}{2} j d$  from the bottom, only the upper two-thirds of a stirrup may be counted in its development; and, since the stress transferred from the stirrup to the concrete in the distance,  $AB$ , is the same as that transferred from the concrete to the horizontal steel in the equal distance,  $CD$ , it is evident that if  $u$  has reached its allowable limit on the horizontal bars, so of the stirrups above the crack must equal so of the horizontal bars, or else the spacing should be reduced in the ratio of these total perimeters. This arrangement is usually difficult to secure, which shows the urgency of effective anchorage at the top as well as at the bottom. Conversely, the bond condition on the horizontal steel is seen to be of vital concern, for it is evident, again, that, since the stress in the stirrup is proportional to the shear, and also since the stirrup stress is limited to the amount that can be transmitted by bond to the horizontal steel in the distance,  $s$ , the capacity of

the beam to resist shear is also limited. Therefore, wherever stirrups are depended on, firm end anchorage of the horizontal steel is essential to safety. (See, also, Fig. 4.)\*

The commonly specified maximum spacings of  $\frac{3}{4}d$  for bent bars and  $\frac{1}{2}d$  for stirrups were determined from tests conducted years ago on beams. In these tests the stirrups were not anchored at the top, and bent bars had sharp bonds and rarely had end anchors. Because the conditions in the test beams reinforced with stirrups are similar to those shown in Fig. 3 (g), the correspondence of the stirrup spacing deduced by Equation (22) with that determined by tests, is close. If each stirrup of Fig. 3 (g) were effectively anchored at the top and all the diagonal compression could be carried down along a single narrow line to the point where the next stirrup joins the main reinforcement, the spacing might conceivably be increased from  $\frac{3}{4}d$  to  $d$ . Unlike a steel truss, in which the diagonal compression may be brought down a comparatively narrow member to a pin panel-point, the concrete cannot transfer, at a single point at the junction of the main steel and stirrup, the diagonal compression which it carries. Thus, the advisability of using the closer spacing is evident. Fig. 3 (g) shows also why the first stirrup should not be farther from the support than  $\frac{1}{2}s$ .

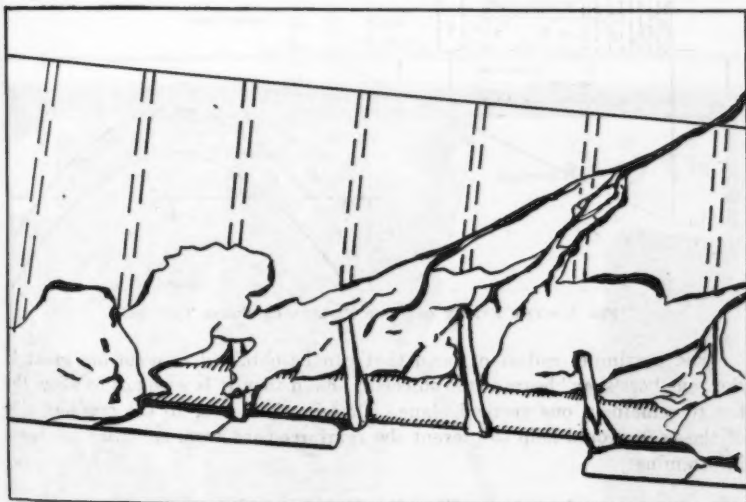

FIG. 4.

The discrepancy between the usual maximum spacing for bent bars,  $\frac{3}{4}d$ , with that deduced by Equation (22), is undoubtedly due to the slipping of bars in the test specimens or the crushing and splitting of the concrete beneath the sharp bends.

\* *Deutscher Ausschuss für Eisenbeton*, Heft 20, and *Journal*, Western Soc. of Engrs., January, 1926, p. 11.

## EFFECT OF BOND FAILURE ON SHEAR FAILURE

The break-down of bond is immediately reflected in a modification of shear conditions. It is common practice to design beams with reinforcement similar to that of Fig. 5. The shear formulas may indicate that the spacing is quite satisfactory, but suppose that the diagonal bars are  $1\frac{1}{2}$  or  $1\frac{1}{4}$  in. square and are stressed to 16 000 lb. per sq. in. Unless the beam is very deep, there is no possible chance of developing a stress of this magnitude in the sloping part of the bar by bond alone. Hence, practically all the stress is either carried by bearing on the concrete under the bends, or the beam fails at these points.\* In a continuous beam, the case is even more serious, for each set of bars crossing the support must be completely developed by bond or bend beyond the point where the previous set was bent down. This bond length is usually short because the bars are bent down at frequent intervals to resist shear; hence, the dependence is largely upon the bend. Fig. 6 shows the result. Even worse, it is the practice in some instances to reduce arbitrarily the computed negative moments over supports.

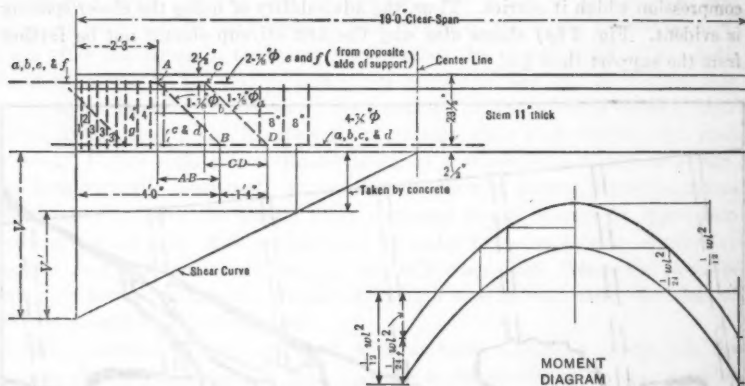

FIG. 5.—THE EFFECT OF BOND FAILURE ON SHEAR FAILURE.

The maximum radius of bend that can be obtained is none too great if the "one boss-shay" beam is the objective. Even then it is wise not to allow the bar to remain in one vertical plane. Crossing bars over to the opposite side of the beam would help to prevent the reinforcement from splitting the beam into laminae.

## AMOUNT OF WEB REINFORCEMENT REQUIRED

Referring again to Fig. 3 (g), it will be seen that the pull on one stirrup is equal to the increment in total tension in the horizontal steel in the distance,  $s$ . Neglecting the small amount of shear "taken by the concrete", the total pull on all stirrups will equal the sum of all the increments in the horizontal steel, that is, the total tension. If the same unit stresses are used, the

\* Deutscher Ausschuss für Eisenbeton, Heft 12, by Dr. C. Bach and Prof. O. Graf.

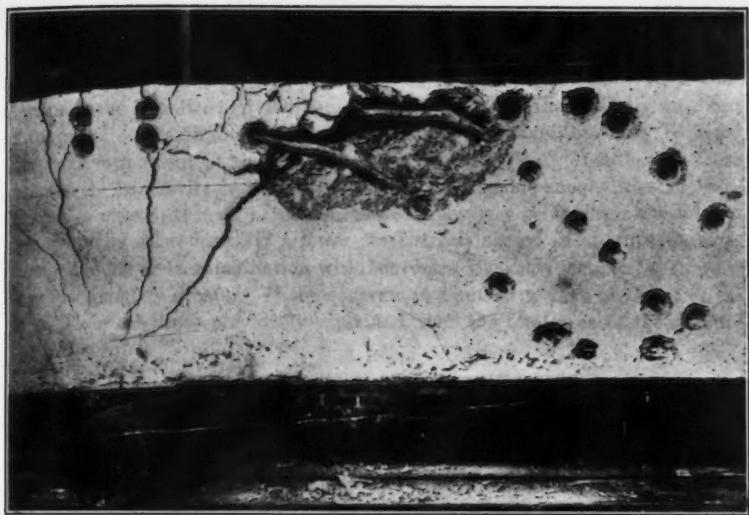

FIG. 6.—SIDE VIEW OF TEST BEAM.

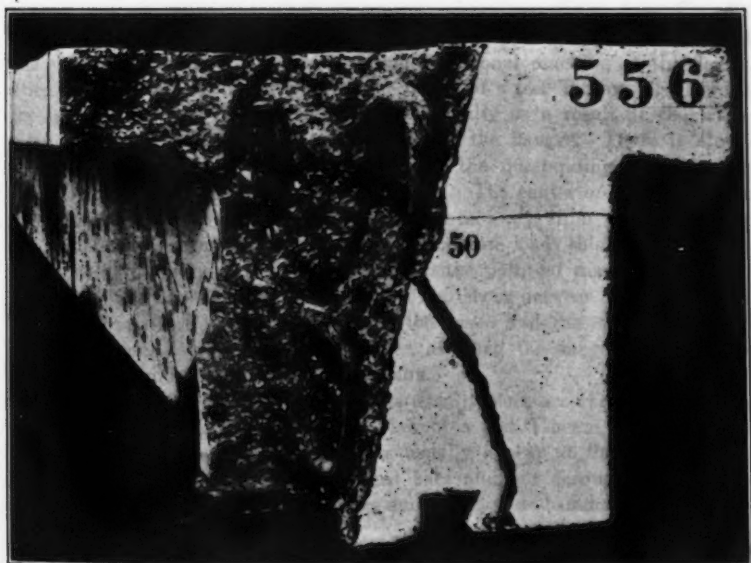

FIG. 7.—END VIEW OF A TEST T-BEAM.

View of the lake and the mountains.

total cross-sectional area of all the stirrups in a simple beam between the point of maximum moment and either support will equal the cross-sectional area of the horizontal steel at the point of maximum moment. In a continuous beam it will equal the sum of the steel areas theoretically required at the point of maximum positive moment and that simultaneously required for negative moment at the support under consideration. If either of these moments is arbitrarily increased to provide for possible inequalities in loading (as is usual), it will, of course, not be necessary to increase the stirrup area. On the other hand, if a lower steel stress is used in stirrups that are arranged alone or in combination with bent bars, the cross-sectional area must be proportionately greater. If the concrete is assumed to take any part of the shear,  $V$ , in the sense previously explained, then the total area of the stirrups will be decreased in the ratio,  $\frac{V'}{V}$ .

Similarly, if bars are bent up when not required for moment, at a spacing not exceeding  $1.207 j d$ , the tension in the bent part of the bar, at the higher loads from which working stresses are deduced, equals the increment in horizontal steel stress, and again the required area in bent bars equals the cross-section of longitudinal reinforcement.

#### JUNCTION OF FLANGE AND STEM

In T-beams, the junction of flange and stem is a region subjected to various stresses, which together produce a critical condition (see Fig. 7). There is the longitudinal shear which tends to push the flange lengthwise past the ends of the stem, as well as to produce diagonal cracking of the flange. (See Fig. 8, which is the top view of the flange of a test T-beam.)\* There is the tendency for the beam to crack longitudinally as a result of the transverse moment due to the downward flexure of the flanges. There is also a moment resulting from the compression in the outstanding flanges. Let Fig. 9 (c) represent the top view of a T-beam. The center of compression in the outstanding flange, acting at some distance away from the face of the stem, produces a moment,  $M$ . Under even moderate loads this will result in a crack, as at  $d$ , which rapidly develops from the point of maximum moment toward the end of the beam. If the horizontal shear between flange and stem is high, the failure between the end of the crack and the end of the beam will be sudden. Any load on the flanges, as when the flange is part of the floor system, tends to accelerate such action.

Again, the upper ends of bent bars, as usually bent, are very destructive in this region. Fig. 7,† giving the end view of a test T-beam, illustrates how destructive this action may be. Cracks usually appear at the middle of the upper surface or directly over the bent bars and cut through the beam to the root of the angle between the flange and the stem and under high stress the flange will be thrown off violently.‡

† See, also, *Deutscher Ausschuss für Eisenbeton*, Heft 12, by Dr. C. Bach and Prof. O. Graf.

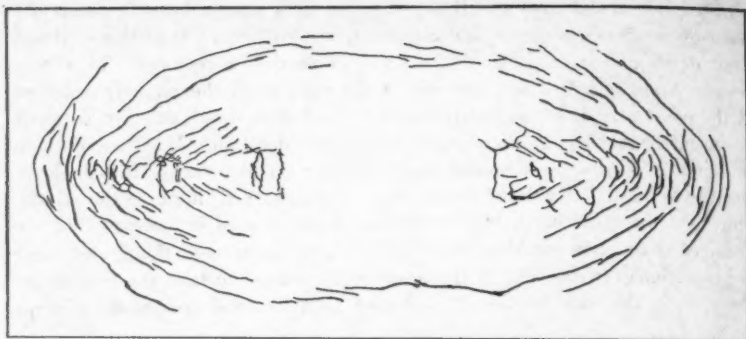

FIG. 8.—TOP VIEW OF THE FLANGE OF A TEST T-BEAM.

Clearly, cross-reinforcement is essential. As already implied, the amount should be at least equal to the cross-sectional area of the main longitudinal steel, since reliance on the concrete at such a place is unsafe. However, it is evident that since the T is called upon to resist positive moment only, in continuous T-beams the area of cross-reinforcement needs only to equal the area

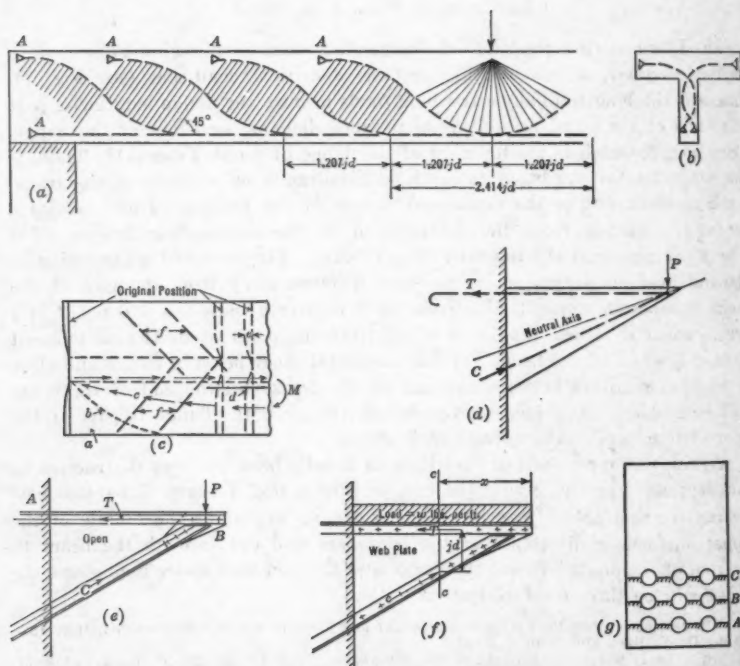

FIG. 9.—MISCELLANEOUS DETAILS.

of the longitudinal steel-resisting positive moment. The disposition of this reinforcement is of considerable importance. If placed in the form of cross-bars only it can effectively resist the transverse flexure caused by load on the flanges, as well as the moment,  $M$ , of Fig. 9 (c), and the splitting tendency of hooks on the main reinforcement. It cannot resist the tendency to push the slab lengthwise on the stem, nor the formation of the diagonal cracks in wide-flange T-beams. (See Fig. 8.) Such forces will merely bend the stirrups out of line as shown at  $e$ , Fig. 9 (c). All the forces may be resisted, however, by steel placed at an angle of  $45^\circ$  with the axis of the beam, and effectively anchored at both ends, as at  $f$ , Fig. 9 (c). This is perhaps most easily effected by bending all the main reinforcement up through the stem and out into the flanges, anchoring the ends firmly. (See Fig. 9 (b).)

If the main reinforcement is not bent up and outward into the flanges the stress in the cross-reinforcement should be kept low, say, not more than 10 000 lb. per sq. in., in order to prevent incipient splitting and damage from hooks. The required area of steel used will thus be proportionately increased.

The amount of cross steel in the flange is often expressed as a percentage of the flange area, but it would seem more nearly direct to specify it in terms of the longitudinal steel.\*

#### WEDGE-SHAPED BEAMS

Just as with the bond formula,† the usual formulas for shear do not apply to beams in which the main tension reinforcement is not parallel to the compression face. In Fig. 9 (d), for example, both the tension,  $T$ , and the compression,  $C$ , are constant from load to support; and, from statics, the vertical component of  $C$  must be equal to the load,  $P$ . If the beam is proportioned so that the concrete is not over-stressed in compression, then shear failure cannot result, and no shear reinforcement is necessary. In such a beam the critical condition arises from the total lack of bond and the complete dependence on anchorage of a kind that will not damage the concrete.

This case is analogous to that of the structural steel bracket shown in Fig. 9 (e), and no designer will question the necessity of complete development at  $A$  and  $B$ , nor will he worry about shear in the diagonal strut as long as it is good in compression.

If the load is uniformly distributed, as in Fig. 9 (f), then either the top member must be capable of resisting bending, with its accompanying shearing stresses, or a web-plate must be introduced to take the net shear. The vertical component of the inclined compression on any vertical section,  $C-C$ , is no longer equal to the shear on the section. In Fig. 9 (f), the horizontal component of the inclined compression, at Section  $C-C$ , is:

$$c_h = \frac{w x^2}{2 j d} \dots \dots \dots (23)$$

The vertical component of  $c$  is:

$$c_v = \frac{c_h j d}{x} = \frac{w x^2}{2 j d} \times \frac{j d}{x} = \frac{w x}{2} \dots \dots \dots (24)$$

\* See, also, *Deutscher Ausschuss für Eisenbeton*, Heft 12, by Dr. C. Bach and Prof. O. Graf.

† See, *Journal*, Western Soc. of Engrs., January, 1926.

That is, in a beam of triangular elevation, uniformly loaded, in which the flanges alone are assumed to resist the tension and compression due to bending, the vertical component of the inclined compression or tension at any section is equal to one-half the vertical shear on that section. The web must resist the other half. Therefore, if a uniform load instead of a concentrated load were applied to the reinforced concrete beam of Fig. 9 (d), the web reinforcement would have to be capable of resisting one-half the vertical shear at any section.

If the beam does not come to a point, but has any one of the forms shown in Fig. 10, then analysis\* will show that in the general case the shear to be resisted by the web reinforcement is equal to the total shear on the section minus the vertical component of the inclined main stress. This result is confirmed by an inspection of the simple statics of the case, and would apply not only to sloped-top footings, counterforts, balcony girders, and crane girder brackets, but also to the brackets introduced at the supports of continuous beams. The latter, if not sloped too sharply, will assist, therefore, in resisting both compression and shear.

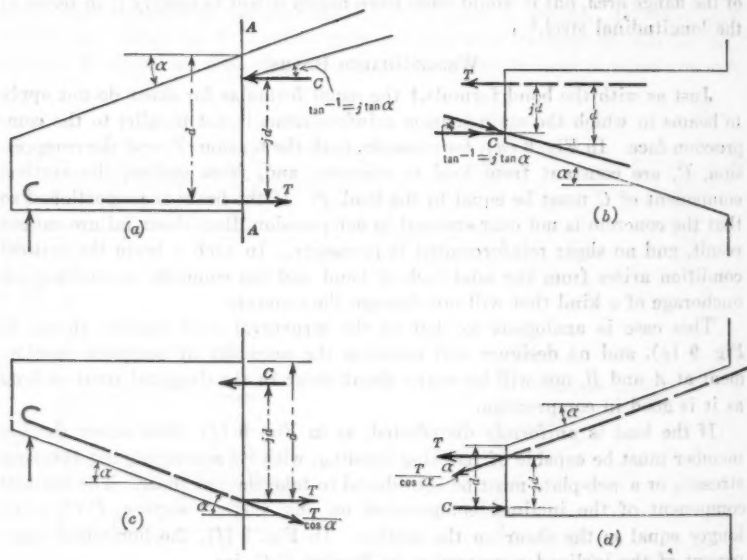

FIG. 10.—ODD-SHAPED BEAMS.

#### CROSS-SPACING OF THE MAIN REINFORCEMENT

The spacing of the main reinforcement with reference to the cross-section of the beam is wholly or partly dependent on the value of the concrete in pure shear. Let Fig. 9 (g) represent the cross-section of a simple beam. If none of the bars is bent up, any difference in stress on the bars,  $A$ , between two

\* Similar to that in *Journal*, Western Soc. of Engrs., January, 1926, pp. 21-22.

adjacent vertical cross-sections must be taken up by bond on the surface of the bars and transferred upward by horizontal shear to the compression side of the beam. That part of the bond on the lower half of the bars must be transferred across the narrow section of concrete at Section A. If the value of the concrete in horizontal shear is the same as the intensity of the allowable bond, then the clear space between the bottom bars should not be less than  $\frac{1}{2} \pi d$ . Similarly, the spacing of the bars on the next layer should not be less than  $\frac{3}{2} \pi d$ .

Based on this reasoning, specifications often include clauses limiting the bars to two layers and the spacing to three times the diameter. The value of good concrete in shear, however, is four or five times as great as its value in bond. In a simple beam uniformly loaded, too, the bond stress developed is small where the bars are most numerous; that is, at the point of maximum moment; and near the ends, many of the bars have either been bent up or cut off, leaving a greater net horizontal section of concrete. Thus, it is not particularly objectionable to have three or four layers of bars in such beams.

In the continuous beam the same holds true for the part subjected to positive moment, but in the region of maximum negative moment the highest bond stress exists at the place where the negative reinforcing bars are most numerous. Here, conditions should be carefully watched and the effective anchorage of the negative steel is again seen to be of great importance.

A practical feature, often overlooked, has a great deal to do with bar spacing, namely, the size of the coarse aggregate used. If large stones lodge between bars, there will always be open pockets beneath, and cases sometimes occur in which the concrete around the lower steel can easily be removed.

If the bars are bent in such a manner that the bends will serve as anchors, this is more unsightly than serious; but, if the bars are straight, particularly if some do not reach the support, they are of little more use than if simply stuck on the bottom of the beam. It need scarcely be added that to stagger the rows of bars so that each bar comes directly over the space between the bars in the layer below is to invite trouble.

#### CONCLUSION

The purpose of reinforcement is to make two wholly unlike materials act together as nearly as possible as one homogeneous material. Many of the difficulties have been met with empirical rules, but in a few cases unique ideas of some merit have been tried. In 1909, Locher\* arranged the reinforcing bars so as to follow the tension stress trajectories. Later, Gilchrist† designed some heavy beams using the same principle. The writer's suggestions have been advanced with somewhat the same idea.

Many of these suggestions may seem extreme; for example, crossing bars to the opposite side of the beam; bending them with extremely large radii; bending them out into the flange; and providing them with anchorage capable

\* See Marsh, "Reinforced Concrete," Third Edition, Second Imprint, 1909, p. 24.

† *Engineering News*, March 12, 19, and 26, 1914.

of developing the ultimate strength of the steel without appreciable slip. No form of hook will accomplish the last of these. With steel of structural or intermediate grade some of these precautions might be unnecessary, for due to the comparatively early yield of the steel, failure would also be comparatively early. The yielding of the steel would cause undue deflection, which, in turn, would concentrate compression stress near the extreme fiber and result in "compression failure". In such a case anchorage would be of use only in developing the yield point of ordinary steel. On the other hand, bond failure is responsible for failure in many beams in which the steel stress is less than the yield point. Many failures of this type have been called "tension failures" or "diagonal tension failures". It is surprising to what an extent the strength of a beam may be raised, without changing the quality of the concrete, by the use of steel with a high elastic limit, designed so as to eliminate the numerous types of secondary failure discussed. It may be added that all the precautions listed are necessary in order to achieve this object. A brief résumé of these suggestions will show their bearing on design.

Let Fig. 9 (a) and Fig. 9 (b) represent a simple beam carrying a single concentrated load at mid-span. The steel should have a high elastic limit. The number of bars chosen should be such that they can be bent up at a spacing not exceeding  $1.207 j d$ . The bends should be of the largest possible radius. This is accomplished by bending the bars so that at mid-height they would have a slope of  $45^\circ$ , bending horizontal in the top again at the same radius. The ends should be fixed with anchors that cannot damage the concrete. If the beam is T-shaped, the alternate bars should be bent out into opposite flanges. For the sake of symmetry, it would be preferable to bend up the bars in pairs or in groups of four, one bar, or pair of bars, from each group being bent outward into each flange. The last bent bar, or pair of bent bars, should become horizontal over the support, leaving one horizontal in the bottom of the beam. Thus, practically all the steel transfers its own stress to the compression side of the beam, eliminating questions of diagonal tension and connection of flange to stem.

With such an arrangement of reinforcement—bars being bent up gradually where not needed for moment—the effective cross-section of the bars varies from a maximum under the load to nearly zero at the support, which will result in a practically constant unit steel stress from mid-span to the support. The steel stress being constant, bond stress plays no part in the design, but full anchorage is essential. In T-beams it is advisable to bend the bars from one flange over to the opposite side of the stem, as shown in the end view of Fig. 9 (b), to preclude any possibility of the bars pulling through the corners. This will also have the effect of helping to prevent the splitting of the beam into laminae. The structure thus becomes equally strong in all parts. Such an arrangement was devised a few years ago by William Fry Scott, M. Am. Soc. C. E.—the tests being witnessed by the writer—and the results confirm in every case the statements of this paper.

With these suggestions the designer can extend the application of the principles mentioned to the cases of beams uniformly, or otherwise, loaded, continuous beams, counterforted walls, and other structures.

## DISCUSSION

EDWARD GODFREY,\* M. Am. Soc. C. E. (by letter).—The writer is in complete accord with Professor Mylrea in his emphasis on the importance of re-examining "the basis of structural theory to check the assumptions on which it is founded." This is particularly true in any case in which the basic theory has been questioned and the arguments of the questioner have not been squarely met and answered.

One of the most vital questions in the field of reinforced concrete design is the stirrup or short shear member. It is of exceeding importance that free discussion be entered into and a conclusion reached as to the value of the stirrup—if it has any real value—and its proper place in design.

Professor Mylrea clearly considers of no importance the fact that stirrups in a whole beam have little or no stress. In the writer's judgment there is a real significance in this fact of test and analysis which is closely connected with the efficiency of stirrups as shear members. Experimental evidence shows that stirrups do not act until the concrete cracks. Analysis anticipates the same thing, for there can be no action in a homogeneous concrete beam that would elongate the beam in a vertical direction. Conceding the fact, then, that the stirrups in a reinforced concrete beam do not come into action until the beam cracks, the question arises as to what this involves. The unit shear allowed by some modern standards on the cross-section of a beam is a large fraction of the shear at which the first crack in the web takes place in test beams.

Modern specifications allow a large share of the beam shear to be taken by the concrete. The margin between the shear allowed on the concrete web and that which cracks the concrete is small. In fact, it is not unusual to find beams in which the concrete web is cracked under safe load. What of the part of the shear allotted to the concrete web? A cracked web, unaided, could take no part of this shear. It will be thrown, therefore, into the stirrups, and it is largely in excess of the shear for which the stirrups are designed. Here is a condition, then, that can be expected in a standard design, namely, large over-stress in the stirrups.

In no other analysis of stress action is it assumed that any part of a structure is idle and inoperative until some other part fails. The writer does not believe this is sound analysis, particularly since there is a means of reinforcing a beam for shear that is free from this objection, both in its analysis and in its agreement with tests.

Professor Mylrea refers to tests by A. N. Talbot, Past-President, Am. Soc. C. E., which proved that stirrups take no stress until the concrete cracks in shear. Tests by this same experimenter† prove that beams reinforced for shear by bending up the main reinforcing rods with a long flat bend, gave high stresses in the bent-up part of the rods. Furthermore, in the beams reinforced with stirrups, in an actual building, cracks were easily found in

\* Structural Engr., Pittsburgh, Pa.

† Bulletin No. 64, Univ. of Illinois Eng. Experiment Station.

the concrete; whereas in beams reinforced for shear by bending up rods with a flat angle and crossing them over the support, no cracks could be found.

Analysis agrees perfectly with this, for both the shear deflection and the deflection due to bottom tension are accompanied by elongation in the beam in the diagonal direction in which the bent-up and anchored rods lie; and, since the rod is there to take the stress, cracks in the concrete are prevented.

A simple test and one that can be made in an office is as follows: Take a straight stick of wood about as long as a desk and about  $1\frac{1}{2}$  by 2 in. in cross-section. Fasten mandolin wires in screw-eyes as indicated in Fig. 11. Introduce small bridges to give a tension. Place this beam on two books and pick the wire. Then press down at the middle of the stick. The tone of the wire will immediately go up, proving the existence of tension in the direction in which the wire is stretched. It is in this position and direction that bent-up main rods are or should be placed, and every increment of load adds stress in these rods. Furthermore, failure of the beam in shear is impossible unless this rod severs or is pulled out of its anchorage. This cannot be said of any stirrup installation.

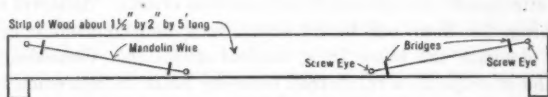

FIG. 11.—EXPERIMENT TO DETECT TENSION IN BENT-UP ROD.

It is manifest that a test made on this wooden beam with vertical wires on the sides, corresponding to stirrups, would not exhibit any increment of tension in the wires. Sharply inclined wires would show little if any added tension.

The author states that the introduction of vertical stirrups would greatly delay failure, and this, he points out, is the function of such stirrups. Unless they can prevent failure entirely, and surely, some other form of shear reinforcement is a necessity. He assumes that the concrete beam cracks at an angle of  $45^\circ$  with the vertical, and the stress in a stirrup is worked out on this assumption. The angle of this crack is the determining factor in finding the stress to be allotted to the stirrup, so there should be some good reason for the selection of 45 degrees. If the tangent of the angle is more than one, the stress in the stirrup is less in the inverse ratio. If that tangent is less than one, the stress allotted to the stirrup is greater.

There is no law that would compel the cracks to take an angle of 45 degrees. In fact, Fig. 6 shows cracks that are almost vertical. The writer has seen many actual beams and has read descriptions of many more that failed in wrecks by cracking at the line of support in practically a vertical plane. When actual beams fail at wall supports by breaking part of the concrete over the support itself, and when they carry with them the stirrups that were intended to prevent this failure, as the writer has observed to be the case, what ground can there be for the assumption that the concrete will crack some distance from the support and at an angle of  $45^\circ$  with the vertical? In Fig. 6, the cracks start at the support.

Continuous and restrained beams tested by Withey\* are shown in many cases to have cracked exactly at the support. These beams had stirrups, but were not reinforced by bending and anchoring the main reinforcing rods as the writer would have done.

Assume a case in which a  $45^\circ$  line would cross three stirrups, and suppose, instead of cracking at  $45^\circ$ , the crack crossed only one stirrup. The stress in this stirrup would be three times that allotted to it by the designer. This increase of 200% in the stress in the stirrup would be merely the result of a crack in a concrete beam taking a different course from that assumed by the designer, and there is nothing inherent in the beam that would prevent it from cracking in that manner. In fact, the crack may miss the stirrups altogether, and a beam designed according to standard rules could fail in shear without in any manner disturbing or stressing the steel reinforcement placed in that beam to take the shear.

It is a fact that, between any two stirrups and between the last stirrup and the support, there is nothing to take the shear of a beam except the concrete and the horizontal steel. These would be there if no stirrups were used.

The author uses the truss analogy to explain and determine the stress in the stirrup. In the truss analysis the web members cut by any section, whether vertical or inclined at any angle, must be capable of taking all the shear of the truss. The analogy breaks down, therefore, when the inclination of the cut is arbitrarily assumed to be  $45^\circ$ . The case then resolves itself into one of an arbitrary allotment of stress having no relation to steel truss analysis.

In another vital respect the truss analogy fails. In every truss, in steel design for example, every pound of stress in a web member must be traced through some adequate detail to an adequate resistance and, finally, to the reaction of the support. Professor Mylrea's analysis does not follow the stress of the stirrup beyond the end of the stirrup itself. The stirrup is said to be anchored. The nature of this anchorage corresponds to the end detail of a truss member. It should, of course, be capable of taking the full stress of the stirrup. The paper does not place much emphasis on the need of adequate anchorage, or of ways in which it can be obtained, and this should be a matter of searching inquiry, since it is a governing feature in the strength of the beam.

The anchorage at the bottom of the beam seems to be by a loop around one or more reinforcing rods. At the top of the beam it appears to be a short hook around a reinforcing rod or merely in the concrete. These are the standard and common end anchorages for stirrups.

No designer would seriously consider that a rod  $\frac{1}{2}$  in. square, for example, is adequately anchored for its safe load as a hanger if it is merely buried with a small hook about 2 in. long, or even looped about a rod close to the bottom of a beam with this same hook. Why should not the same principles apply in the case of a stirrup as would obtain in the case of a hanger on which an actual load is to be applied?

\* Bulletin No. 115, Univ. of Wisconsin Eng. Experiment Station.

If it is assumed that the concrete itself furnishes the anchorage for the stirrup, how does that concrete deliver the shear load to the support where it must ultimately go? In a whole beam how does this avoid or lessen the diagonal tension in the concrete web? And if it does not accomplish this, why use the stirrup? In a beam, cracked at an angle of  $45^\circ$ , how can the concrete at the tip of the triangle in Fig. 1 (*h*) be considered capable of anchoring the last stirrup cut by the  $45^\circ$  plane to the full value of that stirrup? Here, again, a designer would not seriously consider placing a capacity load on a hanger anchored in this manner.

By Professor Mylrea's reference to Fig. 2(*g*), it is evident that he considers the pull of a stirrup to go directly into the horizontal rods as a vertical load. This means that the load of the beam is hung as a vertical shear load on the horizontal rods. Analysis cannot justify this disposition of the shear load. Steel rods embedded in concrete cannot take any appreciable shear until the concrete fails in shear. The idea that steel rods as pegs could take shear at 10 000 to 12 000 lb. per sq. in. was discarded from specifications long ago. After the concrete fails in shear the horizontal rod would be in bending, and the capacity of a reinforced concrete beam would be little if dependence were placed on the bending strength of the rods to carry the shear to the supports.

While the author emphasizes the necessity of anchoring the web reinforcement "at both top and bottom strongly enough to develop its full tensile strength", he does not explain the nature of that anchorage, nor how it could be effected at the top and bottom of the beam, which mark the extreme ends of the stirrups. *Technologic Paper No. 314*, U. S. Bureau of Standards, is referred to several times. This report describes tests in which the stirrups on shear members were fully anchored at the level of the top and bottom of the concrete web. In fact, they were anchored into heavy beam heads which, in the investigation, were eliminated from consideration, so far as shear is concerned. For this reason the writer believes that those tests were of little or no value as teaching any lesson concerning reinforced concrete beams. Such beams, as constructed, do not carry with them large surplus depth that can be ignored in the calculation and yet be taken advantage of as anchorage space for stirrups.

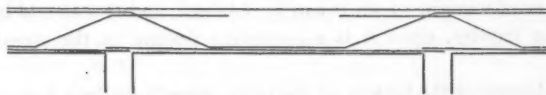

FIG. 12.—MAIN BARS ARRANGED TO RESIST SHEAR.

Beam analysis must be based on beams as it is practicable to construct them. The tests described by the U. S. Bureau of Standards were on a comparatively thin concrete web fixed in a heavy concrete frame into which the web members were fully anchored and which was quite outside the area considered as concrete web. This does not correspond in any way with a reinforced concrete beam; hence analysis of a reinforced concrete beam cannot properly be based on results of these tests.

The author emphasizes the importance of properly anchoring stirrups "at the ends". Also, he states that "sharp bends are taboo". He does not refer to

the impossibility of fully anchoring a rod at its end. Unless a nut and steel plate is used, full anchorage at the end of a rod is not possible. A small hook either in concrete or around a main rod is taboo, because it involves a sharp bend. Anchorage in concrete requires a considerable part of the entire rod. Professor Mylrea states that no form of hook will accomplish the anchoring of steel to develop the ultimate strength without appreciable slip. It would not be an unusual condition for a stirrup to require one-half the depth of the beam for the 100% anchorage that Professor Mylrea states is necessary. The web member is of zero length, and the truss analogy fails.

The author rightly emphasizes the importance of end anchorage of main reinforcing rods. In fact, with the top and bottom rods firmly anchored into the support, a large shear can be carried by the concrete even if it is cracked. The friction acting between the compression surfaces—if the crack is vertical—will take the shear component. It is allocating this shearing strength of the concrete web to stirrups, in interpretation of tests, that has given the stirrup a place in design that its nature does not warrant.

If a continuous beam should crack a short distance from the support, namely, at the point of inflection, there would be no compression surface, because the moment is zero. A vertical crack at this location would create the dangerous condition of all the shear being taken by horizontal rods. If main reinforcing rods are bent up and crossed over the supports, as in Fig. 12, any section, cut at any angle, between the support and the bend in the rod, has a positive shear reinforcement that effectively prevents failure by direct tension in that reinforcement. The main rods are amply capable of "carrying" this tension and "delivering it" to its anchorage over the support where the reaction of the beam must be met.

Professor Mylrea intimates that in future designs higher unit stresses will be used in concrete webs. The tests of the U. S. Bureau of Standards, to which he refers, showed cracks in the concrete webs at units of 200 to 300 lb. per sq. in. A concrete section nearly twice the nominal web area was actually in shear. These test beams, which were reinforced with stirrups with an efficiency that could not be approached in a practical design, failed in their concrete webs at about the allowed safe unit shear of standard specifications. They, therefore, did not even justify the units of those specifications.

C. A. P. TURNER,\* M. A. M. Soc. C. E. (by letter).—The author attempts to analyze the web resistance of concrete beams which is a special case of the general problem.

Prismatic beams of homogeneous material were treated by Mariotte on the assumption ("on peut concervoir") that there were as many fibers compressed as stretched and, later, because the cross-section of the prism resisting horizontal shear was far greater than that resisting moment stresses, horizontal shear strain was neglected in the Bernoulli-Eulerian investigations which constitute the common theory of flexure as taught to-day. Mathematically considered, this neglect of shear strain is equivalent to treating the shearing modulus of the prism as infinite. This is the same as stating that a

\* Cons. Engr., Minneapolis, Minn.

plane section normal to the axis remains normal to it after flexure and without distortion; that is, it still remains plane. This important normal relation is commonly overlooked in stating the hypotheses of the ordinary theory. An exact analysis of the trapezoidal components of deformation of the prism was thus developed, needing only the superposition thereon of the pure shear distortions to arrive at the exact theory of beams. The common theory is sufficiently approximate for the practical computation of the elastic behavior of simple prismatic beams having a length ten times their depth, but when the horizontal cross-section is reduced to a thin web, as in the broad flanged I-beam, or in the case of reinforced concrete beams, shear strain cannot be neglected for even approximate accuracy. For the restrained beam the greatest tensile fiber stress computed by the common theory is ordinarily from 20 to 30% greater than when computed by exact theory. Deflection in restrained beams is reduced by the interference of shear distortion. In the simple beam, on the contrary, the deflection is greater than that computed by the ordinary theory but the extreme fiber stress is the same at the section of maximum moment for symmetrical loading.

Weisbach suggested\* the influence of pure horizontal shear on the position of the neutral plane in the homogeneous beam as one of the problems in developing the exact theory of flexure, but he neglected to solve the problem. Professor Karl Pearson proved that a neutral plane (defined as the locus of points at which tension and compression balance) does not in fact exist along the length at the gravity axis of the simple homogeneous beam. The writer has found† that the true neutral plane of the homogeneous beam curves downward toward the end of the beam approximately nine-tenths of the depth by equilibrating—by the parallelogram of forces—the center of the shear stress area as the reaction to the fiber stress area.

The true location of the neutral plane is thus a curved surface of the same order as the slope curve. This is true also of the neutral plane of the reinforced concrete beam. The stress mechanism in the composite beam differs, however, from that in the homogeneous beam in that, although at the neutral plane there are right shearing stresses, they are oriented differently. The curves of horizontal shear are tangent to the neutral plane in the homogeneous beam, but they intersect the neutral plane of the composite reinforced concrete beam because the shear between the concrete and metal is equilibrated at the surface of the steel at the bottom of the beam. Accordingly, instead of curves of principal tension, curves of horizontal shear pair (symmetrically opposite, that is, with respect to the neutral plane) with curves of principal compression and the curves of tension in the concrete cut across the beam, assuming a position in the tension zone comparable to the curve of greatest shear in the homogeneous beam. With such a stress mechanism it is obvious that the neutral plane (in which the intensity of tension, compression, and shear are equal) is compressed along its length in proportion to the load applied as shown, but not recognized, in tests by the U. S. Bureau of Standards.

\* "Mechanics of Engineering," 1846.

† "Elasticity and Strength of Materials," Section II.

Accordingly, the neutral plane in the composite beam cannot be located by finding the locus of zero stress as may be done with a homogeneous beam. This radical difference in stress mechanism between the homogeneous and composite beam renders the investigation of the characteristics of the concrete beam by analogy to the homogeneous beam somewhat misleading. In vertical planes parallel to the axis, however, the curves of displacement are similar to those of the homogeneous beam, intersecting the neutral plane at a more acute angle than is the case with the homogeneous member.

There are two kinds of rotational distortion in a beam whether of reinforced concrete or homogeneous material. The rotational strain that is caused by the sharpness of curvature represented by trapezoidal deformation gives rise to equal diagonal tensions in the face of an originally square element in the tension zone and to equal diagonal compressions in an originally square element in the compression zone. The intensity of these diagonal stresses increases from zero at the neutral plane to a maximum at the outer fiber. This kind of strain causes cracking in the shallow beam toward the center.

The second kind of rotational deformation is that of pure shear, or the tendency of the outer fibers to slide as two planks slide, one upon the other, when supported at their ends and loaded. This deformation produces a rhombic (pure shear) distortion, which is zero where the moment area is divided into equal segments (moment areas to the right and left of this section give rise to opposite shears which are equal to each other as action and reaction are equal) and increasing from that locus toward the end of the beam when simply supported. In rhombic distortion one diagonal of an originally square unstrained element is stretched; the other is compressed. Consequently, the maximum diagonal tension will occur at the location where these deformations, superimposed one upon the other, give the greatest diagonal strain. Because the rhombic deformation is proportional to the slope and the trapezoidal deformation is proportional to the sharpness of curvature, which, in turn, is proportional to the bending moment, it is possible to lay off two curves—one upon the other—so as to predict the location of the first crack that may occur in a concrete beam. The upper curve is of the same order as the slope curve, and the lower curve the same as the moment curve. If the maximum ordinates of these curves are made proportional to the deformation which they represent for a given beam, then the greatest diagonal tension will occur where the joint ordinate is greatest. It is thus possible to determine the location of the first crack in the concrete beam or the place at which the web of an I-beam will buckle for a given length of beam under a given load.

From the equations of beam theory the external shears are equal to the sum of the loads from the center toward the end. By taking the summation of shear areas from the end toward the center of a beam the magnitude of the moment ordinates can be determined. The summation of moment areas, in turn (divided by  $EI$ ), gives the tangent of the slope angles along the loaded beam, and the summation of these tangents determines the deflection according to the ordinary theory of flexure. Because the horizontal shears are determined by summing the horizontal fiber stresses, rhombic shear strain is the reaction to the moment stresses. Hence, it is proportional thereto and

the shear deflection, therefore, bears a constant ratio to the moment deflection in a given elastic beam for any loading whatever; but this ratio differs in beams of different span lengths because the magnitude of the rotational pure shear distortion depends on the relation between the horizontal section resisting horizontal shear and the vertical cross-section resisting moment stresses. The relative magnitude of the shear deflection in beams of various lengths follows a different proportionate law from the magnitude of moment deflections.

As a steel I-beam has the flange resistance concentrated at the top and bottom, its web stresses are comparable to those of a concrete beam in which the tensile flange resistance is concentrated in the reinforcing steel. A graphical analysis of the rotational strains of the web of the steel I-beam will illustrate the solution of both problems.

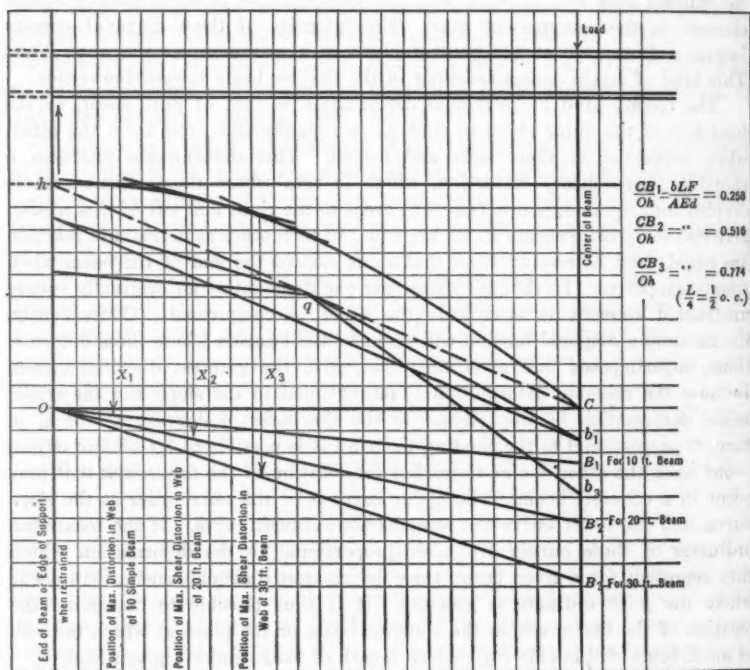

FIG. 13.—ANALYSIS OF ANGULAR SHEAR DISTORTION IN WEB OF 15-INCH, 38-POUND I-BEAM CENTRALLY LOADED, LENGTH SIMPLY SUPPORTED AND RESTRAINED.

In Fig. 13 let  $OC$  represent the half span with a concentrated load at the center. The moment curves are, therefore, straight lines. The slope curve is of the second degree and the magnitude of the rotational strain represented by  $Oh$  at the end and the ordinates of the curve,  $hC$ , may be taken as representing the relative magnitude of the pure shear strains. The magnitude of the trapezoidal distortion is proportional to the ordinates measured from  $OC$  to

$O B_1$  for the 10-ft. beam;  $O B_2$  for the 20-ft. beam; and  $O B_3$  for the 30-ft. beam.

The sum of the ordinates of the two rotations is a maximum for the 10-ft. beam at  $X_1$ ; for the 20-ft. beam at  $X_2$ ; and for the 30-ft. beam at  $X_3$ . Conversely, if the beam is restrained at its ends the moment passes through zero at  $q$  and the closing line of the slope curve is  $h C$ . Then  $q b_1$  and  $q b_3$  represent the moment curves for the center or suspended-span part, and corresponding curves to the left of  $q$  are for the cantilever part. Obviously, the maximum rotational strain in the restrained beam is roughly one-third as great as in the simply supported beam of the same section subjected to the same external shear force. This illustrates the illogical nature of the rules of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete\* and building code laws in computing the web stress of beams. Fig. 13 discloses clearly why, as the beam becomes longer and more shallow, the maximum rotational strain moves from the end toward the center in the simple beam and from the quarter-point toward a position between the quarter-point and the support, as the span increases in the restrained beam. It thus becomes possible to predict with a high degree of certainty where the first crack in a concrete beam will occur, or where the web of the steel beam will commence to buckle. Because the concrete has a smaller limit of rotational strain before cracking than that possessed by the steel before the yield point is reached, proper attention must be given to the percentage of steel used in the shallow concrete beam.

If the rigidity of the beam is such that plaster will not crack, its deflection under working loads should not exceed  $\frac{1}{1200}$  of the span.

In order that the deflection shall not increase more rapidly than the fixed proportion of the span length it is customary, with a long shallow beam, to reduce the steel percentage; this requires the development of a rational deflection formula.

For a given fiber stress in the homogeneous beam, or a given steel stress and a fixed percentage of steel in the concrete beam, the deflection increases with the square of the span and it is desirable to develop the relation of the percentage of steel. Turneaure and Maurer have developed the following formula on the assumption that the concrete may resist tension:

$$D = \frac{c_1}{c_2} \frac{f_s k^2}{E_s d} (p j) \frac{n}{\alpha}$$

This is developed from the ordinary flexure formula by using as the moment of inertia with respect to the neutral axis of the section in compression,  $\frac{1}{3} b k^3 d^3$ ; that of the concrete in the tension zone,  $\frac{1}{3} b (1 - k)^3 d^3$ ; and that of the steel,  $n A (1 - k)^2 d^2$ . Hence,

$$I = \frac{1}{3} [k^3 + (1 - k)^3 + 3 n p (1 - k)^2] b d^3$$

\* Proceedings, Am. Soc. C. E., October, 1924, Papers and Discussions, pp. 1193 et seq.

or,\*

$$\alpha = \frac{1}{3} [k^3 + (1 - k)^3 + 3 n p (1 - k)^2]$$

In explaining this formula Messrs. Turneure and Maurer note that the concrete may crack, but apparently they are inclined to consider that it resists tension after it has been cracked by tension. However, the fact that horizontal shear in the concrete beam, parallel with the steel, replaces horizontal tensions of the homogeneous beam furnishes the solution of this enigma.

The manner in which horizontal shears may cause or oppose bending in the concrete beam may be illustrated by testing a 12 by 16-in. beam, 14 ft. long, centrally loaded, but resting on symmetrical supports 8 ft. apart, allowing 3 ft. over-hang at each end. With 2% of reinforcement the first crack in the concrete will occur in the top of the beam in the overhanging part where there is no applied moment; hence, it is apparent that the horizontal shear in the concrete, parallel with the steel, actually forms that part of the bending resistance which has been erroneously attributed by theoretical writers to the tensile resistance of the concrete.

With this explanation the moment of inertia developed by Turneure and Maurer appears to be satisfactory. It shows clearly that the percentage of steel should be reduced as the span increases, and that the tension zone of the concrete may not be disintegrated by repeated loading if the designer wishes to develop, economically, the value of the steel element.

Stirrups are of much less value than is commonly supposed because of the nature of the stress mechanism, and bent-up rods should follow the curve of tensile displacement which is about 30° to the horizontal instead of 45° as commonly but erroneously assumed by designers.

The multifarious difficulties with the three bases of inductive reasoning presented in the paper and upon which erroneous code rules and committee recommendations are based, are as follows:

1.—The stress mechanism of the homogeneous and reinforced concrete beams are nearly antipodal, and inductive reasoning from opposites tends to invite error in the conclusions drawn.

2.—Truss analogies are misleading because, while the greatest web stress in the truss occurs next the support at the locus of greatest external shear force, in the beam whether steel or concrete on the contrary the location of the greatest web stress is unrelated to the location of the greatest external shear force, but is fixed by the internal stress mechanism and varies in position from near the support for the short deep beam to near the center of the shallow beam.

3.—General reasoning from the locus of cracks back to elastic resistance involves both the variation of location dependent upon the steel percentage and ratios of depth to span length combined with the practical consideration that the concrete should be designed to remain intact and uncracked under repetition of working loads; hence the laws of elastic resistance should be applied to secure this desideratum.

\* "Reinforced Concrete", by Turneure and Maurer, p. 204, Equation (5).

H. E. ECKLES,\* M. Am. Soc. C. E. (by letter).—The author's clear presentation of this important subject will be very valuable to structural engineers interested in economical and careful design. It is an unfortunate fact that, from the standpoint of design, web reinforcement is very often one of the weakest features of reinforced concrete structures. This is frequently due to confidence in the effectiveness of vertical stirrups which the author's analyses show clearly is unwarranted. He has stated that the function of vertical stirrups is to delay failure which has already become a fact, and that they do not take any stress before this stage is reached. These are facts which have been established from the time of the earliest reliable tests of reinforced concrete beams, and it has been equally well known that these drawbacks do not apply to the use of bent-up bars. It is rather inconsistent to design a structure for a condition of failure which, when reached, will necessitate its being replaced, particularly when it may equally well be designed so as not to reach this stage, by the use of bent-up bars.

The author has very significantly stated that bent-up bars may act as web reinforcement before cracks appear in the concrete, and that they act as well to delay failure afterward, in a manner similar to that claimed for vertical stirrups. The statement is also made that bent-up bars deliver their tension as main reinforcement to the compression side of the beam with the result that questions of diagonal tension are eliminated, and that when diagonal bars are used the unit web shear is one-half that in beams with vertical stirrups. These and other considerations make it highly desirable that careful consideration be given to the use of diagonal bars in preference to vertical stirrups. Bent bars may be made thoroughly effective in a much simpler way than that suggested by the author.

The danger of bent-up bars breaking out at the sides of a beam, or causing a beam to split, is unfortunately exaggerated by laboratory tests of beams to destruction. This danger may be avoided by the use of a short, heavy transverse bar placed on the inside of the bends or hooks. This will keep the bent-up bars away from the sides of the beam; will distribute better the bearing of the bent-up bars on the concrete at the bends; and will tie the concrete together transversely. Short hooks or bends at the ends of this transverse bar may well be adopted in important work, and this avoids two of the principal difficulties in design, namely the use of bends of long radii and the splitting of the concrete at the bends. The exterior bars should be kept straight to avoid the danger of failure shown in Fig. 6. Failure, as shown in Fig. 7, will be avoided by the use of short, heavy transverse bars with hooked ends, if the beam has uniform bearing.

A third difficulty to be met in the use of bent-up bars is that of anchorage. The author's suggestion (Fig. 9(b)) to bend the bars sidewise out of the vertical plane is unnecessary and highly objectionable from the standpoint of bending, transporting, storing, and placing the bars in the structure. When main reinforcement must stop over supports an initial slipping of the bar may often be reduced by using end hooks of short radii and a short

\* Chicago, Ill.

transverse bar at the bends, rather than hooks of long radii and free ends. Sufficient anchorage in other cases can readily be secured without resorting to unusual bends.

The importance of good anchorage for the main reinforcement was clearly shown in the earliest important tests of reinforced concrete beams. It was then stated that a greater resistance of the beam would be secured against initial failure by shear if, instead of using vertical web reinforcement, the amount of main reinforcement used at critical shear points was increased. The author's analyses suggest this in a different way. Design that will delay initial failure is much to be preferred to that merely delaying final failure in a structure that will have to be replaced if the initial stage is reached. Since the concrete takes all the shear when vertical stirrups are used, it is preferable to take the material ordinarily used for vertical stirrups as additional main reinforcement or bent-up bars. This would lower the unit bond stress of the main reinforcement and the neutral axis of the beam at the critical shear point, and thus reduce the tendency for cracks to develop which are caused by initial failure. At the same time, this would give a greater amount of concrete in the section to resist shear, with the result that initial failure would be delayed longer than when vertical stirrups are used in any amount whatever. The author has stated that the total cross-sectional area of vertical stirrups in one end of a beam will generally equal that of the main reinforcement at the points of both maximum positive and negative moment, from which it will be seen that the amount of steel in the vertical stirrups would increase considerably the main reinforcement if used in this way, and would materially raise the useful limit point of the beam.

The author might have gone further in pointing out the comparatively greater value of diagonal web reinforcement over vertical stirrups. Diagonal bars are much more effective in preventing diagonal cracks in the tension side of the beam for both the positive and negative moment areas, since their direction in both cases is nearly at right angles across such cracks. When the sets of diagonal bars are spaced at a less distance apart than  $jd$ , they will be very effective for this purpose; vertical stirrups are of no practical value in preventing diagonal cracks, because of their direction. There is a serious defect in the author's analysis of vertical stirrups by the truss analogy since this assumption leads to the anomalous situation of having tension in the concrete in the direction of the vertical stirrup in the compression area. This has been emphasized by the conclusion that hooks are needed at the ends of vertical stirrups. An examination of Fig. 2 and Fig. 3 will help to make clear how this tension must be erroneously assumed. If any considerable tension exists in any part of the length of a vertical stirrup the concrete there must be stressed in tension beyond its point of failure, a condition which would develop cracks throughout the length of all vertical stirrups which are assumed to be functioning. This has a special significance when considering the section of a vertical stirrup which is above and to the left of a major crack, as shown in Fig. 2 (a) and Fig. 3 (a). In that area the unit tension in the concrete is that in the vertical stirrup divided by  $n$ .

All this raises the question of whether the required tension in the stirrup in the compression area must be assumed to exist only if major diagonal cracks occur there. This, in turn, would require the assumption that major cracks exist throughout the length of the beam to the support. This cannot be the case, however, for such cracks exist only at the point where substantial slippage of the main reinforcement has stopped, or where the main reinforcement is greatly overstressed. Tests do not show the existence of numerous cracks such as these before failure has resulted. In the case of continuous beams no substantial slippage can occur where the main reinforcement extends any distance beyond the point of contraflexure, or is properly bent into the compression area of the beam. This renders the use of vertical stirrups entirely futile in such beams. Reducing the main reinforcement over supports merely increases its unit stress and reduces the shearing resistance of the concrete at the most dangerous point, due to increasing the amount of concrete that is broken up by tension in the tension side of the cross-section of the beam. Differences in the moments of inertia of cross-sections at the supports and at the middle of the beam have little effect on the relative moments at these points, since the points of contraflexure are changed but little by these differences. The danger in this region from improper design is well illustrated by Fig. 6.

After all, the concrete must take the shear very largely in all sections of a beam. Tension is developed in diagonal bars to some extent because their direction is at right angles to the diagonal tension cracks in both continuous and simple beams, and, because of this tension in the tension side of the beam in the diagonal bars which is developed by moment, will be of substantial value if properly spaced.

Their effectiveness is apparent by virtue of their being in the direction of rotation about the centroid of compression at a point such as *A*, Fig. 1 (*h*). This makes them effective at the beginning of stress in the beam, in contradistinction to the lack of such action in vertical stirrups before initial failure takes place.

Reliable tests show that concrete has a shearing value of about two-thirds that of its compressive strength, and good design requires only that tension in the concrete be taken care of by suitable reinforcement. When the specifications are such as to insure this, the author's suggestion that higher unit shearing stresses be allowed, may well be adopted. The suggestion to use a higher unit tension stress in the main reinforcement, however, should be examined very carefully. It would reduce the percentage of main reinforcement and hence the area of concrete under compression. In the end it would result in increasing the dead load, in reducing the very effective area for shear on the compression side, and in producing undesirable effects on bond anchorage.

JACOB FELD,\* ASSOC. M. AM. SOC. C. E. (by letter).—In analyzing the action of web reinforcement the author has developed his ideas clearly and has checked his theories by comparison with reinforced concrete beams tested to

\* Cons. Engr., New York, N. Y.

destruction. He might simplify his analysis of the stresses in reinforced concrete by starting with more fundamental ideas than such expressions as "diagonal tension." All strains can be resolved into two types:

(a) Tension or compression, acting along a line, accompanied by strains of the opposite type acting along the other two axes.

(b) Shear which is a strain causing no change in volume and is equivalent to a compression along one axis, a tension along the other axis, and no stress along the third axis.

In other words, all strains must be considered along three axes. Referring to reinforced concrete, tension in the embedded steel rods must be accompanied by compression along the axes at right angles to the rod. Shear stress can be resolved into compression and tension along two axes at right angles to each other. This is the source of the mysterious diagonal tension in concrete beams.

The strength of concrete in compression is greater than in tension. However, all concrete must have some strength in tension, otherwise it could not take shear. The strength of concrete in shear is governed by its strength in tension and the assumption of a beam made of concrete capable of taking shear but not tension, is misleading. This double assumption is impossible.

In resisting compression, concrete fails more quickly by its inability to take care of the resulting tension strains (Poisson's effect) than it does in resisting compression strains. The writer has never seen an example of failure of concrete due to pure compression strains. Such a failure would only occur if it were capable of resisting considerable tension.

In resisting shear no cracks develop until the tension component of the shear overcomes the ability of concrete to resist it. It is very difficult to understand why the measured values of the tension in web reinforcement do not appear until cracks develop, because, if the concrete takes tension in resisting shear, certainly the embedded steel along such lines must also take it. However, when concrete sets, the embedded steel is compressed, and it is more than likely that whatever tension is developed in the web reinforcement before cracks develop does not compensate for the initial compression in such steel due to the setting of concrete.

In deep beams, which give a large section of concrete toward the resistance of shear stress, failure in test specimens is not in shear if the tension bars are well anchored. Failure in many specimens is due to splitting, as is well shown by Figs. 6, 7, and 8, because the compression in the concrete has induced tension stresses at right angles to the axis of the compression and no provision has been made to take such tension. The author's suggestion (Fig. 9(b)) that rods be bent into opposite flanges would take care of such tension stresses and would permit higher compression stresses in the concrete before cracks appear in the compression face.

HARDY CROSS,\* M. A. M. Soc. C. E. (by letter).—The author has treated so many aspects of his subject and has described them so fully that the writer has little hope of adding much by this discussion. Those who have been familiar

\* Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

with Professor Mylrea's extended researches in this field will value highly his recommendations.

The author has brought out clearly the importance of the stress trajectories, or traces of the planes of principal stress, in determining the direction at which cracks first appear. Within limits, however, the direction is necessarily a matter of chance. Until these cracks appear there are lines of tension sloping upward toward the end of a simply supported beam and lines of compression sloping downward toward the support. These may be regarded, respectively, as strings with a strut along the top supporting the load in tension and as tied arches supporting the load in compression all within the beam which supports the load in flexure. The arch action and catenary action which designers are constantly discovering in concrete beams, are, therefore, perfectly real; but they are no more real than they are in timber beams or steel beams; they are different aspects of one and the same phenomenon, and not separate things at all.

As cracks occur along the lines of tension the arches carry more and more of the load. It would now seem as if these arches could not fail in shear; but elongation of the main reinforcement and diagonal shortening of the concrete and especially bond slip—all somewhat similar to rib-shortening as usually conceived in arch design—throw secondary bending into these remaining arches and the thrust lines are now inclined to the arches.

The writer thinks that such conceptions as these are rarely satisfactory. They do, however, have some value in bringing attention to the importance, in dealing with a brittle material, of phenomena which are often thought of as secondary. They lead here to a word of caution in dealing with beams with sloping faces, because of these secondary effects. Because concrete is so brittle, it should be fully reinforced.

There are four methods of studying structural design: Analysis, tests, experience with structures in service, and imagination as to possible methods of failure. In reinforced concrete no one of these alone can be called either the proper method or the scientific method of study; all have been at times neglected or over-emphasized; all have proved at times powerfully illuminating and, at other times, deceptive and discouraging.

Perhaps the chief value of the paper is in correlating these rational, semi-rational, and empirical viewpoints and especially in suggesting the importance of secondary modes of failure, such as crushing at bends or splitting from hooks, the importance of which so many designers fail to realize.

P. WILHELM WERNER,\* Assoc. M. Am. Soc. C. E. (by letter).—The writer believes that vertical stirrups, although useful from certain practical points of view, should not be relied upon to resist shear. Under normal conditions, pure shear can generally be cared for easily by the concrete alone. If the diagonal tension in reinforced concrete cannot be taken by the concrete, it should be taken by bent-up bars.

The writer would emphasize the importance, under certain conditions, of providing ample reinforcement crossing the lines of support, of both diagonal

\* Stockholm, Sweden.

bars and lower horizontal steel. Actual beams often show nearly vertical cracks at the lines of support. A really dangerous condition may then occur, especially if the beam is also stressed in tension over its entire cross-section. Diagonal bars are capable of taking a component of the direct tension stress in the beam, whereas stirrups are quite ineffective under such loading.

Unless engineers can produce a concrete capable of taking considerable tensile stress, the raising of the stresses in the reinforcing steel must involve a greater risk of cracking. Therefore, although the raising of certain allowed unit stresses in reinforced concrete may be warranted for structures in air, it is doubtful whether it would be wise to adopt a general increase of the same stresses for structures in water. Cracks appearing in structures in air are unsightly, but need not necessarily be a matter involving danger. On the other hand, even small cracks occurring in such structures as are subjected to water pressure from one side constitute a source of serious weakness.

In this connection the writer would call attention to the possibility of grading the allowable unit stresses in relation to the character of the structural element in which the stresses occur. Compare, for example, a single beam with a flat slab supported along two opposite edges. Assuming exactly comparable outer forces in both cases, it seems reasonable (with a brittle material like concrete, which often shows a wide variation in strength) to adopt a lower unit working stress in the beam than in the slab, as in the latter case the influence of a batch of inferior quality would be distributed over a comparatively large width. This principle, of course, applies not only to shearing stresses, but to any stress or stress combination induced. Although the writer is aware that it is hardly practicable to burden standard specifications with stipulations of this nature, he thinks the point is worth considering in practical design, as it involves an economic factor of importance.

The writer would emphasize more distinctly the practical feature mentioned by Professor Mylrea, of providing for a bar spacing in proper relation to the maximum size of the coarse aggregate used. This relation has a special bearing on the design of structures in water, as it may affect the durability of the concrete. A grid of heavy reinforcement must inevitably act somewhat as a screen, retaining the larger stones. Thus, although the concrete may have the proper grading when arriving in the forms, a change in the grading will most likely occur during the pouring, and that on both sides of the reinforcing bars. Consequently, the concrete around the bars may be more or less porous and pervious, and subjected to the deteriorating and corrosive action of percolating water.\* Aside from this, however, there seems to be no doubt that crushed stone up to 3 in. in size can be used, even for heavily reinforced concrete, without causing "pockets".

Professor Mylrea's suggestion to use unusual bends for anchorage, etc., although for the present rather objectionable from a practical point of view, may prove sooner or later to be an economical success. Every country is developing a nucleus of highly skilled workmen for reinforced concrete. What is considered as complicated to-day, may prove to be a comparatively simple matter in the future.

\* "Corrosion of Concrete," by John R. Baylis, Assoc. M. Am. Soc. C. E., *Transactions, Am. Soc. C. E.*, Vol. 90 (1927), p. 791.

T. D. MYLREA,\* M. Am. Soc. C. E. (by letter).—The writer has been impressed with the view, expressed by several contributors, that cracking and failure of reinforced concrete beams are synonymous. This is not necessarily the case. The occurrence of fine cracks means simply that the reinforcement is being stressed, and if reinforcement is present in the proper amount and distribution, such cracks need cause no apprehension. Prominent cracks may indicate one or more of several things. Wide vertical cracks, or more often, one wide crack in a region of low shear usually accompany stress beyond the yield point in the reinforcement. In simple beams they may indicate slip of the main reinforcement. Wide diagonal cracks between the supports and mid-points of simple beams generally mean slip of bar or crushing of concrete under the bends of the web reinforcement. These cracks are particularly dangerous, for they show that the load limit of the beam is reached, and that real failure, even under a decreasing load, may follow quickly. Thus, cracking may or may not mean danger. The cracking is not necessarily dangerous, if the reinforcement is adequate.

Mr. Godfrey has presented a number of interesting points. For example, he questions the validity of the  $45^\circ$  assumption in the development of the formulas for web reinforcement. If a reinforced concrete beam were truly homogeneous, such cracks as occurred would tend to form at right angles to the tension stress trajectories. If the beam could be modified so that the horizontal components along all tensile stress trajectories were resisted by the horizontal steel, then the diagonal tension and diagonal compression components of the vertical shear on any vertical section would be a maximum on planes inclined at  $45^\circ$  to the vertical, and cracks above the steel and below the neutral axis would occur at an angle of 45 degrees. In regions of low vertical shear, where they are not dangerous, cracks would be slightly inclined. It is a fact that in simple beams cracks generally occur in this manner. Where, owing to slip of the main reinforcement, a dangerous diagonal crack occurs, the crack is more nearly horizontal for some distance along the bar, gradually approaching  $45^\circ$ , and then tending toward the horizontal again. Even here, where vertical stirrups would be of little help, the  $45^\circ$  assumption as to the direction of crack is on the safe side.

In continuous beams the stress trajectories become horizontal over the supports, and vertical cracks may form in the top of the beam at the face of the support. Within the angle formed by the face of the support and a line extending at  $45^\circ$  from the junction of the lower surface of the beam and the face of support, cracks will tend to form at angles between the vertical and 45 degrees. Fine cracks within the  $45^\circ$  line are not necessarily dangerous, for, as Mr. Godfrey states, "with the top and bottom rods firmly anchored into the support, a large shear can be carried by the concrete". The resistance to the formation and development of these cracks is furnished by the horizontal negative reinforcement, not by the web steel. If the negative reinforcement is deficient in amount or in anchorage into the support or out into the beam proper, these cracks will develop, and no type of web reinforcement will prevent trouble. This, however, is no concern of the web reinforcement, for

\* Prof., Bldg. Constr., Carnegie Inst. of Tech., Pittsburgh, Pa.

it can only reinforce the web outside the  $45^\circ$  line. Thus, again, the  $45^\circ$  assumption seems not erroneous for use in the design of the web steel. Mr. Godfrey mentions the weakness at this point, and so does Mr. Werner, but if the horizontal steel were deficient the diagonal bars recommended by Mr. Godfrey could function only by sidewise bearing in the concrete, which he, himself, points out as being ineffective. It seems to the writer, then, that while Mr. Godfrey's method of web reinforcement is undoubtedly a good one, the  $45^\circ$  assumption is satisfactory as a basis for working formulas.

Mr. Godfrey also mentions the difficulty of anchoring bars properly and compares an anchorage to the end detail of a truss member. In this the writer heartily concurs; but because he had presented a former paper\* dealing exclusively with this subject, he did not develop the point further at this time.

The writer has observed a curious phenomenon in simple beams tested to destruction. When uniform loads were used, the dangerous diagonal tension crack formed at about the quarter-point of the span, whereas when concentrated loads were used the important crack ran diagonally upward from the reinforcement toward the load point at an angle of about  $45$  degrees. Mr. Turner's discussion may hold the clue to this phenomenon. It seems to the writer that if stirrups are necessary at all in simple beams they should be carried at least to the quarter-points.

It was not the writer's intention to bring bi-axial strain into the discussion, as suggested by Mr. Feld, for he feels that web reinforcement can be designed effectively and economically without such complication. Professor Cross has well summarized some of the writer's ideas in the last paragraph of his discussion; but it is the writer's intention also to point out that when steel of a high elastic limit is used, great progress is still possible in reinforced concrete design. If the designer wishes to take advantage of these possibilities, he must constantly keep in mind all the precautions pointed out, even if, as Mr. Eckles states, some of them may appear to be extreme.

#### EXPERIMENTS ON DISCHARGE OVER SPILLWAYS AND MODELS, KEOKUK DAM\*

By FLOYD A. NAGLER† and ALBION DAVIS,‡ MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. B. F. JAKOBSEN, J. B. SPIEGEL, DANA M. WOOD,  
S. P. WING, E. A. RUDOLPH, C. H. PIERCE, LUDWIG A. OTT, B. F. GROAT,  
AND FLOYD A. NAGLER AND ALBION DAVIS.

#### SYNOPSIS AND CONCLUSIONS

This paper describes rather unusual discharge measurements made on the crest of the spillways of the Keokuk Dam, in Iowa. These studies were supplemented by tests made on a laboratory model, in order to determine a more accurate spillway rating than had formerly been available and in order to make possible a final and precise revision of the daily flow records of the Mississippi River at this point. Volumes of flow averaging about 4 000 sec-ft. were measured in the 30 ft. of spillway width, at heads slightly less than 11 ft.

Unless one has attempted to measure water running 24 ft. per sec. he cannot appreciate all the difficulties attendant on an accurate spillway crest gauging under a head of 11 ft. Special equipment was required to handle properly the stay-wires supporting the meters. By this means it was possible to make about 150 velocity observations in each gauging, fully exploring the entire cross-section up to within 0.4 ft. of the spillway edge. It was also possible to measure all the vertical and horizontal angles of flow and to rate the meters so as to obtain results that were accurate within 2 per cent.

It was found that opening the gates adjacent to the spillway where the water was being measured had a very considerable effect on the discharge

\* Published in February, 1929, *Proceedings*.

coefficients. In the formula,  $Q = CLH^{\frac{3}{2}}$ , the coefficient,  $C$ , for the normal operating head\* of 10.8 ft., varied from 3.71, when a single spillway was discharging, up to 3.90, when many spillways were discharging. The gaugings also showed clearly that, with a crest unobstructed by piers,  $C$ , for a 10.8-ft. head, increased to 4.00.

The coefficients developed by these measurements are in rather striking contrast to the conservative coefficient of 3.33 that was used in providing spillway capacity in the Keokuk Dam, notwithstanding the fact that in designing the dam it was realized that the actual coefficients would probably be considerably greater than 3.33. The use of the new spillway rating yields flood flows that are in some cases 10% in excess of the former determination.

The field measurements were followed by a study of the behavior of a model of three of the spillways built to a scale of one-eleventh the size of the Keokuk Dam in the Hydraulic Laboratory of the State University of Iowa.

These experiments duplicated the results observed at the dam itself under normal conditions with remarkable reliability, and studies were made to determine the probable behavior of the Keokuk spillways when discharging under abnormal pond levels.

Experiments were performed on the model when its surface was both smooth and rough, and with and without a fill of sediment up stream from the dam. It was demonstrated that, in experimenting with such a large model, the relative amount of friction caused by the varying surface conditions of the model was of small significance.

Several pier shapes differing from those used at Keokuk were constructed on the model. Extending the pier nose up stream, or giving it a tapered form so that it attained its full thickness a short distance down stream from the highest part of the spillway crest, produced a dam with a greater discharge than that obtained with the Keokuk design.

#### HISTORY OF THE CALIBRATION OF THE SPILLWAYS

Both prior and subsequent to the actual construction of the water power development, the engineers of the Mississippi River Power Company have kept continuous records of daily flow at Keokuk, as well as at other points on the Upper Mississippi River.

The flow record at Keokuk subsequent to the construction of the dam has been computed with considerable accuracy by calculating the discharge through the water turbines, and the quantity of surplus water discharged over the spillways. Field measurements of the hydraulic efficiency of the various turbine units were available. These served as a basis for accurate computations of turbine discharge.

Pond elevations taken every hour and a record of gate operations permit computation of the flow over the spillways by the use of a weir formula. The coefficients for this formula to compensate properly for the nappe contractions over the crest and around the piers, however, must be determined definitely by measurements if an accurate record of discharge over the dam is to be obtained.

\* Throughout this paper,  $H$  in this formula denotes the depth of the pond water above the highest part of the concrete crest.

Previous to 1924, coefficients had been used which were based partly on some early measurements made on the discharge through single spillways at times when the pond level was maintained at an elevation of less than 5.28 ft. above the crest, and also on a rating curve for these spillways prepared by John R. Freeman, Past-President, Am. Soc. C. E., and derived from experiments on models of the Croton Dam. The normal operating head on the Keokuk spillway is 11 ft., a head much in excess of that existing in any of these tests, and much higher than had existed in any measurements known to the writers.

For some time it was feared that the coefficients obtained in this manner were too small for use under heads as great as 11 ft., perhaps to the extent of 10%, but no change was made from the original rating so that all records of daily flow would be comparable. From the daily computations of flow over a period of several years, and from current-meter measurements of flood discharge above and below the dam, several fairly definite conclusions were developed. It was noted that there was a tendency for the computed flow at Keokuk to be lower on Sundays than during week days when there had been no apparent change in natural flow entering the pond. The only difference in Sunday operation was that more water passed over the spillways and less through the water turbines than on contiguous week days. Flood discharges computed from the several measurements in the open river invariably indicated a higher flow than those computed from the records of plant and spillway operation. It became evident that a new and more nearly correct rating of the spillways must be obtained if the Keokuk records were to represent the true discharge at that point. The tests described herein were undertaken as the first step toward making the flow records available for publication for the benefit of the profession.

The co-operation of the engineers of the Hydraulic Laboratory at the State University of Iowa was enlisted in obtaining the actual measurements of flow through the Keokuk spillways. The Laboratory Staff was interested in undertaking this work as a research problem, not only because of the value to the Engineering Profession of the actual field measurements of discharge over the Keokuk spillway, but also because of the opportunity afforded thereby to make comparisons between the large-scale results and the performance of models.

Eight measurements of the discharge over the spillways were made by operating Ott current meters in the cross-section of the nappe above the crest during the period from April 29 to May 8, 1924.

A model of three sections of the spillway one-eleventh of the full size was constructed in the testing canal of the University of Iowa Hydraulic Laboratory, and studies were made during the period from September 16 to October 29, 1925.

Before removing the model from the testing flume, an investigation was made to compare the contraction effects of certain other forms of piers with those of the Keokuk design. These experiments were performed during the period from November 19, 1925, to May 5, 1926.

## DESCRIPTION OF SPILLWAY

The actual dam consists of 119 spillway sections extending from the Illinois shore to the up-stream corner of the power house. A view of the spillway is shown in Fig. 1. Each spillway section is 30 ft. wide with a crest about 30 ft. above the former natural stream bed. The spillways are separated by piers which are 6 ft. thick, with a cross-section at the up-stream end in the form of a semi-circle (see Fig. 2).

The typical cross-section of the spillway shown in Fig. 3 gives the details and dimensions of the form of the crest. Soundings made up stream from the spillways selected for the tests indicated that the bed of the stream approaching the dam is much higher than the natural stream bed at these points. This is due in some cases to coffer-dam material left in place and, in other cases, to natural sedimentation. In the twelve years since the construction of the dam, there has been considerable silting in front of those gates that are operated very infrequently and where "dead water" exists nearly all the time. In front of the gates that are operated more frequently, however, there is practically no sedimentation.

Fig. 2, which is a view of the up-stream face of the dam, shows the well-rounded approach to the crest of the spillway. Extending from the concrete crest upward there is a slot 21 in. wide and 14 in. deep in the face of each pier, in which steel gates, 11 ft. high and 32 ft. wide, are operated. The water level behind the dam is maintained at all times close to the top of the gate, which is about 11 ft. above the crest of the dam. The steel gates, which are of the plain sliding variety without rollers, are finished on the bottom with a timber sill which makes the water seal against the carefully finished concrete crest of the dam. The gates are raised by electrically operated traveling cranes, and are always lifted clear of the water surface, so that a spillway discharges to its full capacity. What little leakage there is when a gate is lowered, is cut off effectively by a few shovelfuls of cinders, when the leakage becomes a factor in the operation of the plant.

The spillways are numbered in order from the Illinois shore toward the power house. The discharge measurements were made on Spillways Nos. 68 and 103. Spillway No. 68 was chosen as representative of those near the center of the dam, and Spillway No. 103 was selected from among those nearer the power house where the pond is deeper.

CURRENT METER DISCHARGE MEASUREMENTS AT KEOKUK DAM,  
APRIL 29 TO MAY 8, 1924

After a careful study had been made of the various possible methods of accurately measuring the discharge through the spillway, it was decided to operate current meters in the nappe as it flowed over the crest of the dam. It was appreciated, however, that stream velocities would be nearly 25 ft. per sec., which is greatly in excess of speeds ordinarily encountered in current meter practice; and that, in parts of the nappe, stream filaments would approach a rigidly supported meter at a considerable angle with the meter axis. Non-rigid suspension of metering equipment was entirely out of the question.

SECTION SHOWING EQUIPMENT FOR HANDLING CURRENT METER

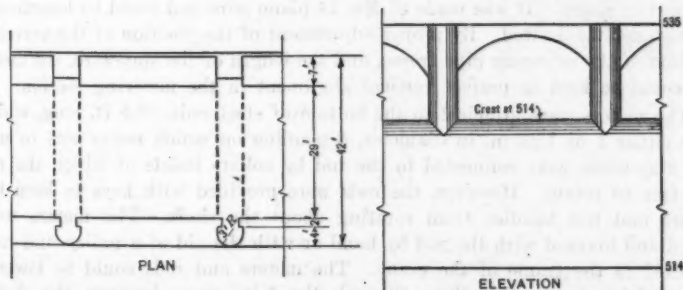

FIG. 3.—DETAILS OF SPILLWAYS IN THE MAIN DAM.

*Development of Method of Measurement.*—The Ott type of current meter seemed admirably adapted for these measurements, not only because it measures the normal component of angular currents more accurately than other types, but also because the bearing at the end of its horizontal axis is capable of taking the strong horizontal thrust caused by these high velocities. A Price meter was used successfully in one attempt to measure the velocities all the way through the nappe to the crest, but considerable wear was noted on the pivot point and sides of the cone bearing. This indicated that the pivot shaft was rubbing on the metal side of the bearing and that this type of vertical shaft meter could not long withstand the thrust from high velocities of current.

The section of the nappe between the gate slots was selected as the more economical and the safest place for measurement, but to hold a meter steadily against the forces encountered when the water flowed under 11 ft. of head proved to be no small task. A 1-in. pipe with a fulcrum 4 ft. above the water could be immersed only 3 ft. before it was permanently bent. When a 2-in. pipe was tried with a similar fulcrum, it could be lowered but 6 ft. before permanent deflection occurred. It proved absolutely impossible to force these rods to the crest of the spillway through the sheet of moving water.

After considerable experimentation and deliberation, it was decided to hold the lower end of the rod in position by means of a stay-wire attached to an adjustable and movable framework extending up stream from the dam. It was considered too dangerous to attempt the meter work from a temporary platform built close to the swiftly moving water at any lower section of the nappe.

*Metering Equipment.*—A framework made of standard pipe was attached to one of the two traveling cranes which are used to raise and lower the spillway gates. Figs. 3 and 4 show the details of the design of this framework and its relation to the metering operations. By means of the traveling crane it was possible to move the framework to any lateral position relative to the spillway, and the outer end of the lower section of the framework to which the stay-line pulley was attached could be lowered or raised to any desired depth. The stay-wire that passed over the pulley and through the water was divided about 5 ft. in front of the measuring section in order to support the rod in two places. It was made of No. 14 piano wire and could be lengthened or shortened as desired. By proper adjustment of the position of the traveler, location of the swinging pipe frame, and the length of the stay-wire, the meter rod could be kept in perfect vertical alignment in the metering section.

The meters were attached to the bottom of steel rods, 23.5 ft. long, which were either 1 or 1.25 in. in diameter, depending on which meter was in use. The stay-wires were connected to the rod by collars inside of which the rod was free to rotate. However, the rods were provided with keys to keep the meters and rod handles from rotating about the shaft. The meters were raised and lowered with the rod by hand or with the aid of a pulley and rope attached to the frame of the crane. The meters and rods could be lowered into position by passing them through the 5-in. space between the downstream side of the gate and the up-stream face of the concrete deck of the

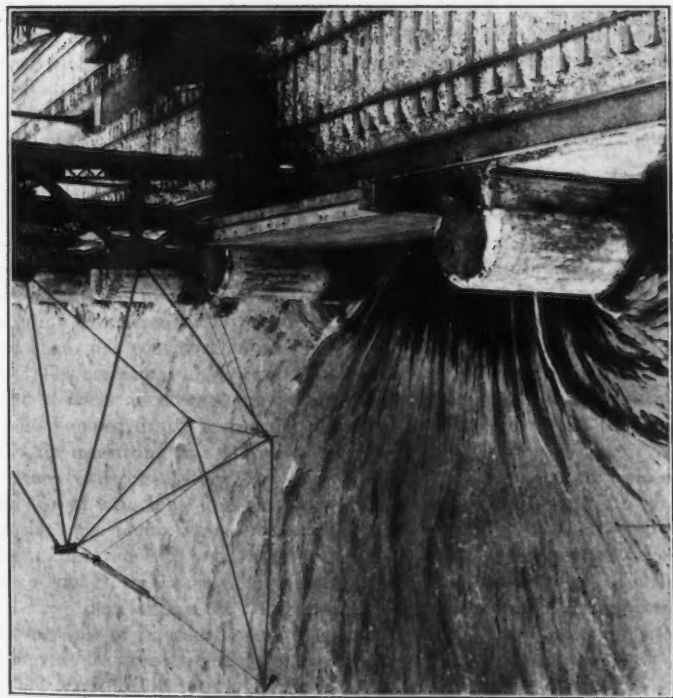

FIG. 4.—FRAMEWORK FOR HANDLING STAY-WIRES FOR THE SUPPORT OF THE CURRENT METER ROD.

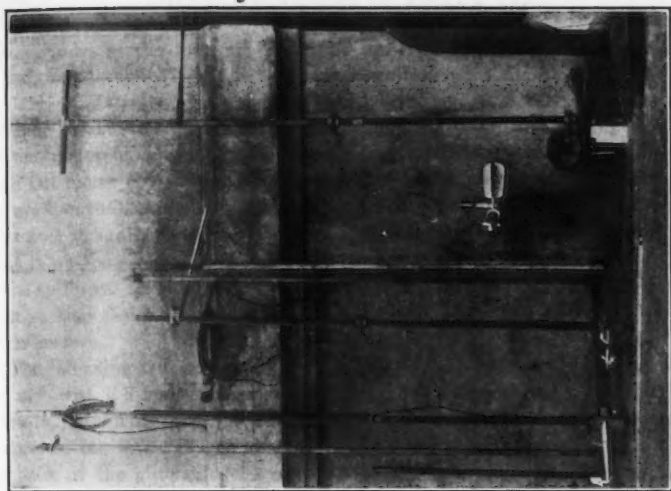

FIG. 5.—METERING EQUIPMENT USED IN KEOKUK MEASUREMENTS.

dam. Guides at the top and bottom of the gate were used to plumb the rod at designated verticals in the measuring section.

*Current Meters.*—Three meters of the Ott type were used in making the different measurements, although the equipment permitted the operation of but one meter at a time. (See Fig. 5.) Most of the work was done with a small Ott meter (No. 2908) which had a propeller with two blades. Soon after the work started, this meter was equipped with a special tail-piece and a guard to protect it against striking the face of the concrete pier. With this instrument it was possible to make velocity measurements within 0.4 ft. of the side of the spillway. A steel rod, 1 in. in diameter, was used and this whole equipment seemed easier to handle and keep under control than that used with the larger meters.

The Mensing-Ott meter (No. 3246) was used with a 3-blade propeller, and also with a 2-blade propeller. With the 3-blade propeller it had characteristics in measuring angular currents which were superior to the others, but because of the wheel it was lowered with difficulty in the small space between the back of the gate and the concrete deck of the dam, and because of the larger rod, was not as easily handled in the swiftly moving water as the smaller meter. It did not prove practical to make measurements closer than 2 ft. from the pier with the larger meter because of the danger of the rod becoming unmanageable in moving from one section to another in the oblique current and striking the pier. At one time, when the rod got out of control, the meter struck the pier, but the propeller escaped damage because of the recess at the gate slot. When the larger meter was used, the part of the discharge nearer to the piers than 2 ft. was measured with the small meter provided with a steel guard.

While the vertical rod held the meter in a horizontal plane at all times, no attempt was made to keep the meter axis in a line perpendicular to the measuring section. The meters were supplied with longer tail-pieces than are ordinarily used, and were allowed to swing into the thread of the current. Throughout the major part of the spillway the vertical plane through the thread of the current was perpendicular to the metering section, but near the piers there was considerable contraction of the nappe, with resultant oblique flow. The horizontal angle assumed by the meter axis was measured for every point in order to correct the velocity measurements for this deflection. A handle clamped firmly to the rod near its upper end furnished the necessary index for measuring this deflection.

Much experimentation was done with various forms of tail-pieces and methods of attaching the stay-wire to the meter rod. On four different occasions the piano wires broke despite the care taken in their preparation. Once, when the lake was rather rough, the twist on the meter rod became severe enough to shear off the screws holding the key in place. During the first three days of the tests the bending of the rods was a daily occurrence. In every case of trouble, however, the man operating the rod was quick enough to prevent losing or seriously damaging any of the equipment.

The strain of operating the small meter in the high velocities was so great that during the tests it proved necessary to make a new steel shaft for this

instrument due to the excessive wear that had taken place in the ball races of the guide-bearing near the propeller.

A special device was constructed to measure the vertical as well as the horizontal angle of the current in the nappe. It was operated from the upstream side of the gate and was constructed so that the center of the tail-piece stood in the plane of the measuring section. The tail-piece was about 2 ft. long and was hung about 5 in. down stream from the 1-in. pipe which supported it. The up-stream end of the tail-piece was pinned to a  $\frac{3}{8}$ -in. iron rod which passed inside the 1-in. pipe and extended through a hole in a tee at the top. All parts adjacent to the vane were thinned down and given streamline surfaces to offer the least resistance to flow. Handles for operating the equipment were screwed to the tee. The pivot point was located so that the weight of the tail-piece balanced the weight of the  $\frac{3}{8}$ -in. iron rod. The stay-wires were connected to the pipe in a manner which left it free to rotate. Horizontal angles were indicated by the angle which the handles made with the face of the gate; the vertical displacement of the  $\frac{3}{8}$ -in. rod through the tee at the top gave the data required to compute the sine of the vertical angle of the current. The equipment was very rugged, but, nevertheless, dependable and accurate.

*Rating of Current Meters.*—During the tests the water attained velocities of 13 to 26 ft. per sec. and struck the meter at angles with the axis of 0 to 22 degrees. It was impossible to secure ratings in velocities as high as most of those encountered, but after a survey of the possibilities at various rating stations, the meters were sent to the U. S. Bureau of Standards where they were calibrated in velocities as high as 16 ft. per sec. Since the bearing friction becomes a negligible force at high velocities of flow, the rating curves for all these meters were straight lines at velocities greater than 2.5 ft. per sec. They were thus extended to give the rating throughout the range of velocities encountered. The meters were rated both before and immediately following the measurements at Keokuk. A special rating of Meter No. 2908 was made with the guard mounted on the meter frame. While no part of this guard was within 2 in. of the propeller, this obstruction behind the wheel retarded the revolution approximately 2 per cent.

The meters were also rated with the water approaching the propeller at horizontal and vertical angles. These ratings showed little if any difference in the registration, with currents approaching at the same angles from various directions. In streams of great obliquity the three Ott meters under-registered the axial component of the currents by different amounts, the 3-blade meter having by far the best characteristics. Fig. 6 gives the amount of the under-registration in currents of high velocity as obtained from the ratings at various angles. In other words, it shows the correction (in percentage) to be added to the measured velocity in order to obtain the actual component of velocity along the axis of the meter. The meters used were rated by the U. S. Bureau of Standards during April and June, 1924.

*Discharge Measurements.*—Three discharge measurements (Tests 1, 2, and 8, in Table 1), were made when the spillway being metered was remotely isolated from others that were open. Column (4) of Table 1 gives the location

of the tests. Test 1 was performed merely to familiarize the observers with the operation of the equipment.

Tests 3 to 7, inclusive, were performed on Spillway No. 68 in order to determine the effect of the operation of adjacent spillways on the discharge through the spillway under test. Thus, in Test 3, the adjacent spillway, No. 69, was open. In Tests 4 and 5, one spillway on each side of No. 68 was opened. These two tests were performed under exactly the same spillway conditions, but with different meters, in order to check the accuracy of this work; also, because parts of Test 4 were performed on different days, it was thought desirable to repeat this test in a continuous run. In Test 6, the spillway observed was the end one of a series of five that were open, and in Test 7 the measurements were made on No. 68 when operating as the center spillway of a series of seven which were discharging fully.

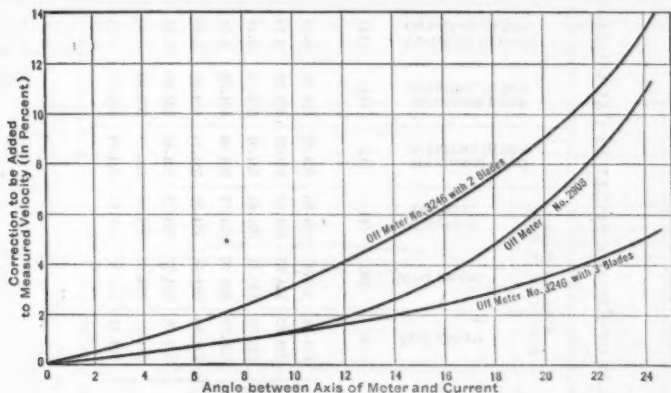

FIG. 6.—CORRECTION TO BE ADDED TO MEASURED VELOCITY.

Individual velocity measurements adequate in number and location to determine definitely the vertical variation in speed of current were taken in vertical lines located at the following distances, in feet, from the side of the spillway: 0.4, 1.0, 2.0, 3.5, 5.0, 7.0, 11.0, 15.0, 19.0, 23.0, 25.0, 26.5, 28.0, 29.0, and 29.6.

The meter revolutions ordinarily were measured at points 1 ft. apart in each vertical, except near the spillway crest, the water surface, and in the shallower verticals near the edge of the spillway, where observations were made at  $\frac{1}{2}$ -ft. intervals. The period during which the meter revolutions were counted was generally between 30 and 60 sec.

The section in which the metering was done proved to be an ideal one in many respects. The water being accelerated as it passed over the crest, flowed with remarkable uniformity in smooth stream lines and was free from the characteristic pulsations in velocity and annoying vortices which so often accompany the phenomenon of flow in other channels. Many checks of observations were made at certain points after short lapses of time, with the inviolable result of duplicating the previous readings exactly or within slight

## SPILLWAY DISCHARGE OF KEOKUK DAM

TABLE 1.—GENERAL SUMMARY OF RESULTS OF KEOKUK SPILLWAY CALIBRATION, APRIL 29 TO MAY 8, 1924.

Test No.	Date of test.	Total duration of test, in hours and minutes.	No. of gate tested.	Average elevation of spillway crest, in feet.	Nos. of adjacent gates open.	Meter used on Stations 2 to 28.	Meter used on Stations 0.4, 1, 29, and 29.6.	AVERAGE POND ELEVATION, IN FEET.			Maximum pond elevation, in feet.	Minimum pond elevation, in feet.	Variation in pond elevation, in feet.	Area of gauging section, in square feet.	Average velocity in gauging section, in feet per second.	Measured discharge, in cubic feet per second.	Head on crest of spillway, in feet.	Coefficient of discharge, $C_d$ , in $\frac{Q}{LH^{3/2}}$	Discharge for Pond Elevation 524.80, in cubic feet per second.

differences of not more than a fraction of a second. The variation in velocity from the water surface to the crest also was remarkably uniform. In many verticals, a long section of the velocity curve was almost a straight line. This insured the determination of this curve to a high degree of accuracy.

*Nappe Cross-Section.*—The physical dimensions of the spillways were measured at the dam. The upper surface of the nappe at the section where the meter propeller was operating was determined at each vertical by taking a rod reading with the propeller at the water surface. As a check on these readings the surface was also measured with a steel tape, at sections under both the up-stream and the down-stream side of the gate before and after each discharge measurement. The three sections thus obtained during Test 8 are shown in Fig. 7, the metering section being about midway between the other two. At times of little wind there was no difficulty in determining the water surface of the nappe at the point of measurement within a few hundredths of a foot, and under no condition were there surface waves of sufficient magnitude to render this measurement uncertain by as much as 0.5% of the total depth.

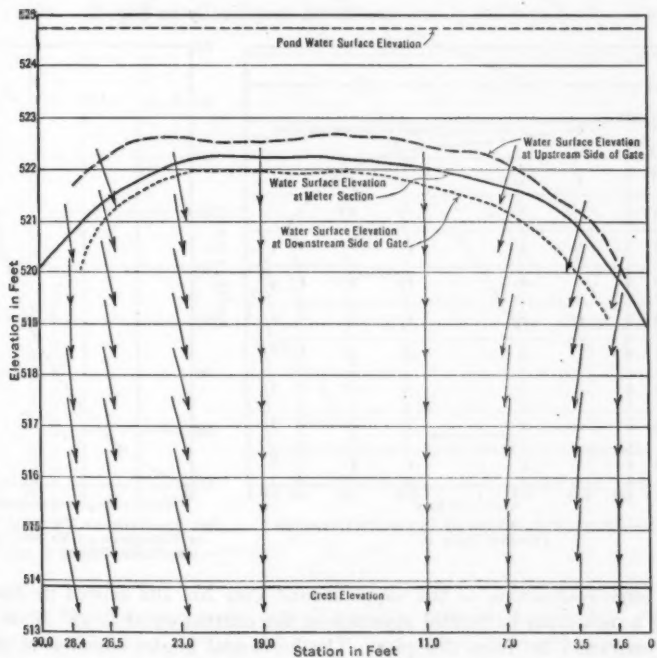

FIG. 7.—HORIZONTAL ANGLE OF CURRENTS OBTAINED DURING TEST 8.

*Pond-Water Level Measurements.*—As 3 to 9 hours were required to make a single measurement of discharge it was fortunate that the lake was large and little variation in pond level occurred during the tests. The maximum

difference in pond level of 0.35 ft. occurred during Test 5, but the average maximum for the eight tests was only one-half this difference. (See Table 1.)

Elevations of the pond-water surface were recorded every 15 min. during the test by Gurley printing water-stage registers located on Piers No. 30 and No. 90 and close to Pier No. 119. In addition, the water level at points near certain closed spillways between the two recording gauges were read with a tape and weight in order to detect the amount of depression in the pond-water surface approaching the open spillways under test.

*Obliquity of Currents in Nappe.*—Using the current direction meter, measurements of the vertical as well as the horizontal angle of the current were made in connection with Test 8 on Spillway No. 103 discharging alone. These readings were then repeated on this same spillway (as Test 9) with the nappe greatly contracted on one side, caused by the opening of Spillways Nos. 104 to 109 during the test. Readings were taken at most of the verticals used in the current-meter work and at intervals of 1 ft. in elevation.

In Test 8, the maximum horizontal angle of approach of the current ( $18^{\circ} 30'$ ) was observed at the surface 3.5 ft. from the pier. The horizontal angles observed at other points are shown graphically in Fig. 7.

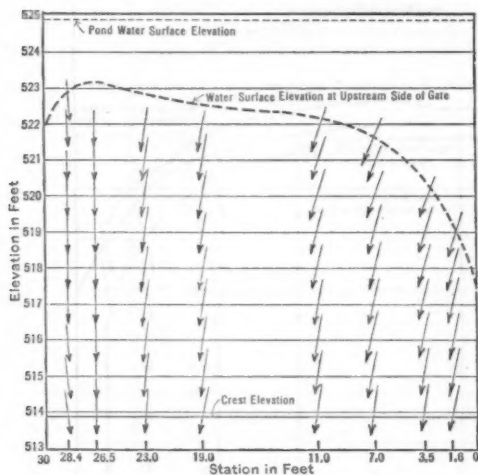

FIG. 8.—HORIZONTAL ANGLE OF CURRENTS OBTAINED DURING TEST 9.

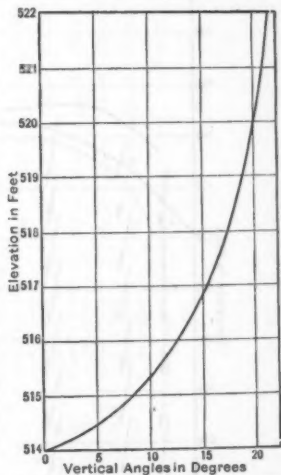

FIG. 9.—AVERAGE VERTICAL ANGLE OF CURRENTS AT VARIOUS ELEVATIONS, TESTS 8 AND 9.

A large contraction of the nappe around Pier No. 102 existed in Test 9, giving a maximum horizontal approach of the current equal to  $22^{\circ} 10'$  at the water surface 7 ft. from this pier. The horizontal angles observed at other points are shown graphically in Fig. 8.

The vertical angles at which the current approached the metering section were remarkably constant at a given elevation above the spillway crest. The average results from the observations in Tests 8 and 9 are shown in Fig. 9. Only twelve of the readings taken in Tests 8 and 9 gave values which were

more than  $3^\circ$  from this curve, and in no case was there a departure of more than 5 degrees. This average curve was used as the basis for all computations involving the evaluation of the vertical angle of approach of the water toward the meter.

*Computation of Actual and Normal Current Velocities.*—Meters, held rigidly on a vertical rod that was free to swing with the current, registered only the component of the stream velocity in the horizontal plane passing through the meter. If the vertical angle of approach was significant, even the value of this component was under-registered by the Ott meter. The treatment of the measured current values in one of the fifteen verticals constituting Test 8, is illustrated by Fig. 10 and the data are shown in Table 2.

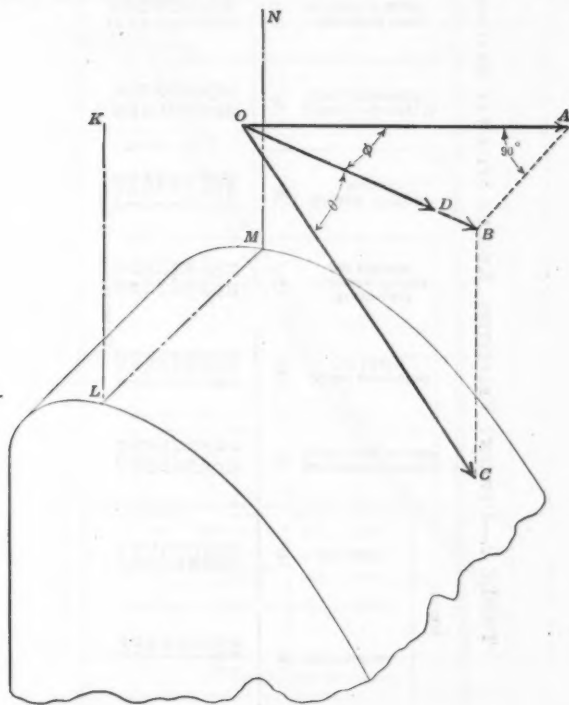

FIG. 10.

These ratings were made with Meter No. 2908 at Station 23.0. It was rigidly clamped to a vertical rod free to swing about its vertical axis so that the meter axis lay within a vertical plane passing through the thread of the current with the propeller located at Point O in Fig. 10. In measuring the velocity of the current passing in the direction,  $OC$ , the meter should have registered its component,  $OB$ , projected vertically into the horizontal plane passing through the axis of the meter. The ratings showed that as a matter

Water surface of nappe.

of fact the Ott meters sometimes under-registered this component, obtaining the value,  $OD$ , which is less than  $OB$ . It was necessary, therefore, to correct some measured velocities by applying the small under-registration factors shown in Fig. 6. Thus, Column (7) in Table 2 is the product of Columns (5) and (6). The actual value of the current velocity,  $OC$ , was obtained by multiplying the horizontal component,  $OB$ , by the secant of the vertical angle,  $\theta$ . The average value of this angle was read from Fig. 9 and was tabulated in Column (2). The component of the stream velocity which was perpendicular to the gauging section is  $OA$  (Column (13)), and was obtained by multiplying the horizontal velocity,  $OB$  (Column (7)), by the cosine of the horizontal angle,  $\phi$ , the sine of which was observed at every point at which the velocity was measured.

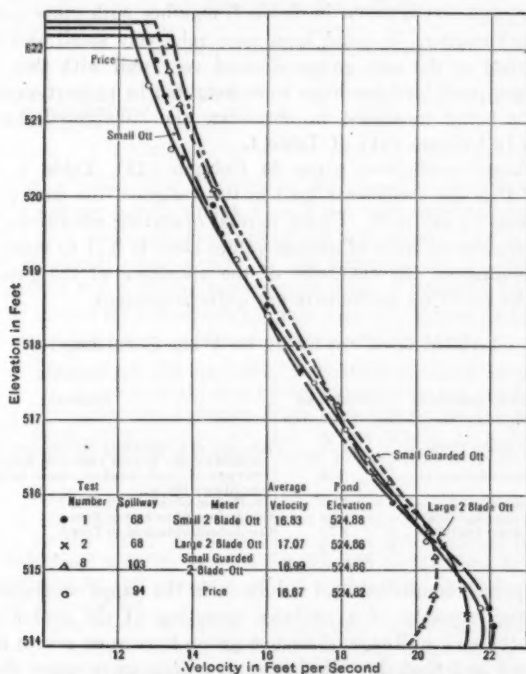

FIG. 11.—COMPARISON OF VERTICAL VELOCITY CURVES.

*Computation of Spillway Discharge.*—Table 2 is a sample showing the results obtained from the meter measurements in a vertical line 23 ft. from Pier No. 103 in Spillway No. 103 during Test 8. The results of all observations in each test were computed in this manner, and from such tables, curves were plotted showing the distribution of velocities in the different vertical lines. Such curves are shown in Fig. 11. The average velocity in each vertical was obtained by applying Simpson's rule to twenty equally spaced points on each vertical velocity curve. The values of mean velocity thus

found were remarkably uniform across the spillway section. The maximum variation obtained, including tests with the most contracted nappes, was only 17 per cent.

When symmetrical conditions of flow existed there was little variation in depth of the nappe and current velocities in the middle half of the spillway, but the pier contractions caused a rapid decrease in depth at points closer to the face of a pier. It is chiefly for this reason that the distance between the vertical lines of measurement was decreased near the edge of the spillway.

The discharge of the spillway was computed from the data on average velocity and nappe depth in the manner commonly used in stream measurement; that is, by computing the average velocity, depth, area, and quantity of flow, in the nappe sections between verticals. A summary of the computed discharge for each test is given in Table 1, together with other essential data.

While the variations in pond level were relatively small and the average of that recorded at the east gauge checked very well with that recorded at the west gauge, pond level readings were weighted in proportion to the quantity of water being measured in obtaining the "Weighted Average Pond Level" given in Column (11) of Table 1.

The discharge coefficients given in Column (19), Table 1, verified the earlier belief that the coefficients used in the design of the dam were conservative by at least 10 per cent. Under normal operating conditions, the correct weir coefficients varied from minimum values close to 3.71 to maximum values of 3.90, depending on the character of the operation of the gates. Table 3 shows that the resulting coefficients are quite consistent.

TABLE 3.—COMPARISON OF WEIR COEFFICIENTS.

Method of spillway operation.	Coefficient.	Remarks
One spillway operating alone....	3.71	Average of coefficients obtained in Tests 1 and 2 on Spillway No. 68 and Test 8 on Spillway No. 105.
Middle of three open spillways...	3.78	Average of coefficients obtained in Tests 4 and 5 on Spillway No. 68.
Middle of seven open spillways...	3.90	Coefficient obtained in Test 7.
End gate of two open spillways...	3.74	Coefficient obtained in Test 2.
End gate of five open spillways...	3.72	Coefficient obtained in Test 6.

Better approach conditions and reduction in the nappe contraction increase the discharging capacity of a spillway operating at the center of a larger group, while the end spillways of such a group have such severe contractions around the end pier that they discharge very little more water than a single spillway operating alone.

*Contraction of the Nappe Around the Piers.*—The piers reduced the discharge of water to a greater extent than that by which the area of unobstructed spillway was reduced by the concrete in the piers themselves. The weir coefficients in Table 4 were computed from the discharge flowing in the 8-ft. section remote from pier influence at the center of the nappe, in those tests in which the nappe was symmetrical. The reduction in discharge caused by the lateral contraction of the nappe as it passes around the piers with only one spillway open is more than twice that observed with many spillways open.

The form of the water surface of the nappe at the metering section which was observed in Tests 2, 3, 5, and 6, is shown in Figs. 12 and 13. Note the unsymmetrical form of the nappe surface in Tests 3 and 6 performed on a spillway at the end of a set of open spillways as compared with the more balanced surface curves in the other tests. There was less contraction in the nappe of Test 7 with many gates open than in Tests 2 and 8 on a single open spillway. The deeper pond near the power-house end of the dam seemed to produce a slight difference in the nappe contraction at the two sides of the spillway in Test 8.

Middle of seven open spillways...	4.00	3.90	2.5

*Distribution of Velocities Within the Nappe.*—The contours in Figs. 12 and 13 and in similar curves drawn for all the tests show the actual velocity of the water which was measured throughout the nappe. The velocity shown is not the component perpendicular to the metering section, but the actual current velocity in the metering section regardless of direction of flow.

A study of these curves discloses the following significant facts with regard to the behavior of the water as it passes over the spillway:

(1) Throughout the center of the spillway there is a remarkable uniformity in the velocity at a given depth below the pond level.

(2) The velocities increase from a minimum at the water surface to maximum values which are only a few tenths of a foot above the crest, there being but relatively little retardation at this point due to friction.

(3) Higher velocities than those existing in the center of the spillway are encountered a few feet from the pier faces where the nappe is formed by the water which is turning the bend around the pier nose. This increased velocity exists from the top to the bottom of the nappe as indicated by the elevation of the contours as the sides of the spillway are approached.

(4) Those tests in which meters were operated close to the pier faces show a small stream of slowly moving water at the crest in the outside corners, indicating that the water followed with difficulty the contour of the spillway at these places.

In making comparisons between the several tests and various parts of the same spillway, cognizance should be taken of the fact that slight differences in the pond level which existed at the time of measurement in a given section may be responsible for small variations in contour position.

It is scarcely possible, from these figures based on slightly varying conditions, to note the significant facts disclosed in Fig. 14. In plotting this diagram the velocity readings taken at the middle of the spillway have been reduced to corresponding values such as would have existed with a uniform

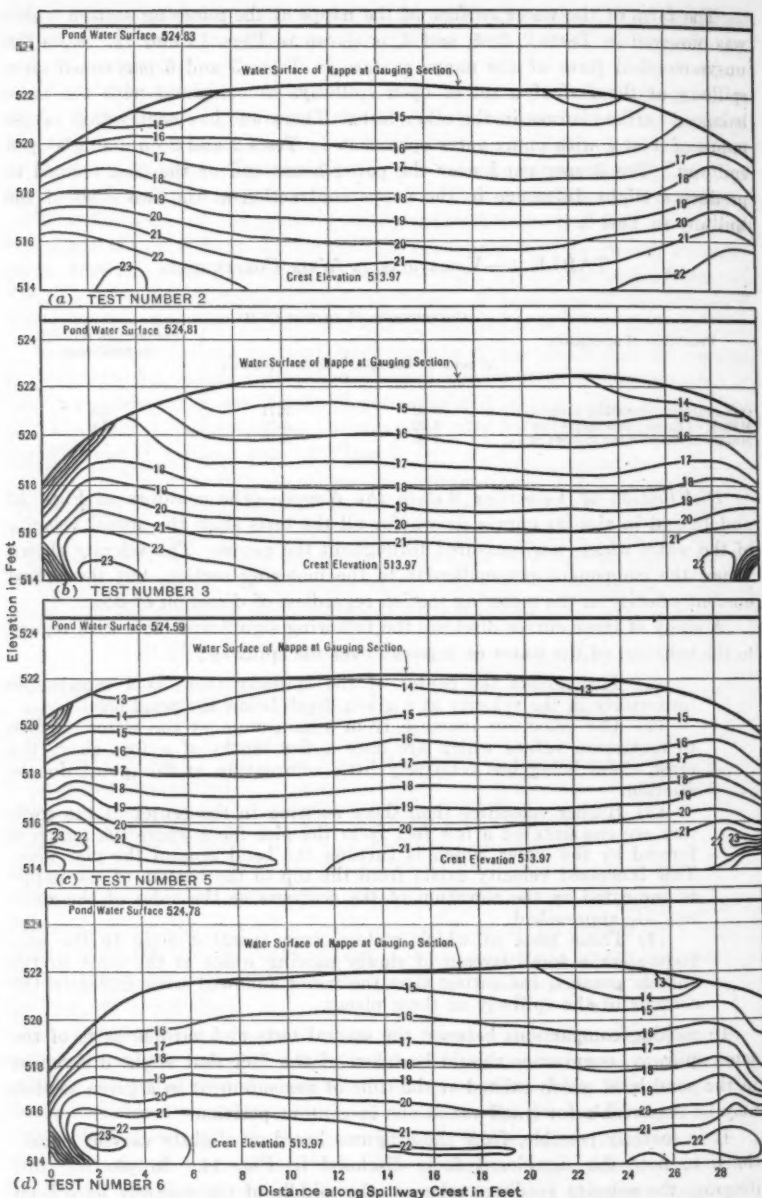

FIG. 12.—ACTUAL VELOCITY CONTOURS, IN FEET PER SECOND.

pond level at Elevation 524.80. A progressive increase in the number of open spillways seems to be accompanied by a progressive increase in the velocity and a depression of the nappe surface at the point of measurement. Thus, the larger spillway discharge coefficients with the greater number of open spillways may not be due entirely to the decrease in contraction of the nappe around the piers, but may also be produced by the higher velocities within the nappe itself when water is being drawn from a larger area in the pond, acquiring some initial velocity before reaching the spillway. This increase in velocity must be accompanied by a corresponding decrease in the pressure within the nappe. Considering the fact that the axis representing zero velocity is some distance to the left of the diagram, the difference in velocities is really of small consequence, hardly exceeding 5 per cent.

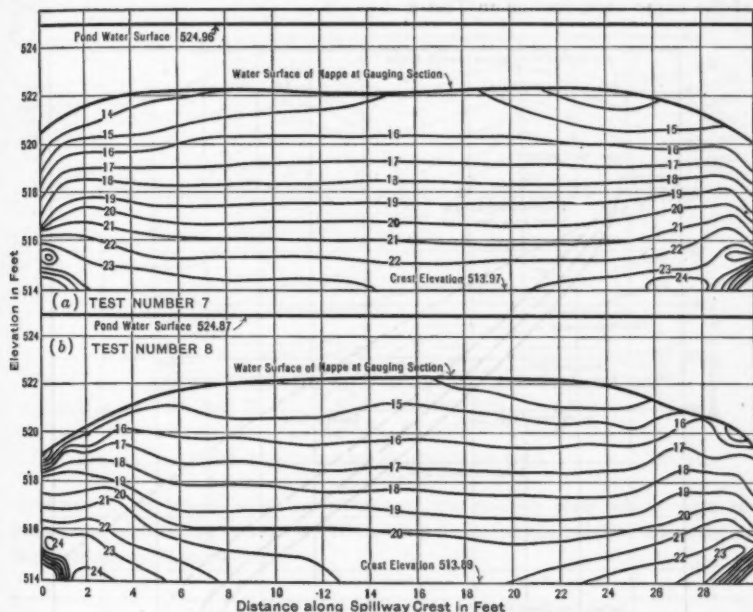

FIG. 13.—ACTUAL VELOCITY CONTOURS, KEOKUK SPILLWAY CALIBRATION.

The curves of Fig. 14 indicate that the velocity at the surface of the nappe may exceed that acquired by the water in falling from the pond level to this point. This excess, although small indeed, was observed in many instances and may be created by the friction of the lower filaments of the nappe upon the slower moving filaments at the surface. It is possible, however, that this phenomenon may have been caused by an initial wind surface current, or a tendency on the part of the meter to over-register near the water surface, although observations generally were not made within 6 in. of the surface.

The higher nappe velocities near the piers result from lower pressures in the interior of the nappe, but even at these places the maximum nappe veloc-

ities did not attain the limit which would exist if the interior nappe pressure were reduced to zero.

*Condition of Stream Bed Up Stream from Spillways.*—Soundings were made to determine the elevation of the bed of the river within a distance of 25 ft. from the spillways upon which tests were made. These soundings were made with a steel tape from the platform of the traveling crane. Contours of the bed of the pond are shown in Fig. 15 and profiles at certain sections are shown in connection with Fig. 3. There is evidence of sedimentation on top of the irregular deposit of construction materials ahead of most of the spillways, although all this material was at least 7 ft. below the crest of the spillways under investigation. The nature of the stream bed ahead of Spillway No. 103 was obviously responsible for the slightly unbalanced form of the nappe cross-section in Test 8.

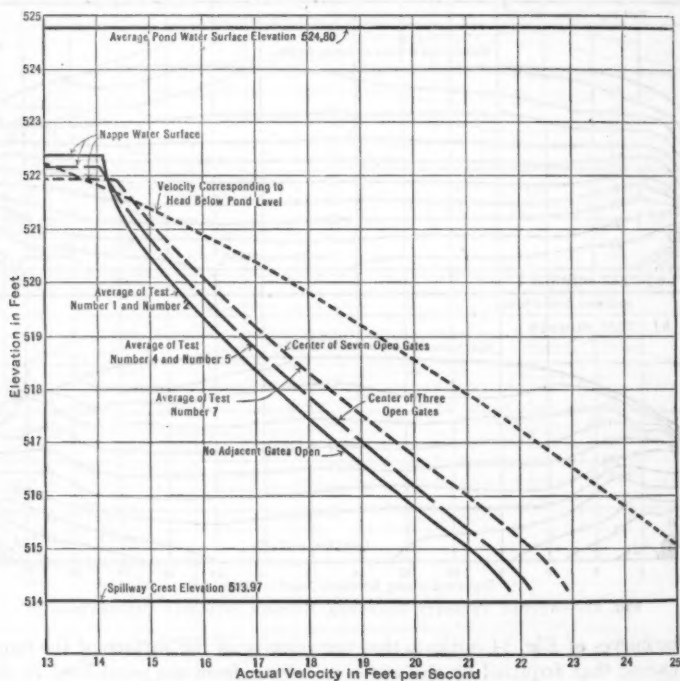

FIG. 14.—CURVES OF ACTUAL VELOCITY, STATION 15, KEOKUK SPILLWAY CALIBRATION.

*Surface Drop Near Open Spillway.*—Water surface elevations were taken in the immediate vicinity of Spillway No. 94 when discharging alone with no closely adjacent spillways open, in order to show accurately the shape of the depression of the water surface within 25 ft. of an open spillway. The result is shown by the contours in Fig. 16. It is interesting to note the change from the convex to concave contour as the nappe passes over the spillway. This

work was done when the lake was very calm. A tape with a heavy sounding weight attached at the zero end was lowered from the platform of the traveling crane, and readings of the tape were taken with a level set up on the dam. Observations which were correct within 0.02 ft. were probably obtained in this manner.

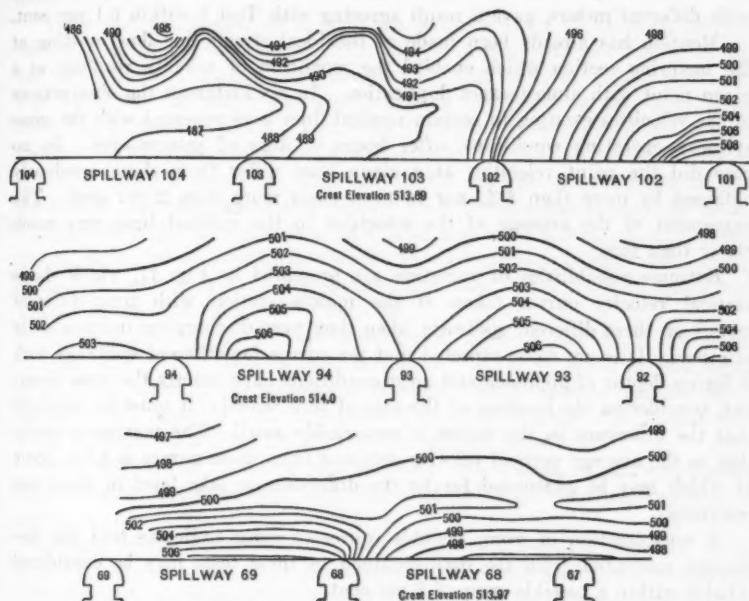

FIG. 15.—CONTOURS OF BOTTOM OF POND.

*Accuracy of Work.*—The agreement of the various tests which were repeated under differing conditions is one indication of the relative accuracy of the discharge measurements.

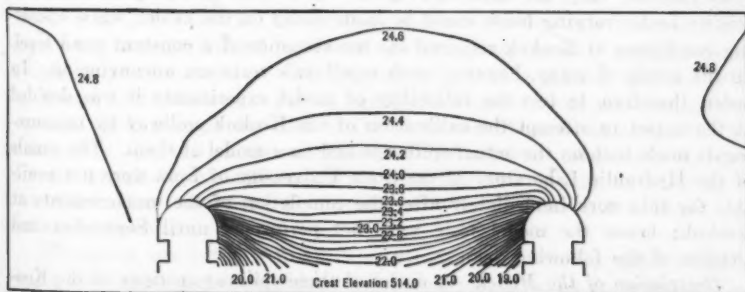

FIG. 16.—WATER SURFACE CONTOURS, SPILLWAY NO. 94, KEOKUK DAM.

Although Test 1 was regarded from the outset as a preliminary run, resulting in the more or less awkward and experimental handling of the equipment, its result departs 2.1% from Test 2 performed on the same gate with the same meter, and under the same conditions. Test 8 differs only 0.8% from Test 2, although it was performed on a different spillway with a different meter, but under similar operating conditions. Test 5, a repetition of Test 4, performed with different meters, gave a result agreeing with Test 4 within 0.1 per cent.

Mention has already been made of the ideal stream-line flow existing at the metering section which enabled the repetition of velocity readings at a given point with almost exact duplication. In six instances the observations of the velocities existing in certain vertical lines were repeated with the same spillway operating conditions, after hours or days of intermission. In no case did the point velocities at a given level differ from those previously obtained by more than 5%, nor in most cases more than 2 per cent. The agreement of the average of the velocities in the vertical lines was much closer than this.

Extreme possibilities of variation are presented in Fig. 11, which shows vertical velocity curves taken at the middle station with four different meters on three different spillways when they were discharging independently of others. It is not to be expected that the curves for different spillways with differing depths of approach and crest conditions have exactly the same form; but, considering the location of the axis of zero velocity, it must be admitted that the difference in the curves is remarkably small. The maximum variation in the average vertical velocity obtained from these curves is 2.3%, some of which may be accounted for by the difference in lake level in these two instances.

A consideration of every possible source of error indicates that the discharges computed from the data obtained in these tests may be considered reliable within a possible error of 2 per cent.

#### EXPERIMENTS ON A MODEL OF THE KEOKUK SPILLWAYS

The possibility of determining the proper discharge coefficients for the Keokuk spillways by means of small-scale experiments on a model of the dam was suggested before the field experiments at Keokuk were started. The model tests involved only one-sixth the expense of the full-scale experiments, and studies under varying heads could be made easily on the model, while operating conditions at Keokuk required the maintenance of a constant pond level. In the minds of many, however, such small-scale tests are unconvincing. In order, therefore, to test the reliability of model experiments it was decided at the outset to attempt the calibration of the Keokuk spillway by measurements made both on the actual spillways and on a model of them. The canals of the Hydraulic Laboratory of the State University of Iowa were not available for this work immediately after the completion of the measurements at Keokuk; hence the model tests were not performed until September and October of the following year.

*Description of the Model.*—A model of three spillway sections of the Keokuk Dam was constructed of wood on a scale of one-eleventh the size of the

actual dam, a section of which is shown in Fig. 3. Great care was taken in duplicating exactly to scale the form of the crest, and the shape and spacing of the piers. The wood which was chiefly redwood, was planed and sand-papered to a smooth finish for use in the early experiments, although in later tests it was given, successively, a smoother finish with shellac and a rougher finish with sand.

The model was erected 80 ft. from the entrance to the 10 by 10-ft. concrete testing canal of the laboratory. The three spillways with two full piers and two half piers at the canal sides occupied the full width of the canal exactly. The water for the canal was supplied from the pond on the Iowa River above the University Dam. The river furnished an unlimited quantity of water for these experiments (an average flow of 1 500 cu. ft. per sec.). Baffles in the canal a few feet down stream from the head-gates thoroughly diffused the stream filaments before they passed down the channel toward the model. Leaving the model the water entered a basin and, after passing through baffles, it had 50 ft. of unobstructed channel in approaching a suppressed, sharp-crested, rectangular weir at the down-stream end. The weir and basin were 10 ft. wide and 7 ft. deep below the crest.

Views of the up-stream and down-stream faces of the model are shown in Figs. 17 and 18. The spillway sections are 2.727 ft. wide, corresponding to the 30-ft. width of the spillway at Keokuk. Water passing over the model spillways at a depth of 1 ft. duplicated the normal condition at Keokuk with a lake elevation of 525 ft., 11 ft. above the spillway crest.

Each spillway of the model was provided with a gate, so that experiments could be made upon the dam with any combination of the three spillways in operation.

*Nature of the Experiments on the Model.*—The primary objective in the model experiments was to obtain values of discharge coefficients under conditions similar to those which existed during the Keokuk measurements and, by varying the water level above the model, to determine values for these coefficients under abnormal pond-level conditions, such as existed during the early years of operation at Keokuk.

During each experiment the water level above the model was carefully observed by taking ten to twenty readings on a hook-gauge set so as to read the level in a stilling-well connected to the canal about 10 ft. up stream from the model. Likewise, the quantity of water passing over the model during each test was measured by observing the head on the weir as indicated by a hook-gauge operating over a stilling-well connected to the weir channel 16 ft. up stream from the weir. Ten to twenty readings were secured during each run, and their average was used in the Bazin weir formula in computing the rate of flow. Careful measurements were made and levels taken daily throughout the period of experimentation on both the weir and model in order to detect the slight variations which change in temperature and moisture conditions produce on such apparatus.

The model was tested with all three gates in operation through a range in water level above the crest which varied from 0.4 ft. to 1.5 ft., corresponding to a variation from 4.4 to 16.5 ft. at Keokuk. Other discharge experiments

were conducted when only single gates were opened with the spillway discharging under a head close to the normal head of 1 ft.

For these tests the model operated under the following conditions:

- 1.—Planed wood surface on model duplicating Fig. 2 with no deposit of silt against the dam.
- 2.—Planed wood surface on model with a deposit of sand against the dam duplicating the field conditions ahead of Spillway No. 68 as shown by the contours in Fig. 15.
- 3.—Shellac finish on the model with the deposit ahead of the dam.
- 4.—Sand finish on model with the deposit ahead of the dam.

In addition to the four series of discharge experiments, six other tests were made to determine the velocity distribution within the nappe when the model was being operated under conditions similar to those existing during the Keokuk measurements. A small Ott current meter and a Pitot tube were used for this purpose.

In order to compare the shape of the nappe flowing over the model spillway with that passing over the Keokuk Dam, during eight of the tests, measurements of the surface of the nappe were obtained across the section corresponding to that in which the meters were operated at Keokuk.

*Experiments on Effect of Condition of Model on Discharge.*—In building a model of the concrete spillways at Keokuk, the actual roughness of the surface probably should be scaled down according to some ratio as well as the dam itself. Since the surface of the concrete in the full-sized dam appeared to be remarkably regular for this class of work, it was thought that the surface of the model should be at least as smooth as wood could be planed. Accordingly, the first series of experiments were performed on the planed and sand-papered model as constructed in the canal with no surfacing of any kind. The resulting coefficients when the water was passed over all three spillways are shown by the points in Fig. 19 which define Curve 1.

A deposit of sand was next placed above the dam in an attempt to duplicate that existing above the Keokuk Spillways Nos. 67, 68, and 69, where most of the field measurements were made. Small stakes were cut to proper length and fastened at points corresponding to those places where the soundings had been taken for the preparation of Fig. 15. Wet sand was then packed against the dam and filled in between the stakes forming the most natural surface between the tops of the sticks, leaving them barely exposed. The sand was further compacted by inundation in passing water over the dam, and its surface remodeled until it was firm enough so that but little alteration of its contour was caused by further inundation or experimentation. The results from this series of experiments are shown by points defining the position of Curve 2 in Fig. 19.

For all heads on the model above 0.63 ft. the deposit of silt seemed to have caused a lowering in the discharge of the three spillways, although at a head of 1.00 ft. corresponding to the normal head of 11 ft. at Keokuk there was less than 0.6% more water passing over the model without the silt deposit than passed over with it.

The small amount of alteration in the coefficient caused by the deposit that now exists ahead of the Keokuk Dam was also observed in the Keokuk

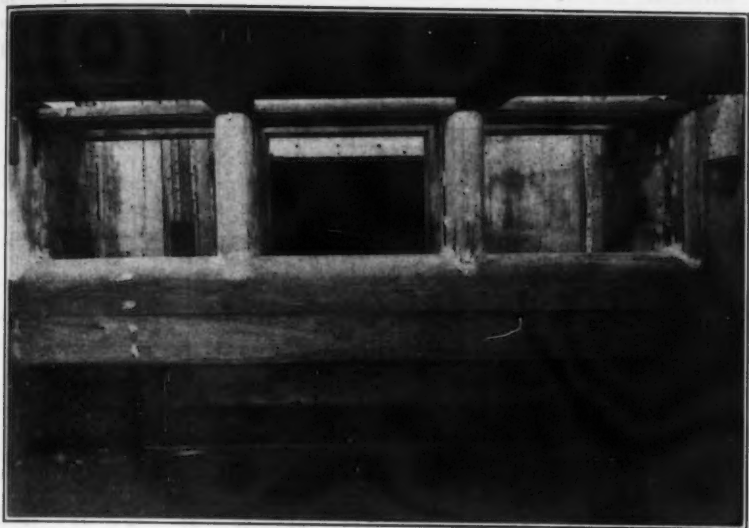

FIG. 17.—UP-STREAM FACE OF MODEL OF THREE SECTIONS OF THE KEOKUK SPILLWAY.

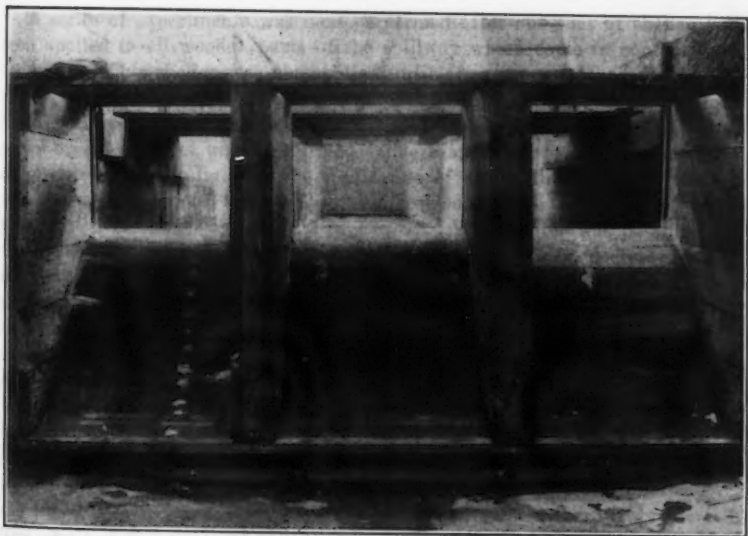

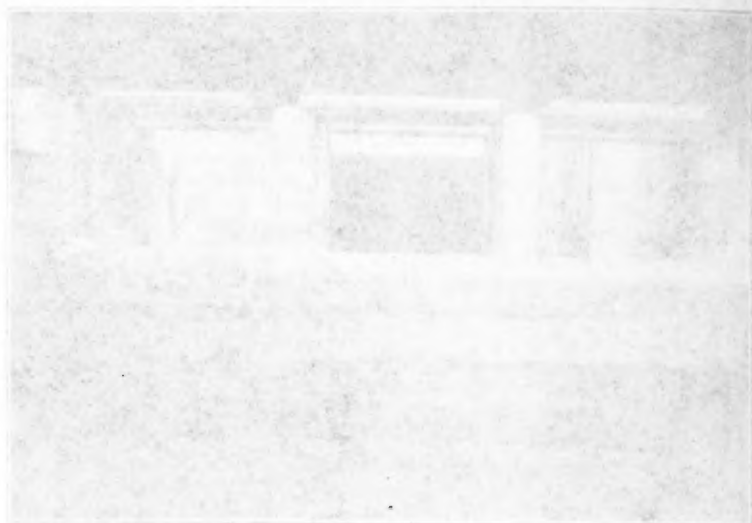

FIG. 18.—DOWN-STREAM FACE OF MODEL OF THREE SECTIONS OF THE KEOKUK SPILLWAY.

measurements, in which the results for Spillway No. 103 were in substantial agreement with the average of those obtained on Spillway No. 68, although the pond was 6 to 8 ft. shallower ahead of the latter spillway.

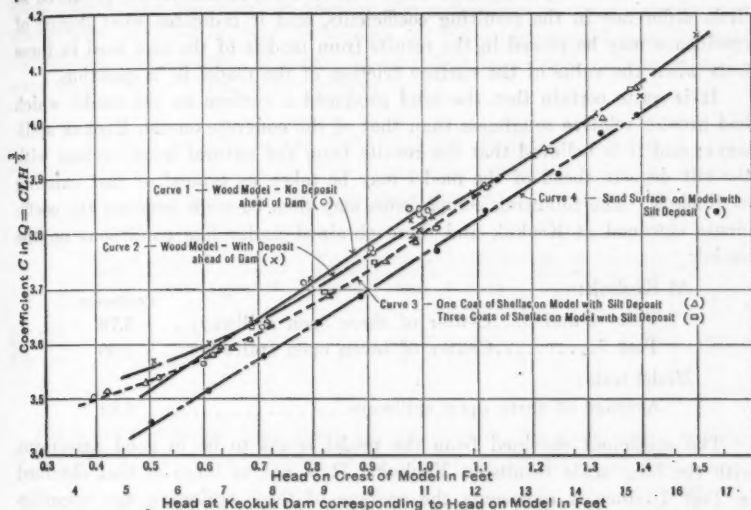

FIG. 19.—DISCHARGE COEFFICIENTS FOR MODEL OF KEOKUK SPILLWAY.

A series of experiments was next performed after one coat of shellac had been applied to all wooden parts of the spillway which came in contact with the water. This shellac was not applied until after the wood had thoroughly dried. Then, suspecting that one coat of shellac might not have produced the smoothest possible surface, two additional coats were applied, and another series of experiments were performed. There appeared to be no measurable difference in the results after the application of one or three coats of shellac, and the application of the shellac itself seemed to alter the discharge relatively little, as shown by Curve 3 in Fig. 19. When water was passing over the model with a head of 1 ft., the discharge seemed to be decreased about 0.4%, although at the greater heads the difference could not be detected. It is perhaps surprising that the smoother surface of the shellac caused a diminution of the discharge. However, this same effect of shellac has been noted in experimentation with other hydraulic apparatus, and it appears that water passes with less friction over a well-smoothed wooden surface (which soon becomes slippery under water) than over a shellac surface to which there may be some molecular adherence.

The shellac surface of the model was next treated with a fresh coat of shellac on which sand (passing a No. 28 Standard Tyler sieve, but held on the No. 48 sieve) was thrown until the entire surface was thoroughly covered. The result of the series of experiments performed on the model in this condition is indicated by Curve 4 in Fig. 19. Except for the lower heads the increased friction of the sand surface caused a diminution of the discharge

amounting to approximately 1 per cent. However, when the head was small the difference was increased.

It was rather surprising that these various surface treatments produced so little difference in the resulting coefficients, and it indicates what degree of confidence may be placed in the results from models of the size used in these tests when the value of the surface friction of the model is in question.

It is quite certain that the sand produced a surface on the model which had greater relative roughness than that of the concrete on the Keokuk spillways; and it is believed that the results from the natural wood surface with the silt deposit ahead of the model may be taken as typical of that existing at Keokuk. The following comparisons may then be made between the coefficients obtained at Keokuk and those obtained under like conditions on the model:

At Keokuk:

	Coefficient.
Tests 4 and 5...Center of three open spillways...	3.78
Test 7.....Center of seven open spillways...	3.90

Model tests:

Average of three open spillways.....	3.82
--------------------------------------	------

The coefficient obtained from the model seems to be in good agreement with the large-scale results at Keokuk. It is not as large as that obtained in Test 7, since it represents the average of three spillways, the velocities approaching the two outside ones being affected by the friction on the sides of the testing canal. It is not as small as that obtained in Tests 4 and 5, since it probably represents the operation of a larger number of spillways, with all extraordinary contraction suppressed.

*Experiments on the Discharge of Only One Spillway.*—Since the discharge as computed over a sharp-crested weir has less certainty under low heads, and that low-head limit for these tests had been arbitrarily set at 0.4 ft., it was impossible by passing the water over the 10-ft. weir to measure accurately the discharge over a single spillway which was less than 3 ft. long when the pond level was less than 0.9 ft. above the crest of the model. Accordingly, most of the tests on the single spillways were performed under a head of about 1.0 ft. which duplicated the normal conditions existing at Keokuk. However, coefficients for the middle spillway of the three were obtained throughout a small variation in head. The discharge coefficients which were obtained are given in Table 5.

The results are in agreement with those obtained when three spillways were operated with regard to the relatively small effect which was produced by the deposit of silt ahead of the dam and the application of the shellac to the surface of the model.

The coefficients are lower than those obtained with the three spillways in operation, due to the extraordinary contraction existing around the piers when the single spillways draw their discharge from the entire width of the channel. The coefficients obtained from the two end spillways are identical as they should be with accurately constructed apparatus; and the discharge

through the center spillway is less than that through either of the end spillways due to the greater contraction of the nappe around both piers in this case. Neglecting the effect of friction along the sides of the canal, the discharge over the end spillway is similar to that which would pass through one of only two adjacent spillways in operation in a pond with more spillways than were provided by the present model.

TABLE 5.—DISCHARGE COEFFICIENTS,  $C$ , IN  $Q = CLH^{\frac{3}{2}}$

Spillway.	WOOD MODEL.			WOOD MODEL WITH SILT DEPOSIT			SHELLAC.		
	No. of experiment.	Average head, in feet.	Average coefficient.	No. of experiment.	Average head, in feet.	Average coefficient.	No. of experiment.	Average head, in feet.	Average coefficient.
East end...	4	0.973	3.77	2	0.980	3.77	1	0.984	3.69

Model tests..... Center spillway.....	3.69
Keokuk Test 3..... End of two open spillways..	3.74
Model test..... End spillway.....	3.77

*Variation in Coefficient with Change in Head.*—Fig. 19 shows considerable variation in the discharge coefficient with an increase or decrease in head from normal conditions. Experiments performed when water was discharging over only the middle spillway gave smaller coefficients increasing less rapidly as the head increases. The resulting curve (Fig. 20) seems to indicate that under low heads there is less difference in the coefficient when many spillways are in operation compared with that when a single spillway is open.

Coefficients which exceed 4.0 are not usually encountered, but it is evident that they may be secured when water discharges at great depths over well-designed spillways.\*

That the coefficient would decrease rapidly for lower heads on the spillway was anticipated from previous measurements on the Keokuk spillway at low pond levels and from gaugings of the Mississippi River during certain floods when low lake levels existed. These other measurements (Table 6), while not comparable in accuracy with the work described in this paper, indicated that the discharge coefficient of the Keokuk spillway decreased to a value close to 3.0 when the nappe passed over the spillway at a shallow depth, duplicating the phenomena of flow over a broad-crested weir with a rounded approach. A comparison of the results from the model experiments with all measurements made at Keokuk is shown in Fig. 20.

\* Water Supply and Irrigation Paper No. 200, Pl. XXXVI, U. S. Geological Survey; Report of Hydraulic Power Committee, National Elec. Light Assoc., 1923.

The model experiments are in good agreement with the 1924 measurements at Keokuk and are in as close agreement with the measurements listed in Table 6 as one could expect from the nature of these other determinations of the discharge coefficient.

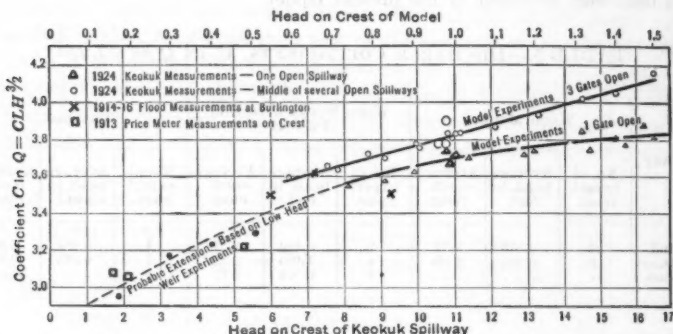

FIG. 20.—SUMMARY OF MEASUREMENTS OF DISCHARGE OVER KEOKUK SPILLWAY.

*Measurements on the Form of the Nappe.*—In order to compare the form of the nappe passing over the model with that measured at the metering section at Keokuk, this exact section was located on the model and, by means of a pointed rod, about twenty readings to the water surface were taken to the nearest hundredth of a foot at varying intervals across the nappe.

TABLE 6.—MEASUREMENTS OF DISCHARGE OVER KEOKUK SPILLWAYS BEFORE 1924.

Date.	Pond elevation, in feet.	Head, in feet.	Discharge per spillway, in cubic feet per second.	Coefficient in $Q = CLH^{3/2}$ .	Remarks.

March 31, 1916.	523.22	9.22	2 942	3.50	Flood flow through 55.1 gates computed from current-meter measurement at Burlington, Iowa.

The nappe surface was measured in this manner when the model with the planed wooden surface was operating with the sand deposit against the dam

and also without that deposit or sediment. Under each of these conditions, measurements were made on the nappe of the center spillway when operating alone, with all three spillways open, and with only one of the other spillways in operation. Readings were also taken to the surface of the nappe of one of the end spillways when operating alone.

A comparison of the results of the measurements on the model with the deposit of silt ahead of the dam and those taken on the Keokuk spillway under similar conditions is shown in Fig. 21. The model tests shown were conducted under the following circumstances: Test 45 was on Spillway No. 2, with Spillways Nos. 1 and 3 open; Test 46 on Spillway No. 2, with Spillway No. 1 open; and Test 47 on Spillway No. 2 and Test 48 on Spillway No. 1, with no other spillways open. The corresponding data for the field tests are given in Table 1. The depths of water in the nappe which were observed at Keokuk have been divided by the scale ratio of 11 in 1, in order that they might be plotted on these diagrams for comparison. In all cases the model seemed to represent quite faithfully the form of the larger nappe. In Fig. 21(c) the difference in average pond level between that existing at the time the model measurements were made and that existing during Test 5 at Keokuk, fully accounts for the separation of the two curves.

The four measurements of the nappe which were made when there was no sand deposit ahead of the dam gave water surface curves very similar to those shown in Fig. 21, except that the surface was lifted between 0.01 and 0.02 ft. uniformly across the entire spillway as if the deeper water ahead of the dam resulted in a very slight thickening of the nappe. A difference of this sort between Spillways Nos. 103 and 68 located in shallower water, was not noted in the tests at Keokuk.

In order to test the accuracy of using the middle third of the Keokuk spillways as an index of what flow would be obtained over an unobstructed crest, the piers were removed from the model spillway and an accurate determination was made of the cross-section of the nappe. Fig. 21(d) gives an interesting comparison between the nappe cross-section at the location of the middle spillway of the unobstructed crest with that observed when one and three spillways were open and the piers were in place. The observations for Test 47 have been reduced to the same pond level of 1 ft. above the crest, which existed in the other two tests. It will be noted that the cross-section of the nappe in the center section of all the tests is practically identical, showing clearly that the flow in the center section of the spillway flanked by piers can be used for a reliable determination of the flow over an unobstructed crest. It is believed that this one experiment proves beyond a doubt the correctness of the analysis which resulted in the coefficient of 4.00 for the normal head on the unobstructed crest at Keokuk.

The amount of contraction of the nappe caused by the piers is very evident from Fig. 21(d) and the fact that it decreases with the opening of adjacent spillways is quite significant. From this diagram it proved entirely possible to compute within 1% the value of the discharge coefficients previously obtained by flow measurements for the two cases—of a spillway discharging by itself and at the center of a group. The computation consisted

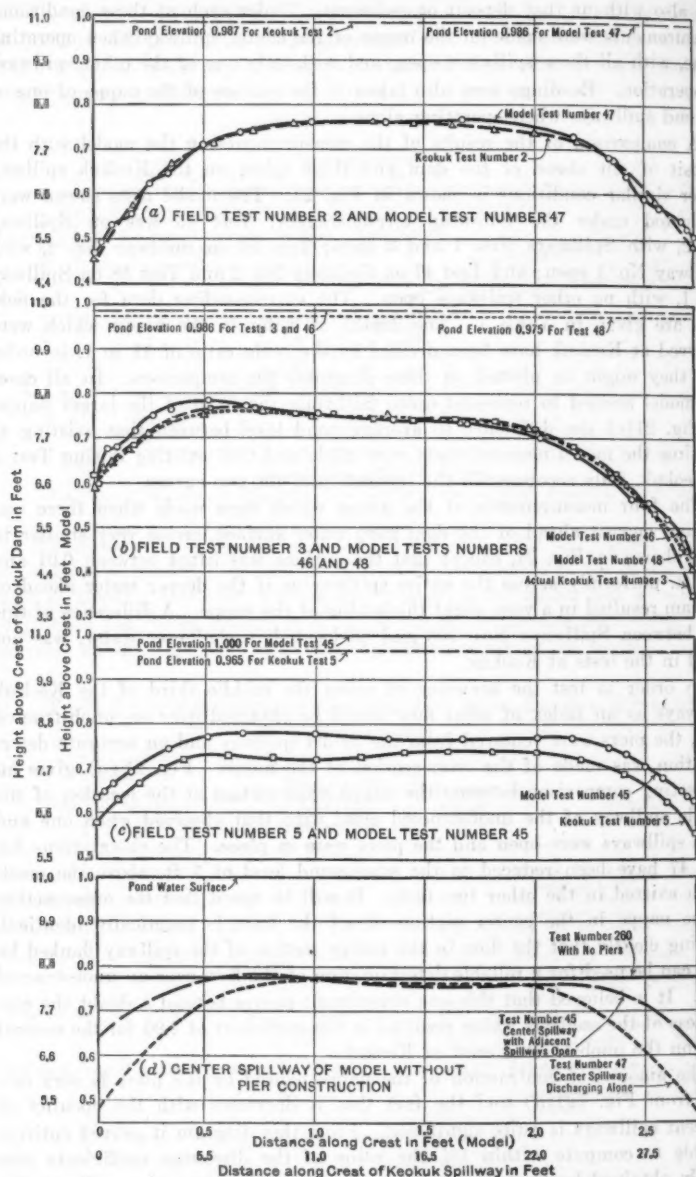

FIG. 21.—COMPARISON OF NAPPE CROSS-SECTIONS.

of subtracting from the quantity of water passing over an unobstructed spillway that discharge which would have passed through the area above the actual nappe section and the level water surface of Test 260. The elements of the computation were as listed in Table 7.

TABLE 7.—VALUES USED IN COMPUTATIONS.

Item.	No piers or obstructions.	Single spillway open.	Center of several open spillways.
Area of nappe, in square feet.....	2.124	1.940	2.072
Reduction by piers, in square feet.....	0	0.184	0.072
Percentage of reduction in area.....	0	8.7	3.4
Ratio of average velocity in reduced portion to average velocity in full nappe....	....	0.78	0.76
Reduction in discharge by piers, in percentage.....	0	6.7	2.6
Discharge coefficients in model experiments.....	3.91	3.69	3.82
Discharge coefficient computed from reduction of nappe by piers.....	3.91	3.65	3.81

It is interesting to note the close agreement between the values of reduction in coefficient given in Table 7 and that computed for the Keokuk measurements in Table 3.

The form of the nappe at the crest of the spillway changed considerably when the head was raised above or lowered below the normal condition. The views in Figs. 22 and 23 with only the center spillway in operation show that the piers cause relatively little reduction of the nappe section when the head is low, but this increases to a very large amount when the head is 50% greater than normal. The increase in the magnitude of the pier obstruction with increasing head is probably responsible for the small increase in the discharge coefficient at high heads when a single gate is open as shown in Fig. 20.

*Measurements of Velocities in the Nappe Flowing Over the Model.*—A small Ott current meter (No. 2914) was first used in an attempt to measure the velocities existing in the center spillway of the model at points in the nappe which were in the section corresponding to that in which the meters were operated at Keokuk. Only two complete measurements throughout the nappe were made with this instrument before it was abandoned in favor of a small Pitot tube made from  $\frac{1}{4}$ -in. brass tubing. The meter had a propeller 0.18 ft. in diameter and, when mounted on a  $\frac{1}{4}$ -in. rod, caused no apparent obstruction to the flow, since the metering section was some distance down the falling nappe. The diameter of the wheel of the meter, however, was almost one-fourth the depth of the nappe, and hence many points in a vertical section could not be taken with this instrument.

The Pitot tube had been previously manufactured and calibrated for use in measuring velocities in the nappe of a sharp-crested weir and proved a very excellent instrument for this kind of work. The use of a tube of this kind in the nappe requires watchfulness in order to prevent the entraining of air when operating near the water surface where the tube is likely to split the nappe and cause a crevice of air behind it. The behavior of the tube

when water approaches it at an oblique angle, as it does in the upper sections and sides of the nappe, is the main element of uncertainty involved in its use, but coefficients under these conditions may be obtained by calibration. There was a striking resemblance between the velocity distribution as observed in the model and that obtained at Keokuk under similar conditions, revealing all the characteristics previously mentioned.

In each test the total discharge of the spillway was calculated by treating these velocity measurements in the same manner as that by which the measurements at Keokuk were computed. This afforded a sort of check on the weir measurements. A summary of these results is given in Table 8.

TABLE 8.—SUMMARY OF DISCHARGE MEASUREMENTS ON CREST OF MODEL.

Test No.	Other spillways operating.	Instrument used.	Number of verticals.	Number of points in vertical.	Discharge by velocity reading.	Discharge by weir.	Percentage of difference.
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
31	None	Meter	8	6	9.67	9.74	-0.9
68	None	Meter	8	7	10.13	9.93	2.0
69	None	Pitot tube	13	9	9.72	9.77	-0.5
84	All	"	14	9	11.15	10.89	2.4
85	No. 3	"	13	9	10.06	10.14	-0.8

It is to be noted that in Column (7) of Table 8, Test 84 is the average discharge of all three spillways which is probably less than that flowing over the center spillway measured by the Pitot tube. In Test 85 it is the average of the center and end spillways which is more than the quantity passing over the center spillway alone which was measured by the Pitot tube.

#### EFFECT OF FORM OF PIERS ON DISCHARGE OVER SPILLWAY

As a conclusion to the tests on the model the effect produced by three other pier forms was investigated in order to compare the behavior under these conditions with that for the model of the Keokuk spillway. These experiments were performed in November and December, 1925, and in May, 1926.

*Description of Pier Forms.*—The additional three types on which experiments were made are shown in Fig. 24 and are designated as Forms B, C, and D. Form A is the pier nose of the Keokuk model. The new piers were made of wood and were duplicated on the two full piers and two half piers of the model. Neither the form of the crest of the dam nor the silt deposit ahead of the dam was altered for these tests, but the sand finish which had been placed on the dam during the previous experiments with the Keokuk model was removed. Piers B and C were formed by extending the piers up stream from the dam in order to produce the lateral contraction of the nappe before it passed over the crest.

Pier D was constructed with a circular nose at the up-stream end of the Keokuk piers, but was formed with only one-half their radius. The further increase to full pier width was made gradually, thus producing a large part

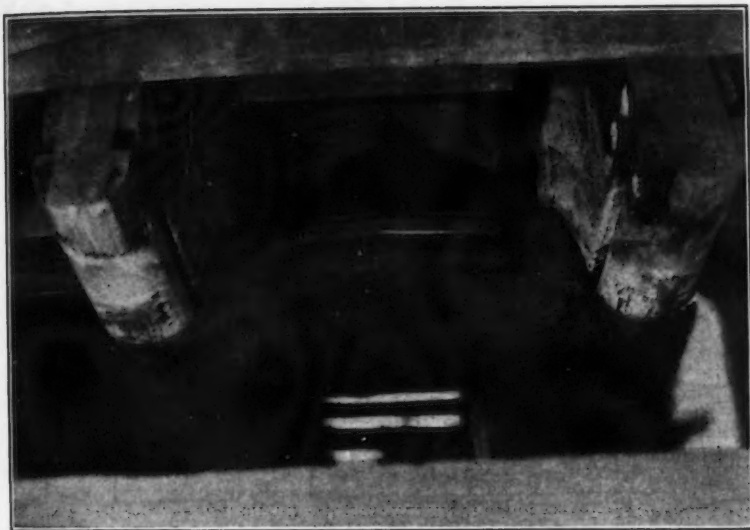

FIG. 22.—WATER DISCHARGING OVER CENTER SPILLWAY OF KROKUK MODEL UNDER A HEAD OF 0.6 FEET.

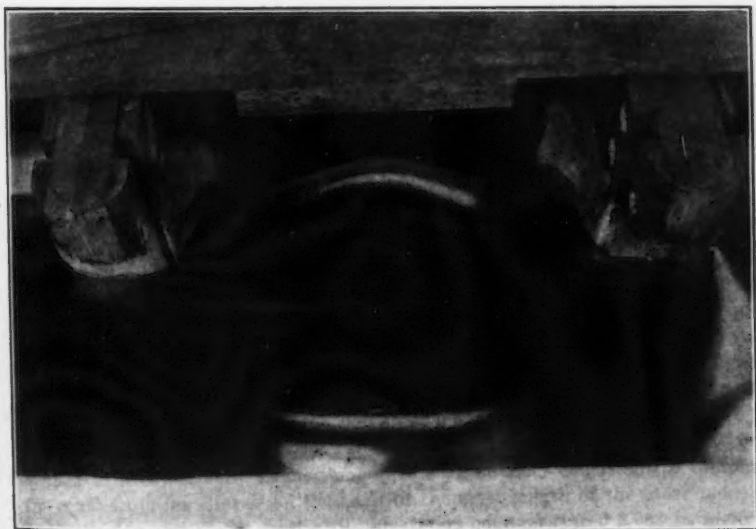

FIG. 23.—WATER DISCHARGING OVER CENTER SPILLWAY OF KROKUK MODEL UNDER A HEAD OF 1.5 FEET.

1. The first photograph was taken at the same place as the second, but the light was much better. The second photograph was taken at the same place as the first, but the light was much worse.

of the lateral contraction of the nappe as it was falling over the crest of the dam. There was no provision for a gate slot in Pier *D*.

*Experiments and Their Results.*—The discharge over all three spillways and the several spillways operating singly was measured in the same manner as in the experiments on the Keokuk model. Finally, all the piers were removed and discharge measurements were made on the spillway, free from all obstructions, occupying the full width of the testing canal. The resulting coefficients when all three spillways were in operation are shown in Fig. 25 (*a*).

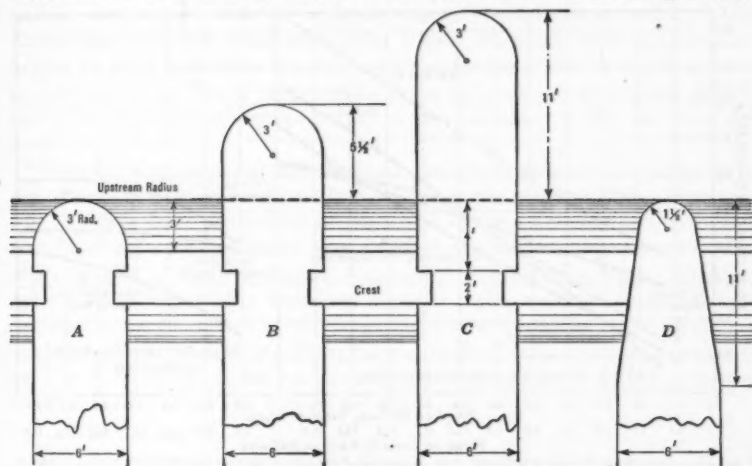

FIG. 24.—TYPES OF SPILLWAY PIER NOSES.

Pier *B*, the nose of which extended up stream from the face of the model dam 6 in. (or 5.5 ft. in the actual dam), gave higher coefficients than the Keokuk model when the head was less than 1.22 ft. In fact, it allowed a higher discharge through the spillway than Pier *C*, with a nose extending 12 in. up stream from the dam, for heads lower than 0.95 ft., which is close to the normal head at Keokuk. Because the coefficients obtained with Pier *B* seemed exceptionally large throughout the lower heads, the entire series of tests on this pier was repeated after a lapse of one week. The results confirmed those of the previous series in every respect. At heads between 0.95 ft. and 1.4 ft. Pier *C* allowed more water to pass than Pier *B*, but the maximum difference amounting to only 1%, is of little significance.

The *D* type of piers allowed considerably more water to pass than any of the other forms as shown by the coefficients in Fig. 25 (*a*), which were computed on the basis of the same net crest length between piers. About 8% more water could be passed over the Keokuk spillway provided the piers were shaped in this manner. It may not have been entirely consistent to compute the coefficients for Pier *D* on the basis of the crest length of the other models, since the flat part of the crest at its up-stream edge measured 2.953 ft. instead of 2.727 ft., which is the width between the piers after the water has passed down the face of the dam. Had the coefficients for Pier *D* been computed on

the basis of a crest length of 2.95 ft., they would have been very similar to those obtained with the Keokuk model throughout the entire range in head.

A series of experiments on the spillway with all piers removed gave coefficients which were higher than those obtained with Piers A, B, and C for all heads greater than 0.94 ft. It is interesting to note that below this head there is some indication that it is possible for a dam with piers to have a higher discharge coefficient per linear foot of open spillway than one without these obstructions.

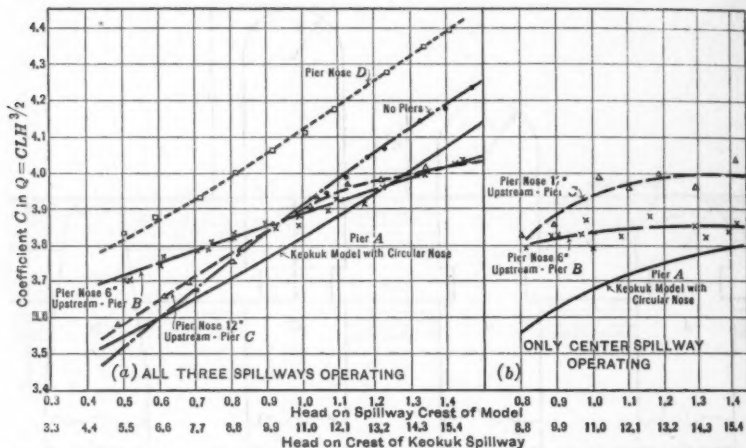

FIG. 25.—DISCHARGE COEFFICIENTS FOR KEOKUK SPILLWAY WITH VARIOUS FORMS OF PIERS.

The Keokuk spillways are 30 ft. wide and the piers, 6 ft. thick. The relative amount of obstruction caused by the different forms of piers may be expressed more clearly by tabulating the discharge over a dam of a certain gross length made up of these piers and spillways with that which would pass over a dam of the same gross length with no such obstructions (see Table 9).

TABLE 9.—DISCHARGE OVER DAM WITH PIERS EXPRESSED IN PERCENTAGE OF DISCHARGE OVER DAM OF SAME LENGTH WITH NO PIERS.

ALL SPILLWAYS IN OPERATION.

\* Normal head at Keokuk.

The small differences between the discharge over the spillways with various pier forms when all spillways were in operation were greatly magnified when a single spillway was operating alone. Tests with the center spillway of the model operating while the other two were closed by gates were performed with Piers *B* and *C*, and had previously been made upon the Keokuk Pier *A*. The results are shown in Fig. 25 (*b*). The curves in this diagram show a decided increase in the discharge accomplished by projecting the pier ahead of the dam. Pier *C* allows about 7% more water to pass through a single spillway than passed over the spillway when operating as a model of the Keokuk Dam. At the lower heads, Pier *B* gave discharge coefficients similar to Pier *C* which had twice the amount of projection ahead of the dam, but, at the high heads, Pier *B* gave results closer to those of the Keokuk model, indicating a positive advantage in the further extension of the pier into the pond.

When the piers extended into the pond, the water surface of the nappe as it passed over the crest was not greatly depressed at the spillway sides. However, Fig. 26 which shows the surface of the nappe at three different sections (only center spillway open) indicates that although the nappe is comparatively flat above the crest at the gate section, 6 in. ahead of this at the face of the dam, the surface is appreciably depressed along the pier walls. The comparison between the nappe surface at the metering section with that obtained on the Keokuk model is interesting. Except at the spillway sides, the nappe produced by Pier *B* is not so thick, but since the total discharge is greater, interior pressures must be less and current velocities more.

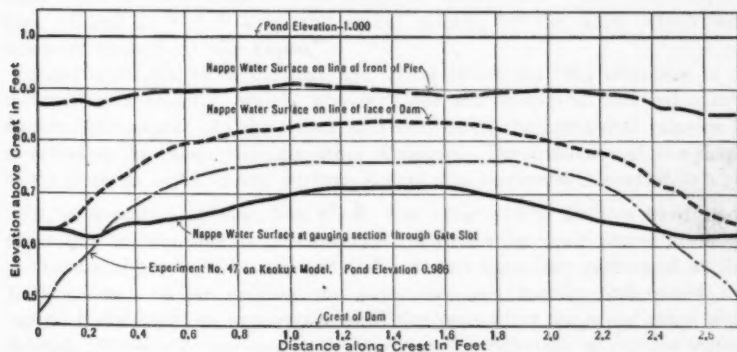

FIG. 26.—CENTER SPILLWAY WITH PIER *B*, COMPARED WITH NAPPE OF KEOKUK MODEL.

#### ACKNOWLEDGMENTS

These experiments were financed by the Mississippi River Power Company and the Hydraulic Laboratory of the State University of Iowa.

S. M. Woodward, M. Am. Soc. C. E., of the Department of Mechanics and Hydraulics, State University of Iowa, made valuable suggestions in the preparation of this paper and with J. B. Spiegel, M. Am. Soc. C. E., District Engineer, U. S. Geological Survey, visited Keokuk and inspected the

work during the progress of the experiments on the spillways. Mr. Paul Mercer, Assistant Engineer, Mississippi River Power Company, and George E. Shafer, Jun. Am. Soc. C. E. (now Assoc. M. Am. Soc. C. E.), Research Assistant in Hydraulics at the State University of Iowa, assisted in making the measurements at Keokuk. The current meters were rated for these tests free of charge by the engineers of the U. S. Bureau of Standards. The following graduate students in Hydraulic Engineering at the State University of Iowa served as observers in performing the model experiments and assisted in the preparation of this paper: T. L. Herrick and J. W. Howe, Assoc. Members, Am. Soc. C. E., W. E. Smith, J. W. Hummer, Glen N. Cox, G. H. Hickox, and J. S. Meyers, Juniors, Am. Soc. C. E., and Messrs. Arnold Neshein, Ned Ashton, H. C. Brockman, and J. C. Ducommun.

FIG. 1. DISCHARGE CHARACTERISTICS OF KEOKUK DAM SPILLWAY. (Data from tests conducted at the State University of Iowa, 1914-1915.)

## DISCUSSION

B. F. JAKOBSEN,\* M. Am. Soc. C. E. (by letter).—These tests are of particular interest, because they furnish information regarding the discharge coefficient for heads up to 11 ft. for the Keokuk spillways. A head of 1 ft. on the model corresponds to 11 ft. on the prototype, and the agreement between the model and the actual structure is quite close (Fig. 20). It would be interesting to have some probable errors calculated for a number of these tests and to determine the coefficient of correlation between the tests on the model and those on the actual structure.

The tests suggests that the discharge coefficient of the Francis formula,  $Q = CLH^{1.5}$ , is not a function of the head, but of some ratio of, or relation between, the length and the head. It is possible that the authors may be able to derive some such relation from the tests already made. If not, additional tests could be made, for example, by introducing a portable pier at Keokuk and also in connection with the model, so as to be able to vary the ratio between length and head. If the authors could establish some such relation, it would be of considerable practical value, since the discharge coefficient,  $C$ , varies from 3 to 4.

With reference to Figs. 12 and 13, it would be instructive to have the value of  $C$  plotted for a number of vertical sections, beginning as close as possible to the piers.

It appears that the authors use the term, "actual velocity", when they mean "maximum velocity". For example, they state: "The contours in Figs. 12 and 13 \* \* \* show the actual velocity of the water which was measured throughout the nappe."

From what follows in the text, the writer infers that the reference is to the maximum velocity, which, however, was not measured, but calculated from measurements. As the writer understands it, the horizontal velocity is as actual as the velocity in any other direction. The influence of the shape of the piers, as noted by the authors, should also be carefully studied.

J. B. SPIEGEL,† M. Am. Soc. C. E. (by letter).—The authors have made a valuable contribution to engineering knowledge by their presentation of the results of the experiments and tests of weir discharge performed at the Keokuk Dam. After reading the paper one can readily understand the reasons that delayed its appearance until five years after the experiments were finished. Those who are constantly studying the behavior of surface waters and who realize how applicable this information is to numerous problems that require solution will be pleased to learn that they may now select coefficients for high-head weir discharges with greater confidence. Uncertainty has always lurked in the minds of engineers concerning the influence of the opening of neighboring gates on individual weir discharges.

Fig. 14 reveals a relationship that is indeed interesting, but leads one to wonder just where the central-weir velocity curves would plot for the con-

\* Cons. Engr. (La Rue & Jakobsen), Los Angeles, Calif.

† Dist. Engr., U. S. Geological Survey, Topeka, Kans.

dition of nine, eleven, thirteen, etc., gate openings. Apparently, the greater the number of openings the closer the results approach the curve of velocities corresponding to the head below pond level. It is appreciated that a greater number of openings at the time these observations were taken probably would have seriously affected the efficient operation of the power plant and would have been wasteful of water.

Since practically all velocity measurements made by the U. S. Geological Survey are obtained with Price current meters, a statement of results as compared with the registered or adjusted values of the Ott meter would be of interest to its engineers. Velocities of more than 12 ft. per sec. are rarely exceeded in ordinary stream-gauging work and no appreciable wear on the meters is noted except when they are used in waters heavily charged with silt.

The Keokuk Dam is situated at a section that carries the discharge from about 119 000 sq. miles of drainage area. The component areas have not been studied comprehensively or continuously. Therefore, no reliable estimate of flow can be obtained, except by use of the Keokuk records and these experiments assure the accuracy of these records for at least the 16-year period of operation of the plant. Gauge-height observations and some discharge measurements on the Mississippi River at this location prior to that period and extending back to the late Seventies afford a record of fifty years or more, which is a valuable contribution to the study of the perplexing Mississippi River flood-control problem.

*Bulletin No. 14*, "The Control of Floods by Reservoirs", issued by the State Engineer of California and the conclusions of the Vermont Flood Commission,\* indicate that engineering thought is directed toward the study of the feasibility of co-ordinating water-power development and flood control. The perfection of discharge formulas for application in such projects, on which weirs often play an important part, is timely and welcome.

DANA M. WOOD,† M. Am. Soc. C. E. (by letter).—This paper brings forcibly to consideration the behavior of current meters when subjected to angular flow conditions.

The ideal meter would be one which, when held rigidly in a horizontal plane and at right angles to the measuring section, would correctly measure that component of the velocity normal to the section. It is to be noted that in the Keokuk experiments, the meter was allowed to swing in a horizontal plane to meet the direction of the average current striking it, the angularity being determined by an indicating device. The meter was not permitted to swing in a vertical plane, except in two special tests. Therefore, the effect of variations in vertical angularity and of minor departures from the average or predominating horizontal angularity, at any point of measurement, was taken account of only in the standard behavior of the particular meter used under the composite conditions existing, with a standard correction obtained from Fig. 9.

For some time it has been known that certain of the standard makes of current meters over-register, and that others under-register, the true normal

\* *Engineering News-Record*, p. 72, Vol. 102, No. 2.

† Hydr. Engr., Stone & Webster Eng. Corporation, Boston, Mass.

velocity when held rigidly in a normal horizontal position and when currents are oblique to the meter in either a horizontal or vertical plane, or a combination of each. To what extent in the Keokuk experiments correction for horizontal angularity only accounts for all possible over or under-registry, is not made clear in the paper. It hardly seems possible that Fig. 9 is applicable to all stations, especially those near the piers.

Furthermore, there is usually not only a difference in the error of registration resulting from horizontal and vertical angularity of currents, but also a difference from currents hitting the meter from the left and from those hitting it from the right. Variations of methods of suspension, and size and shapes of weights, if they are used, affect meter ratings and registration, as has been well proved by the Water Resources Branch of the U. S. Geological Survey. It is open to question whether one standard laboratory correction curve adequately covers variations actually occurring during the measurements.

The matter of whether or not full consideration has been given to all these questions, or whether their effect has been determined to be negligible, in view of other errors of measurement possible, is not made clear in the paper.

It is very important to select the proper type and make of current meter when used for experiments as described. While the Ott type of meter may have been best adapted to the Keokuk conditions, such general statements in favor of its selection as "it measures the normal component of angular currents more accurately than other types", might be amplified for clearness. If the meter is allowed to swing in either a horizontal or vertical plane, and its axis assumes a position parallel to the average stream line, the statement would refer to a plane "normal to the meter" rather than "normal to the measuring section", although the latter is the desired velocity. Accurate results can be obtained only when the direction which the axis of the meter assumes can be reliably ascertained. There may well be a set of conditions in which another type of meter might be better suited for determining the velocity normal to the measuring section even if the Ott type proved best at Keokuk.

The authors state that "with the 3-blade propeller it [the Mensing-Ott meter] had characteristics in measuring angular currents which were superior to the others". In view of the paucity of experimental data on the behavior of current meters under conditions of angular velocity, would it not be well if the authors developed the basis for this statement more fully?

With the lower actual velocity and depth conditions in the model tests, is it safe to assume that, because of the apparent verification of Pitot tube checks, the limit of accuracy of the field tests was within 2 per cent? In view of the care taken in all the work and the study given to the many complicated problems, the conclusion may be correct, but the writer would like to see some discussion from others who have conducted laboratory and field tests on these questions.

S. P. WING,\* Assoc. M. Am. Soc. C. E. (by letter).—Practical hydraulics, being largely an empirical science and one in which the required coefficients have been determined for the most part from tests on structures of a size far

\* Engr., Constr. Dept., British Columbia Elec. Ry., Vancouver, B. C., Canada.

smaller than those used in practice, has been handicapped for the lack of adequate design data. At the time this paper was published, the writer was endeavoring to fix the coefficient of discharge for a large overflow dam. By making use of the data presented he was enabled to make a direct saving in the size of his proposed flood-gates. The work of the authors is of particular value, in that experiments were made on both a model and on the full-sized structure.

Although the theory of models is well established, certain factors cannot be adequately reduced to scale and tests of the full-scale structure remain the final criterion. The high degree of correlation obtained by the authors, between the results of the model and those of the full-scale structure, means that future tests on similar structures can be confined to those made on the cheaper models.

The tests on the model at high heads with the coefficients, as shown in Fig. 19, are of special interest. These reach the value of 4.15 and the curve gives no indication of flattening. The upper limit should be reached when the depth of overflow arrives at a point at which the nappe jumps clear of the face; it would be interesting to know what this limit is. It would also be of interest to know at what point a vacuum begins to form below the nappe.

The economic design of the crest of an overflow dam has two main controlling factors: First, the design should be such that the coefficient of discharge will be as large as possible; and, second, such that no vacuum will take place under the overfalling sheet. With present information as to the shape of the lower nappe, based on Bazin's experiments and as applied in Creager and Justin's *Hydro-Electric Handbook*, if vacuum is to be prevented, the relation of the depth of overflow with respect to the curve of the dam crest must be such that the coefficient of discharge is limited to about 3.9 or 4.0 for an unobstructed crest. It would be of interest to know whether this limit exists in fact, as the profile and the cost of an overflow dam are controlled largely by this consideration.

In applying the results of these tests to other structures, it becomes necessary to find the scale at which the proposed structure most closely resembles that on which the tests were made, and then to make use of this scale in determining the proper discharge coefficient. This fact occasionally has been overlooked, data being published as to the value of the coefficient for certain profiles or for certain depths of flow without giving the full dimensions of the structures and the depths of flow at which the tests were made. In fitting a proposed profile to a test profile to find the scale relationship, probably most weight should be given to the fit of the up-stream face. Small differences at that point have a large effect on the coefficient of discharge as was shown in the model experiments\* made at Cornell University. Additional experiments are needed as to the effect of varying the down-stream profile.

The authors have shown that results with a high degree of accuracy can be obtained from relatively inexpensive hydraulic models. The writer hopes that they and others will make additional tests to obtain coefficients for the lack of which, hydro-electric designers now must use too much guesswork. A foot of head frequently is worth \$100 000, and the economic design of a flow line deserves better data than are now available.

\* *Transactions, Am. Soc. C. E.*, Vol. LXXVII (1914), p. 1199.

E. A. RUDOLPH,\* Assoc. M. Am. Soc. C. E. (by letter).—This paper is particularly timely in view of the growing interest now being manifested by hydraulic engineers in the use of models for the solution of practical hydraulic problems.

The great difficulty and high cost of making accurate measurements of the large quantities of water and high velocities usually encountered in hydraulic structures, have resulted in a scarcity of conclusive information to demonstrate the agreement between model and full-scale measurements. In consequence, engineers have hesitated to adopt the results of experiments on models as a reliable measure of full-scale hydraulic conditions.

The close agreement between model and full-scale measurements obtained through the accurate and painstaking work done at Keokuk should go far toward establishing confidence in results obtained from model tests. Moreover, in view of the large-scale model used by the authors, and the greater possibility of error in the experiments on the full-sized structure, it is possible that the most reliable discharge coefficients of the Keokuk spillway are those determined by the model test.

An essential requirement in any hydraulic model test is that true similarity between model and full-scale conditions be attained. The same reasons which cause engineers to hesitate in accepting model-test results frequently cause them to select, when such experiments are attempted, the largest scale for the model that laboratory facilities will permit. In so doing the true hydraulic similarity between the model and its full-scale prototype is often overlooked. The following example from the work on the Keokuk model illustrates this point.

While the head on the crest of the Keokuk spillway was measured at points where little or no velocity normal to the dam existed and, therefore, required no correction for the velocity of approach, the authors do not indicate that the results obtained from the model were corrected for velocity of approach in the test flume. With all three gates open this velocity would have corresponded to about 1.2% of the normal head of 1 ft. on the crest of the model. Applying this correction to the coefficient obtained for three gate openings, it is reduced to approximately 3.75, a value somewhat more reasonable in the light of Tests 4 and 5 on the full-sized structure. With only one gate on the model open, the velocity of approach becomes so small as to be negligible, and no correction is required. If a model of smaller scale had been used, a greater number of gates could have been accommodated in the 10-ft. width of the test flume and the approach conditions to the spillway could have been made to simulate more truly those of the full-sized structure. The head measurements could then have been made in a location similar to those for the actual spillway, and no velocity of approach correction would have been involved.

Greater precision of measurements will naturally follow from the use of large-scale models, assuming adequate laboratory facilities for measuring accurately the larger quantities of water used. Moreover, the comprehensive study of flow conditions within the overfalling sheet made by the authors

---

\* Engr., Stone & Webster Eng. Corporation, Eldon, Mo.

would require a large-size model. Ordinarily, however, entirely satisfactory quantitative determinations can be obtained from models of much smaller scale than were used for the Keokuk tests.

Experiments in European laboratories have demonstrated that as long as the velocity remains sufficiently high to insure a turbulent or rolling condition of flow, the laws of hydraulic similarity continue to apply. Any difference in results obtained by models of different scales, therefore, will be due to the relative frictional resistance to flow. The discharge of a spillway is affected by frictional resistance of the surface of the structure only in the region of low velocity up stream from, and a short distance over, the crest. Below this point the surface of the overfalling sheet falls below the critical depth, and frictional resistance no longer has any effect on the discharge. For this reason the effect of the relative roughness of spillway models is negligible, a fact demonstrated by the authors by comparing the discharge coefficients obtained from sanded and smooth-surfaced models. The use of a small model, therefore, will affect the accuracy of the results only in so far as it affects the accuracy of the head and discharge measurements. Aside from securing true hydraulic similarity the use of small-scale models has the added advantage of lower cost and increased facility of testing.

The reliability of the model tests having been established by comparison with the test on a full-sized structure, the importance of making model experiments in the design of hydraulic structures is strikingly demonstrated by the experiments performed by the authors, which show the possibility of materially increasing the discharge capacity of the spillway by the adoption of properly shaped piers.

C. H. PIERCE,\* M. Am. Soc. C. E. (by letter).—Ratings of hydraulic structures by means of laboratory measurements on small scale models form one of the most interesting and fascinating subjects in the field of hydraulic research. Experiments and laboratory tests of models have become fairly common in occurrence, but rarely is the opportunity available for comparison of laboratory experiments and tests with the results of measurements made on the full-sized structure under operating conditions. Therefore, the experiments described in this paper should be of especial value.

Some of the earlier tests on models which have come to the writer's attention indicated that the requirements of mechanical and hydraulic similitude were not always fully complied with, and, consequently, the results of the tests were not conclusive. It is possible also that all the laws of hydraulic similitude may not as yet be established or understood. For example, it is only recently that the foremost experimenters in this subject have fully comprehended the time relation for motion picture exposures required for an undistorted time scale from the model.

In 1918, Benjamin F. Groat, M. Am. Soc. C. E., gave a statement† of the "Theory of Hydraulic Models", and showed the derivation of some of the

\* Care, Charles T. Main, Inc., Boston, Mass.

† "Ice Diversion, Hydraulic Models, and Hydraulic Similarity," *Transactions, Am. Soc. C. E.*, Vol. LXXXII (1918), pp. 1108-1190.

fundamental relations which exist between the full-sized object and the model. More recent expositions of these relations have been made by Professor Hubert Engels and others.\*

A condensed restatement of the known laws of hydraulic similitude may be permissible. For a model built to a scale relation of 1 :  $k$ , the coefficients to be applied to the model features in order to transfer them to the full-sized structure are as follows:†

Coefficient.	Kind of Quantities to Be Transferred.
$k^{-0.5}$ .....	Number of revolutions of water-wheels (pumps, turbines); number of motion picture exposures for undistorted time scale.
$k^0$ .....	Constants; ratios (obstruction ratios, flow ratios); relative slopes; unit weights; accelerations.
$k^{0.5}$ .....	Time; velocities.
$k^{1.0}$ .....	Lengths; widths; heights; absolute slopes; velocity heads; friction heads; stresses; strains; wind pressure; towing resistance per unit of area; temperature changes through frictional resistance.
$k^{1.5}$ .....	Discharge volume per unit of time and of width.
$k^2$ .....	Areas (cross-sections).
$k^{2.5}$ .....	Discharge quantities per unit of time for the entire stream.
$k^3$ .....	Cubic contents; water volumes; mass forces (weights, impact, towing forces, wind pressures, reactions).
$k^{3.5}$ .....	Work done per unit of time; magnitudes of movements (impulses).
$k^4$ .....	Movements; work; energies (potential and kinetic energies).

The velocity with which the water approaches the crest is one of the major factors which determine the discharge equation of the spillway, and it is essential that the approach channel of the model shall be constructed so that the relation of velocity heads will conform with the law of similitude. Another important consideration is that the relative slopes of the water surfaces shall be in conformity. The fulfillment of this latter requirement of itself will assure the proper degree of smoothness of the model.

It would be manifestly impossible to reproduce, in an hydraulic laboratory of an engineering school, all the diverse conditions pertaining to the 119 spillway sections which extend across the Mississippi River from the Illinois shore to the power house at Keokuk, Iowa. Certain typical conditions can be evaluated, however, and general conclusions drawn from them. This appears to have been the method of attacking the problem at Keokuk, with respect to the current-meter measurements and the model tests.

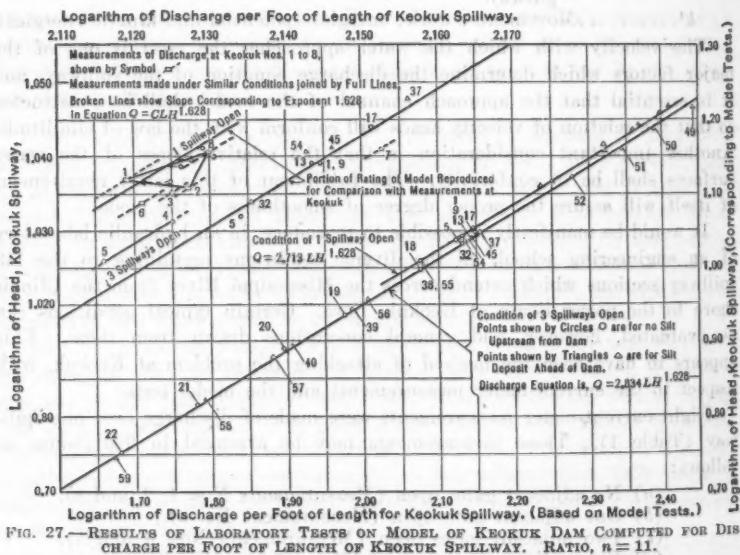

Eight current-meter measurements were made of discharge over one spillway (Table 1). These measurements may be arranged in five groups as follows:

- (a) No adjacent gates open (Measurements Nos. 1, 2, and 8).
- (b) One adjacent gate open (Measurement No. 3).
- (c) Two adjacent gates open (Measurements Nos. 4 and 5).
- (d) Four adjacent gates open (Measurement No. 6).
- (e) Six adjacent gates open (Measurement No. 7).

\* See "Hydraulic Laboratory Practice," edited by John R. Freeman, Past-President, Am. Soc. C. E.; and pub. by the Am. Soc. of Mech. Engrs., January, 1929.

† Arranged from notes of lectures given by Prof. Dr.-Ing. Theodor Rehbock, at Mass. Inst. Tech., March, 1929.

Because of the small range in head between the highest and lowest measurements, (0.37 ft. between the head of 10.99 ft. for Measurement No. 7, and 10.62 ft. for Measurement No. 5), it is necessary to plot them at an extended scale in order to analyze the results graphically. This has been done in Fig. 27, in which logarithms of head have been plotted against logarithms of discharge, using ordinary cross-section paper. The results of this plotting are fairly consistent. Measurement No. 7, which probably had the greatest velocity head on account of the large number of open gates, plots highest on the discharge curve. Group (a), with no adjacent gates open, is consistent with respect to location of the group, although the individual measurements differ somewhat among themselves. Measurement No. 3, with one adjacent gate open, shows a slightly larger discharge coefficient than the average of Group (a), which is as might be expected. The straight line defined by Group (c) shows a still larger coefficient, due to the greater velocity head. At first glance, Measurement No. 6, with four gates open, does not appear to be consistent, until it is noted that the four gates were all on one side of the section, and, consequently, the velocity head at the measuring section was probably about the same as for the condition of one adjacent gate open, as in the case of Measurement No. 3. Measurement No. 7, with six adjacent gates open, and with three gates on each side of the measuring section, shows the highest coefficient of all, about 2.839, with 1.628 as the exponent of the head.

In studying the rating of the model, it will be seen that for the condition of three spillways open, all the measurements made under that condition plot very close to a line the equation of which is  $Q = 2.834 L H^{1.628}$ . The con-

dition of silt ahead of the dam appears to have given results not appreciably different from the condition of no silt deposit. For the condition of one spillway open, the measurements define a line having the equation,  $Q = 2.713 L H^{1.028}$ .

It should be noted that the small group of measurements with one spillway open, which are reproduced at the enlarged scale between the heads having logarithms of 1.035 and 1.041 plot somewhat larger than the average curve for that condition. It is believed, however, that the average curve is more dependable than individual measurements or any one group of observations.

For those who desire to use  $H^{\frac{3}{2}}$  and a coefficient varying with the head instead of the exponential equation as derived from a straight-line log-diagram, the writer would suggest that it is easy to recast the equations mentioned into the form,  $Q = C_{\text{var.}} L H^{\frac{3}{2}}$ . The writer believes that logarithmic plotting affords the simplest and most reliable means of analyzing and evaluating many types of experimental data, especially those obtained from hydraulic experiments.

It is gratifying to note the considerable number of engineering schools and engineering experiment stations which now have equipment for conducting hydraulic experiments on a large scale. These laboratories, with the support and encouragement of engineers who are interested in hydraulic research, can be developed so as to provide ample facilities for the study of any hydraulic problem.

The authors have given the results of a series of very interesting and useful tests made at the laboratory of the University of Iowa. It is probable that there are numerous experiments made at other hydraulic laboratories which would be of value to the Engineering Profession if those in charge of the laboratories could find time to arrange the data for publication.

DR. ING. LUDWIG A. OTT\* (by letter).—This paper is of interest to the writer because it is the first that describes a case in which discharge measurements with current meters have been made under such extraordinary conditions and with such satisfactory results.

The particular difficulties in the measurements at the Keokuk Dam were caused by the presence of very high water velocities combined with great depths and oblique currents.

In high water velocities and at great depths the mechanical stress on a current meter rod of the usual circular cross-section is far greater than one is inclined to believe, if one has not made this problem a special study. Besides, even in uniformly smooth currents, high lateral stress may frequently occur, that may cause intense vibrations of the rod.† Rods of stream-line shaped cross-section are by far the most serviceable. Under equal conditions of water velocity and width of section, the pressure on such a rod is only about one-fifth that on a rod of circular section.

In regard to the current meters themselves, the Ott meters, used in the researches, will withstand the greatest velocities without danger of injury.

\* Math. Mech. Institut, Kempten, Bavaria, Germany.

† See F. Elsner, "Widerstandsmessungen in umströmten Zylindern", *Mitteilungen der preuss. Versuchsanstalt für Wasserbau und Schiffbau*, No. 4, Berlin, 1929.

The most noteworthy examples in this respect are perhaps the measurements reported by F. Kuntschen.\* The meter used in these experiments with entire success at a water velocity of 42 ft. per sec. (corresponding to more than 6 000 rev. per min.) was of the same type as the instrument used at the University of Iowa for velocity measurements in its experiments on the weir model.

In the case of extended measurements under very high stress, however, the particular Ott meters used at the Keokuk Dam are scarcely the most serviceable, because their axle bearings are not devised for such an extraordinary stress for long hours. It would be better to use an Ott meter of a type provided with steel ball-bearings running in an oil bath. This construction permits using the meter with confidence in extremely high velocities without affecting in the least its sensitiveness for a current as slow as about 0.15 ft. per sec.

A third difficulty in making measurements at the Keokuk Dam (which was also overcome satisfactorily) was the existing oblique currents.

The execution of measurements in oblique currents is the more simple and exact, the more closely the behavior of the screw follows the cosine law. Experience has taught that in this respect conical screws with two blades give less accurate results than cylindrical screws with three blades attached to spokes, as has also been proved by the U. S. Bureau of Standards ratings of the meters used. The narrowness of space alone was responsible for the use of the 2-blade, instead of the 3-blade screw, 7 in. in diameter. In connection with the meter equipped with ball-bearings in an oil bath, cylindrical screws, 4 in. in diameter, are furnished which show a particularly small deviation from the cosine law. At an angle of  $20^\circ$  between the direction of flow and the axle of the meter, the correction to be added to the determined velocity (see Fig. 6) is only 2 per cent.

In making the statement that the measurements at the Keokuk Dam might have been carried out more advantageously by the use of a rod with a streamline shaped section and an Ott meter of different type with a 3-blade cylindrical screw, 4 in. in diameter, the writer, of course, intends no reflection on the accuracy of the results obtained by the means used. On the contrary, he considers them to be highly satisfactory.

The comparative measurements at the Keokuk Dam and on a model of the spillways are similar to measurements carried out by the Research Institute for Hydraulic and Hydro-Electric Structures (Forschungsinstitut für Wasserbau und Wasserkraft), in Munich, Germany, at the spillways of the Mittlere Isar River and on a model one-fiftieth of the full size.† In this case the comparison of the results obtained on models and at the actual structure also produced a very satisfactory confirmation of the model rule.

At the writer's request, Dr. Ing. O. Kirschmer, Chief Engineer of the Research Institute for Hydraulic and Hydro-Electric Structures, has compared the results of his measurements with those at the Keokuk Dam with satisfactory results, as follows:

\* "Le moulinet hydrométrique et la mesure de courants très rapides," Communications, Suisse Service Fédéral des Eaux, No. 18, Berne, 1926.

† A report on these experiments is contained in "Hydraulic Laboratory Practice" (pub. by the Am. Soc. Mech. Engrs.), pp. 442-453, under the heading "Experiments to Determine the Discharge Coefficients of Certain Weirs with Round Crests".

During its experiments the Research Institute for Hydraulic and Hydro-Electric Structures has effected many changes in the forms of the weirs. There was little difficulty in comparing the results obtained with those at the Keokuk Dam. After reducing the weir coefficient determined by the Research Institute to existing conditions at the dam, the results obtained in both studies show a very satisfactory agreement. All the results determined on the model at the University of Iowa lay well within the range of "scattering" values observed in the experiments of the Research Institute (see shaded area in Fig. 28).

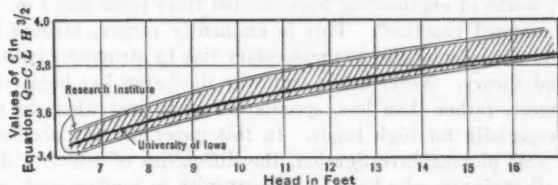

FIG. 28.—COMPARISON OF THE MODEL EXPERIMENTS OF THE UNIVERSITY OF IOWA AND THE RESEARCH INSTITUTE FOR HYDRAULIC AND WATER POWER ENGINEERING, MUNICH, GERMANY.

After very extended studies the Institute has reached the conclusion that on weirs certain variations in the flow condition will arise (instability of the current), and that, owing to this circumstance, various coefficients may be determined under fixed conditions at one and the same weir. For this reason, Dr. Kirschmer has not drawn in Fig. 28 a reduced or mean curve of weir coefficients, but has shown only the upper and lower limit between which the coefficients vary, owing to the unstable condition of the current. If one draws a mean curve within these limits, there remains a negligible difference between this curve and the one obtained by the authors which, perhaps, may be accounted for by the different methods of measuring (volumetric measurements at the Institute and Bazin weir measurements at the University of Iowa). Incidentally, in Germany the Bazin weir formula is now scarcely used for the computation of discharges.

The experiments at the Keokuk Dam can be compared further with those of the Research Institute at the spillway of the Mittlere Isar River with regard to the influence of obstructions, such as piers. In this case there is likewise an agreement between the authors' and Dr. Kirschmer's experiments. This influence on the weir coefficients appears to be somewhat less in the experiments of the Institute than in those at the Keokuk Dam, but it must be remembered that at the Mittlere Isar the thickness of the piers is also less in proportion to the width of the spillways at the Keokuk Dam.

The agreement between the model experiments and the measurement at the actual structure obtained on both parts may also be considered an indirect proof of the reliability of the current-meter method of measuring discharge. By virtue of its previous experience with regard to current-meter measurements the Research Institute is convinced that, with meters of suitable construction, great accuracy of results can be obtained even in very turbulent currents. In order to gain conclusive evidence as to the absolute accuracy of current-meter measurements, the Institute intends to make extended experi-

ments by comparison with the volumetric method. For this purpose the Research Institute has provided for the erection at its laboratory near the Walchensee a measuring tank with a capacity of 53 000 cu. ft., which will soon be put to use.\*

Investigations concerning the accuracy of the various methods of discharge measurements form an essential item in the program of the Research Institute.

B. F. GROAT,† M. Am. Soc. C. E. (by letter).—It is doubtful whether most engineers can appreciate the difficulties of real pioneer investigation. Most of the great works of engineering were erected from plans based on well-tried methods—"accepted practice". This is eminently proper, because lives and dollars should not be subjected to unnecessary risk by structures built on sands of misapplied theory. Nevertheless, spillway discharge has been for years a subject of more, rather than less, speculation as to just what the coefficient should be, especially for high heads. In this paper the authors have joined hands in a real pioneer investigation, the difficulties of which will be fully realized by all engineers who have had opportunity to conduct such researches.

The conditions surrounding experimental work are so complicated and interwoven in relationships that it is often necessary to expend a great amount of time, labor, and experimental mechanism, before any useful result can be obtained. Sometimes, an apparently simple device will be used for years before its unreliability is fully and generally suspected. This was the case with current meters when used for precise water measurements. One of the first, if not the first, to notice the effect of turbulent flow in causing a change of current-meter ratings was the late Charles H. Miller, M. Am. Soc. C. E.‡

Notwithstanding the many criticisms made by later observers, the current meter is to-day frequently used by engineers without regard to Miller's words of caution. It is, therefore, a source of satisfaction to know that the careful experimenters at Keokuk have applied corrections for errors due to angular disposition of the meters. The writer has also made similar efforts to correct the errors of current meters.

In one extensive series of experiments the discharge of large turbines at Massena, N. Y., was measured simultaneously by current meters and chemicals. These comparisons were from the earlier and least accurate of the chemical tests, but, even in these, the results show a high degree of precision in both methods of measurement.§ Omitting three tests in which there were known faults in the laboratory, or apparatus, the results were as given in Table 10.

The current meters used in these tests consisted of three different types, namely, one small Price meter, two Haskell meters, and two Ott meters. They operated on a movable frame, so that, by shifting once at each elevation, the five meters gave records for ten different points of observation in the cross-section. As there were ten elevations at which the meters operated, there

were, in all, 100 velocity readings for one complete sweep of the frame, which corresponds with one test.\*

No such satisfactory agreement could possibly have been attained in these tests had the ratings of the meters not been carefully corrected for errors. This will be appreciated when it is stated that some of the meters (depending on their type and their position in the raceway) diverged from their true ratings by amounts varying from + 10 to - 25 per cent.

The meters were held rigidly with axes pointing up stream, parallel to the axis of the raceway in all cases. The writer is sure that a meter which is allowed to swivel about its support is not as reliable as one fixed in its position, ratings in both cases being corrected for turbulence. Moreover, since there is no meter that gives a correct resolved component of motion, engineers should always use at least two types of meter simultaneously. One of these should be a screw type and the other a cup, because the former is retarded and the latter accelerated. This is not to be considered a criticism of the method of correcting ratings adopted by the authors, however, because the case in hand is rendered far simpler than in one in which there is great turbulence, as shown by the statement that,

"The water being accelerated as it passed over the crest, flowed with remarkable uniformity in smooth stream lines and was free from the characteristic pulsations in velocity and annoying vortices which so often accompany the phenomenon of flow in other channels."

However this may be, the writer believes he is perfectly correct in the following propositions which ought to be considered as theorems of hydraulics:

- (1) Meters should be held rigidly.
- (2) A "rudder", or "tail", is a monstrous absurdity.
- (3) A "screw" type of meter can be designed to give the resolved component.

These statements are not directed toward manufacturers, but to engineers as a whole who take altogether too long a time to make the most of past experience. It is about 250 years since, in a single paragraph, Newton enunciated the principles of similarity and the theory of models, to which no man has

\* "Chemi-Hydrometry and the Precise Testing of Hydro-Electric Generators," *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1270, Table 92.

been able to add one jot of additional theory; yet it is only in the last very few years that engineers have made any use of models as a reliable means for determining a design, especially in hydraulics. Charles Warren Hunt, M. Am. Soc. C. E., has stated\* the fact very tersely as follows: " \* \* \* a model is the only means for reproducing all the complexities of flow caused by natural channel conditions".

It is important to know how small the model may be made without loss of value as a reliable criterion. This is a question of special importance relative to experiments in which a long waterway is involved. In such cases the effects of friction are of much greater account than they are for weir, or spillway discharge, in which there is very little chance for frictional resistances, owing to the short length of the waterway involved.

As a matter of fact, the coefficient for frictionless weir discharge could not differ greatly from the coefficient determined by experiment, since the effect of friction is practically nothing for a weir. When the statement is made that the coefficient for frictionless flow would be about the same as for an experiment, it must be remembered that the equation,  $Q = C L h^{\frac{3}{2}}$ , is not a theoretical formula, but an empirical one. Therefore, the coefficient,  $C$ , for frictionless flow—instead of being unity—would express the numerical value of the function of  $H$  which would convert the empirical formula into the correct theoretical formula. That function, if correct in form, would undoubtedly eliminate  $H$  in terms of a true "head on the weir".

Before considering a weir and its model it will be desirable to acquire an understanding of the true nature of hydraulic friction. In the first place, there cannot possibly be any ordinary "sliding friction" of a fluid along the surface of a solid where there is contact. This theorem has been proved by many experimenters, notably first by Poiseuille in his celebrated experiments on the flow of fluids through capillary tubes. In cases of turbulent flow the velocity a short distance from the surface may be relatively high; but the presence of the "film" is certain, although its thickness may be very slight. The thickness of the film depends on the neighboring velocity of the fluid, the fluid itself, and the character and condition of the surface.

It is this thinning of the film (due to motion near-by) of steam, water, or air, along the side of a radiator which increases the heat conductivity of the radiator enormously. As a matter of established fact, the great resistance to heat transmission through good conductors is due principally to the thermal resistances of the fluid films on the two sides of the conductor, rather than to the resistances of the conductors themselves. For example, water boils only a little more quickly in a thin metal pot than in one of the same material several times thicker, or than in one made of thin asbestós, say. Asbestos is a poor conductor as regards the flow of heat through its material, but, for a thin sheet of asbestos, the resistance of its material is much less than the resistances of the fluid films on the two sides, even if the water be in turbulent motion. No correct estimate of heat conduction through walls from one medium to another can be made unless the films of the media on the walls

\* Transactions, Am. Soc. C. E., Vol. LXXXII (1918), p. 1168.

of the conductor be taken into account. In many cases, the resistances of the conducting materials themselves can actually be omitted without serious error.

The film of water along the wall of a channel (or pipe) is not at rest, except along the surface of contact, even if the thickness is extremely slight. There is undoubtedly motion at an indefinitely short distance from the wall. The experiments in heating and hydraulics have both shown that films are thicker with lesser velocities, and that with certain very small but determinate velocities the entire contents of the pipe acts precisely like the film along the wall. The whole becomes a mass flowing somewhat coherently yet plastically as a thick liquid (molasses) flowing through and out of a pipe. This is the case of pure viscous flow in which there are no eddies at all. It is just a smooth, relatively slow flow, in which, however, there is a transverse velocity gradient, or the velocity increases from nothing at the walls to a maximum at the center.

This transverse velocity gradient, expressed by the ratio,  $\frac{dv}{dx}$ , simply specifies the relative amount of sliding (shearing motion) per second of two parallel lamina of uniformly moving water, at a distance,  $dx$ , apart. The law of viscous friction states that the total shearing resistance,  $F$ , between these two neighboring lamina is  $\mu \frac{dv}{dx} A$ , in which,  $\mu$  is the coefficient of viscosity;  $A$ , the area of either of the two lamina (the area along which the shear occurs); and  $dx$  is indefinitely small. Thus, the intensity of shearing stress is:

$$\frac{F}{A} = \mu \frac{dv}{dx} \dots \dots \dots (1)$$

Concerning the flow in a long straight, horizontal, cylindrical pipe, consider a co-axial cylinder (variable radius,  $x$ ) of water in the pipe. The cylinder of water is being thrust forward by the difference in the pressures upon the two ends of the pipe. Then, the intensity of the shearing stress set up along the convex area of the co-axial cylinder of water is the difference of the end pressures, divided by the convex area of cylinder, or:

$$\frac{F}{A} = \frac{p \pi x^2}{2 \pi x l} = \frac{p x}{2 l} \dots \dots \dots (2)$$

Equating and integrating Equations (1) and (2):  $-\mu \frac{dv}{dx} = \frac{p x}{2 l}$ ,  $v_c = \frac{p r^2}{4 \mu l}$  and  $v = \frac{p (r^2 - x^2)}{4 \mu l}$ , in which,  $v_c$  is the velocity along the axis (central) and  $v$  is the velocity at distance,  $x$ , from the axis.

Then, the total discharge and mean velocity of the water through the pipe are, respectively,

$$Q = \pi \int v (2 x dx) = \frac{\pi p r^4}{8 \mu l} \dots \dots \dots (3)$$

$$V = \frac{Q}{\pi r^2} = \frac{p r^2}{8 \mu l} \dots \dots \dots (4)$$

This analysis is substantially that given by Lamb\* although it is less formal. Equation (3), thus established theoretically, is exactly that found experimentally by Poiseuille in 1840. Equation (4) demonstrates that the pressure drop is proportional to the velocity directly, and not to the square, for pure viscous flow.

The common idea seems to be that turbulent conditions have little to do with viscosity. Lamb states:†

"The resistance, in the case of turbulent flow, is found to be sensibly independent of the temperature, and, therefore, of the viscosity of the fluid. This is what we should anticipate from considerations of dimensions, if it be assumed that  $R$  varies as the square of the mean velocity relative to the wetted surface."

Lamb also quotes formulas for the coefficient of ordinary skin friction as given by Unwin.‡

Notwithstanding the opinions and statements of these profound authorities, it is confidently submitted that all "frictional" resistance to flow is due, either directly or indirectly, to viscosity; and that, if the viscosity of the water were zero, it would be a frictionless fluid in which there could be no such resistances. Of course, there would be resistance to velocity changes, but that would relate merely to "conserved" energy, available to support the flow and would not represent "lost work", as in the case of frictional resistances. Hydraulic friction is due entirely to viscosity acting under one, or both, of two regimens: Direct-shearing; eddy-making and eddy-destroying.

How is it possible to pass from a "perfect" (frictionless) fluid to an actual ("viscous") fluid solely by introducing the character of viscosity, without having all frictional resistances dependent on the viscosity? If vortices could be generated in a perfect fluid at some definite relative rate, then energy would be absorbed by such eddies (that is, in their kinetic energy content) and lost work would result; but it is not apparent how such eddies could be generated in a perfect fluid, and it is very apparent that, if they were generated, there would be continually increasing turbulence progressing down stream, since a perfect fluid could not possibly dissipate any of its internal energy. Liquid motion cannot be "killed" without internal viscous resistances. Otherwise, there is no such thing as "impact" (of fluid upon fluid) in a fluid. Neither can there be impact upon a solid by a liquid in the sense that energy is destroyed by that impact. In every case it must be the property of viscosity which ultimately converts waste motion into heat. In fact, it seems only reasonable to conclude that the whole configuration and character of the eddy system is dependent to a great extent on viscosity, although, of course, the shape and character, as well as the boundaries, of the flow must have also a very great influence on the delivery of kinetic energy to the re-acting viscous resistances.

Consider now the turbulent flow of a river. The channel may be assumed to be uniform in section, that is, of a generally prismatic nature; but the wet

\* "Hydrodynamics," Third Edition, 1906, p. 543.

† Loc. cit., p. 593.

‡ An error in the value of the coefficient,  $u$ , of viscosity given in the Ninth Edition of the *Encyclopædia Britannica*, was pointed out by the writer in 1909 in a paper on "Back-Water," *Minnesota Engineer*, Univ. of Minnesota. This error was carried forward in the Eleventh Edition of the *Encyclopædia*, and was again pointed out in a paper on "The Pitot Tube and Chemical Gauging," *Proceedings*, Engrs. Soc. of Western Pennsylvania, May, 1914.

perimeter is more or less undulatory and "rough". These undulations deflect water from the bottom and project it into the body of the stream, at greater or less velocity. The projected disturbances do not occur as definite streams of water, but as erratic pulsations, eddies, "boilers", and open vortices.

In such a stream, a large deeply floating body, such as a ship, may float down stream either faster or slower (but usually faster), than the mean velocity of the water with which the body is in contact, depending on the distribution of velocities in the stream, the slope of the water surface, and the position, size, shape, and depth of flotation of the body.

In this connection Francis quotes Weisbach as follows: "As a rule \* \* \* the velocity of a swimming body is somewhat greater than the water". This was investigated in an extensive study of the rod float, made by the writer, which is as yet (1929) unpublished.

Incidentally, the rod float is an excellent instrument for the measurement of the mean velocity of flowing water. It has been practically discarded by the profession, despite the fact that it is much more reliable and much simpler, for many purposes (even for refined work) than current meters, especially for gauging flow in canals of prismatic section. This simplification is made possible by the rod-float tables computed during the study.

It is important to note that the late J. P. Frizell, M. Am. Soc. C. E., actually calculated the theoretical velocity from that of a rod float for one condition of flow and depth of immersion. Francis distracted his attention, however, by showing that a float tended to slide down the inclined surface of the water and by stating that he thought it best to use empirical methods. Had it not been for this situation, Frizell would probably have solved the rod-float problem completely.

*Theorem 1.*—If the greater velocities (of an enveloping layer of water around a floating body, as a ship, or rod float) have the greater weights (averaging weights), and impulsive forces (due to skin friction) are proportional to the squares of impinging velocities, the velocity of the floating body is less than the mean velocity of the enveloping layer of water; but if the smaller velocities have the greater weights, the velocity of the floating body exceeds the mean velocity of the enveloping layer.

When the writer first demonstrated this theorem he was apparently squarely against Weisbach's statement that a ship would float down stream more rapidly than the current, because the theorem shows that a rod float will tend to move less rapidly than the water with which it is in contact. Nevertheless, as may be clearly seen, an application of the theorem to the two cases, taking into account the vertical velocity curve of the river (generally concave up streamward), and the size, shape, and position of the floating body, brings all into harmony.

If the law of skin friction relates to the first power of the impinging velocity only, then the floating body moves exactly with the mean velocity of the enveloping layer.

This theorem is independent of the tendency of the floating body to slide down the slope of the water surface, but another theorem shows that this tendency is generally of lesser importance.

*Theorem 2.*—If a body floats in a uniform current, and an independent propelling force acts upon that body in the line of action of the force due to hydraulic slope, then the total change,  $x$ , in velocity, from the condition in which the propelling force acts alone, to that in which the two forces combine, is less than the velocity which the hydraulic slope alone would produce, except the one case in which the propelling force is directed up stream and does not exceed the force due to slope.

The theorem does not except the case when the propelling force is directed up stream and exceeds the force due to slope. When the two forces are equal and opposed the change in velocity is, of course, just equal to the velocity due to slope.

The theorem is illustrated by the fact that a relatively small force will tow a large vessel in still water at a rate of several miles per hour, when the application of that same force in the line of motion when the vessel is being driven at full speed by its own power, would have scarcely any appreciable effect toward increasing, or decreasing, the speed. The theorem shows that the effect of slope is much diminished in the currents of rivers and canals, as against the action of slope in uniformly flowing water, because, in the latter case, there would be no independent propelling force.

These theorems are very important, because they have an illuminating relation to the questions of turbulent flow of rivers. Suppose, for example, a large mass of water is flowing down stream as a unit, with practically uniform velocity. The theory shows that it will tend to flow either faster, or slower, than the mean velocity of the water with which it is in contact. This would mean the generation of eddies and "boilers" around, and finally within, the body of water, so that there would be "internal" frictional losses within the body of water flowing in a stream due to the generation of turbulence internally.

This completes the picture of turbulent flow; it shows that these internal turbulent resistances may still be assumed to result from the effect of the bottom, or wet perimeter, because the variations of velocity must be due ultimately to disturbances emanating at and along the wetted surface.

To analyze this condition assume that the agitating area is the wet surface, measured by  $Pl$ , in which,  $P$  is the perimeter of the cross-section, and  $l$  is the length of, or uniform reach of, the river. The volume of the water agitated along the wet surface is  $nPlv$ , in which,  $n$  is a dimensionless coefficient depending on the shape and character of the bottom, and  $v$  is the mean effective velocity with which the water is deflected from the agitating wet surface. If  $V$  is the actual mean velocity in the section, and  $A$  is the cross-sectional area:

$$nPlv = n \frac{Plv}{AV} Q = n \left( \frac{v}{V} \right) \frac{l}{m} Q \dots \dots \dots (5)$$

since  $\frac{P}{A} = \frac{1}{m}$ ,  $Q = AV$  is the rate of discharge, and  $m$  is the hydraulic mean depth.

This volume of water deflected from the sides with effective velocity,  $v$ , has the kinetic energy,

$$\frac{nlv}{2mV} Q \delta v^2 \dots \dots \dots (6)$$

All this is finally converted into heat by viscous resistances within the resulting eddies and the turbulence. It becomes lost as kinetic energy of the flow. The resulting loss of head is the loss of energy per pound of water discharged (total discharge); that is,

$$h = \frac{n r l}{2 V m} \frac{Q \delta v^2}{w Q} = n \left( \frac{v}{V} \right)^3 \frac{l V^2}{m 2 g} \dots \dots \dots (7)$$

Substituting for the quantity,  $n \frac{v^3}{V^3}$ , the factor,  $f$ , which is the dimensionless coefficient of loss due to turbulence, Equation (7) becomes:

$$h = f \frac{l}{m} \frac{V^2}{2 g} \dots \dots \dots (8)$$

The ratio,  $\frac{v}{V}$ , denotes the ratio of the effective velocity of projection from the bottom to the mean velocity of flow in the river. Its value depends on the shape, dimensions, and other characteristics of the channel. The channel may be that of a pipe, but in that case  $f$  would be different. The reason such a dimensionless ratio can be merged with a dimensionless coefficient so as to form a modified coefficient, is that the mean velocity (as to time) at any given point in a river, in the case of steady flow, bears a constant ratio to the mean velocity of the river flow. This is a condition practically maintained in actual streams as regards mean point velocities in the cross-section, and this proposition is here extended to apply to the average pulsations in disturbances emanating from the wet area. Of course, the ratios change with change of stage, but, then, the dimensionless coefficients change also, so that no new character is attributed to the coefficients by the consolidation.

Observe carefully that Equation (8) is a rigorous theoretical formula except that, as yet, no method is shown for calculating the value of  $f$ . However, since the formula is the same as that used for years, values for  $f$  are available, based on a great amount of experience. As  $f$  is dimensionless, it has the same value in all systems of units, for any given channel. Observe, also, that the formula involves the exact square of the velocity, in so far as it relates to the losses of head resulting from pure turbulence. It is quite wrong to state that the loss due to turbulence (pure turbulence) varies in any other manner than as the exact square of the velocity (the mean velocity) in the cross-section. This is true, because all the velocities to which lost kinetic energy is to be assigned vary as the mean velocity in the cross-section, referring, of course, in each instance, to time averages for properly determined periods.

This discussion has treated separately the two cases—pure viscous flow and pure turbulent flow—each resulting in internal, as well as superficial losses along the wetted perimeter, the energy being dissipated in the form of heat. It is easy to understand that, along the boundaries in slowly moving pools as well as in the border films of turbulent flows, there must be more or less viscous resistance directed against the general flow. There must also be many places in the fluid where shearing resistances occur to check the flow, as it were. Thus, the total loss of head in friction is due to both causes acting simultaneously. Hence it is possible to add the two friction heads calculated in Equations (5) and (6).

tions (4) and (8). Since the pressure head of Equation (4) is  $\frac{p}{w}$  ( $w$  being the specific weight of water):

$$h' = \frac{8 \mu l V}{w r^2} = \frac{2 \nu l V}{g m^2} = \frac{4 \nu l V^2}{m V m 2 g} \dots \dots \dots (9)$$

in which,  $h'$  is used to distinguish any directly effective viscosity resistances that may occur simultaneously with turbulent flow, but not including those viscous resistances which dissipate the turbulent energy by subduing it, so to speak.

Equation (9), however, is not yet fully adapted to be applicable simultaneously with turbulent flow. The velocity in Equation (9) was defined as that due to pure viscous flow. Hence, as in the case of the coefficient in Equation (8), to apply Equation (9) to the case in which both turbulent and viscous resistances act together, it is necessary to introduce a friction factor,  $f'$ . Thus, combining Equations (4) and (8):

$$H^* = h' + h = \left( f' \frac{4 \nu}{m V} + f \right) \frac{l V^2}{m 2 g} \dots \dots \dots (10)$$

which is a perfectly sound formula for the flow of water in any channel. The ratio of pure stream-line velocity (which would be determined by Equation (4)) to the actual mean velocity was assumed to be absorbed in the coefficient,  $f'$ , just as the ratio,  $\frac{v^3}{V^3}$ , was absorbed in  $f$ , in Equation (8).

Of course,  $f$  is not the same in Equation (10) as the usual friction factor. In Equation (10) both  $f'$  and  $f$  are dimensionless friction factors. They depend on the kinematical coefficient,  $\nu$ , of viscosity; the mean velocity in the cross-section; the roughness of perimeter, including curvature; and the dimensionless ratios of channel dimensions, such as  $\frac{l}{m}$ ,  $\frac{l}{P}$ , and  $\frac{\epsilon}{m}$ , in which,  $\epsilon$  is some linear measure of relative roughness;  $l$ , the length of reach;  $m$ , the hydraulic radius; and  $P$ , the bounding wet perimeter of cross-section.

In pure viscous flow,  $f = 0$ . In the case of turbulent flow the writer would not expect to find that  $f'$  has negligible values. In fact, it is perfectly clear that it cannot have such values, since it is well known in hydraulic experience that resistances in turbulent flow vary as a power of the velocity less than the square. When turbulence exists the coefficient of friction becomes:

$$F = f' \frac{4 \nu}{m V} + f \dots \dots \dots (11)$$

and,

$$H^* = F \frac{l}{m} \frac{V^2}{2 g} \dots \dots \dots (12)$$

It is clear from the value of  $F$  (which involves  $V$  in the denominator of one term) that  $H$  depends on a power of  $V$  less than the square, as is well known, but that there is no fixed relation of this kind applicable to all channels alike, and no fixed value for the exponent, even in the case of a given channel,

\* Forms for  $F$  in terms of definite negative fractional exponents of Reynolds' number relate to only one condition of roughness and one shape of channel boundary.

although approximations have been made.\* Equation (11) precludes the possibility of higher powers of  $V$  than the square, although, under extraordinary conditions, erroneous results may be obtained.

The correct solution of Equation (10) for the velocity is:

$$V = - \left( \phi \frac{v}{m} \right) + \sqrt{\left( \phi \frac{v}{m} \right)^2 + \left( \frac{m}{f l} \right) (2 g H)} \dots \dots \dots (13)$$

in which,  $\phi = \left( 2 \frac{f'}{f} \right)$ . The coefficients have been recast to adapt them to the form for the value of  $V$ .

Formulas of the general type of Equations (10) and (11), but without explicit mention of viscosity, have been proposed by eminent writers in the past. Biel's formula† takes into account the viscosity, but strict regard for dimensional form does not seem to have been followed, the idea apparently having been mainly to include two terms in metric units, one term in  $V$ , the other in  $V^2$ .

The idea of introducing  $\phi$  in Equation (13) is to avoid obvious unnecessary mathematical difficulties by regarding  $\phi$  and  $f$  as the only necessary coefficients. It should be noticed, however, that the coefficients of Equations (10) and (11) are properly the ones to be determined by experiment; but, for most practical purposes, the great amount of data available concerning the coefficient,  $F$ , in Equation (11), is quite sufficient.

Equation (13) includes Reynolds' critical velocity. When that occurs,  $f$  suddenly vanishes. By inserting the value of  $\phi$  (that is,  $2 \frac{f'}{f}$ ), it may be shown that Equation (13) reverts to Equation (9) for pure viscous flow. The velocity does not become infinite, as with some formulas.

The object of this discussion of hydraulic friction is not intended so much to adduce a new form of coefficient in terms of viscosity and turbulence, as to offer the true explanation of hydraulic resistance in channels of any kind, including weirs. The proposition that all hydraulic resistance depends ultimately on viscosity, so that, if this property were wanting, there would be no hydraulic resistance (lost work), is bound to meet with some incredulity, until those who think that turbulence resistance is independent of viscosity give the question careful investigation. The writer here takes the anomalous position that there can be no turbulence without viscosity; yet viscosity tends to suppress the initial formation of turbulence, as well as to still it after it has been formed.

As Equation (10) applies to any channel by dividing it into elementary longitudinal sections, it will apply to a weir, either with reference to the entire cross-section, or to the elementary filaments separately. It is clear that the loss of head in friction depends on all the variables on which the coefficients depend, and also on Reynolds' number. If  $f = 0$  (no turbulence) the result is

\* Forms for  $F$  in terms of definite negative fractional exponents of Reynolds' number relate to only one condition of roughness and one shape of channel boundary.

† In 1909, the writer gave an account of Biel's formula in the *Minnesota Engineer*, Univ. of Minnesota, January, 1909.

stream-line flow. In either kind of flow, the total coefficient decreases with an increasing Reynolds' number,  $\frac{m V}{\nu}$ , if  $f'$  and  $f$  do not change sufficiently to the contrary as seems usually to be the case. (Note the behavior in the vicinity of the critical value of Reynolds' number.)

Observe that Equation (10) measures merely the deterrent action of applied friction. That this friction is extremely small for weirs becomes apparent when the condition of a weir is compared with the condition of a canal, or river. Even with large values of the friction factors and with balancing slopes of only a few inches per mile, the velocities in rivers and canals are considerable. In the case of weirs the conditions are reversed, the surface slopes being far greater, while the friction is almost a vanishing quantity. This is due mainly to the small value of  $l$ , which attaches to weirs, in Equation (10), but the values of  $f'$  and  $f$  also become small, for weirs. However, it is well to consider the form of the coefficients in Equation (13).

Almost the entire obstacle to the surface slope and velocity over weirs lies in the acceleration of the spilling water above and beyond the crest. A frictionless weir would deliver only a little more water. Consequently, hydraulic friction is of little or no account in its effects on weir discharge, unless the head is abnormally small or the kinematical viscosity abnormally large. That the acceleration at Keokuk is very important, especially in furnishing a gauging section free from turbulence, is mentioned by the authors. In such a section the effect of any turbulence near the piers must be extremely small, relatively.

In preparing their paper, and in executing their tests, the authors have been careful not to say or do anything which will admit of any great criticism, so that, actually, there is not much to criticize. However, it may be pertinent to comment favorably on some of their statements. Perhaps the main value of the experiments, other than the great practical utility of a ready means for determining exact coefficients for weirs of the Keokuk type, and approximate coefficients for other types, is the information concerning the interior of the nappe. It would have been of great value also to determine internal pressures, but, if this was not done, the writer knows well that one is not usually warranted in going far beyond the immediate objects of experiment to accumulate data on concomitant phenomena.

For many practical purposes Fig. 14 will be all that is desired, but there is need for a true weir formula, especially as an aid in original design. Much of what the authors have done will be useful in framing such a fundamental theory. It is true that there are some remarkable studies in hydrodynamics, but, when it comes to weirs, the theory is lacking, even for the case of two-dimensional flow. The remarks of the authors are, therefore, of very great interest.

They state four significant facts, as follows: (1) Velocities are remarkably uniform within the nappe at a given depth below the pond level; (2) velocities within the nappe increase downward and friction is very small; (3) at the entrance to the nappe, velocities are higher at the bend around the pier noses;

and (4) velocities at the entrance to the nappe are retarded by the restricted, and relatively constricted, paths along the angular corners.

The opinion may be expressed that one reason for the increase in velocity within the nappe, passing downward, lies in the fact that the spillway crest is curved in a vertical plane, and the radius is directed downward toward the center of curvature. Thus, the water in its progress is given an opportunity to turn downward, so that the centripetal acceleration,  $\frac{v^2}{r}$ , produces an upward

directed centrifugal reaction which tends to support the weight of the water above, thus causing a decrease of internal pressure and a resulting increase in velocity, passing downward when comparing conditions. The reverse will be the case in the depression over an apron at the foot of an ogee dam. Velocities will be higher at the surface than at a depth, while the pressure will increase downward, because the concavity of the water surface faces upward. This is exactly the effect obtaining in an eddy with vertical axis (for example, water rotating rapidly in a pail), the difference being that the axis of rotation over the weir is horizontal. This same logic explains the increase in the velocity around the bends at the noses of the piers. The effect is the result of decreased pressure toward the center of curvature approximately according to the formula,

$$\frac{dp}{dr} = \frac{w}{g} \frac{v^2}{r} \dots\dots\dots (14)$$

Equation (14) would be exact if the viscosity were zero; that is, when there are no tangential tractions acting on elementary surfaces along which there is a tendency to slide. In hydrodynamics, when there are no such tractions, it has been assumed that  $v$  varies inversely as  $r$ , which leads to the "irrotational" form of vortex. There is another more or less present cause for reduced pressure on the crest and down along the spillway; that is, the siphonic action of the column of water resting on and against the spillway.

With reference to Fig. 14, it was suggested that possibly the velocity at the surface of the nappe may exceed that due to the head below pond level on the surface point in question. The possible shearing traction exerted by the more rapidly moving water below seems plausible, as a cause, at first sight, but the fact that the excess velocity is negligible, compared to what one might expect, raises some doubt. One may imagine a weir discharging a very viscous liquid, say, semi-liquid tar. With that in mind there does not appear to be any real connection between actual velocities and the broken-line curve of "Velocity Corresponding to Head below Pond Level".

Relative to the Keokuk weir, it may be pertinent to remark that the writer made some study of the plans for that weir and the possible coefficient of discharge, long before it was built. A number of engineers then entertained the idea that the adopted weir coefficients were too small for that type.

The writer's experience on the St. Lawrence and many other large rivers leads him to believe that, if the modeled reach is not too long (say, a mile or two), models using water give surprisingly accurate reproductions of flow. Perhaps longer reaches might prove satisfactory. He does not doubt the approximate accuracy of a model of the Keokuk spillway to a scale ratio of 1 to 100.

However, the writer has shown\* that a mercury "model" of water about one-fifth the full size will give theoretically exact results. That being true, it should be possible to secure the same degree of accuracy with a mercury model one-five hundredth of the full size as with a water "model", one-one hundredth of the full size. One should not hesitate to test and rely on a mercury model of the Keokuk spillway, one-two hundred and fiftieth of the full size, although it would have to be "built like a watch". Such a model spillway must be built of suitable materials in proper condition as to smoothness, etc., in order to avoid distortion caused by excess viscosity and the presence of surface tension. An application of model testing to large structures has been fully described by the writer under the title, "Ice Diversion Works for St. Lawrence River Power Company."†

In closing, the writer may state that he can confirm the necessity of "staying" the meters in swift water. He has used meters in the rapids of the St. Lawrence where there were velocities approximating, if not as great as, those experienced at Keokuk by the authors.

As to the weir, the writer has made some calculations for the internal pressures at several points within the nappe (approximately, at least) and believes that it would be quite possible to frame a true weir formula, basing practical coefficients (dimensionless) on the results presented in the paper.

FLOYD A. NAGLER,‡ AND ALBION DAVIS,§ MEMBERS, AM. SOC. C. E. (by letter).—The writers are deeply appreciative of the constructive comment made by the various discussers. Apparently, little remains to be said in closing the discussion. It is, indeed, gratifying to note the close agreement between the coefficients obtained on the Keokuk model and those presented by Dr. Ott, resulting from experiments at the Research Institute at Munich. The writers' estimate that their experiments were reliable within 2% was not based upon the laboratory verification by means of the Pitot tube alone; it was a judgment based upon the general reliability of the current-meter methods and ratings used in the field, together with the various checks which were afforded by other measurements and the model tests.

Additional data were requested§ relative to the behavior of various types of current meters in streams with varying degrees of angularity, both from the left and the right. The average corrections applied in the paper were based on angular calibrations made at the U. S. Bureau of Standards. However, these were subsequently checked in an extensive investigation|| at the laboratory of the University of Iowa, made in conjunction with the Bureau of Public Roads, U. S. Department of Agriculture.]]

### ELASTIC EQUILIBRIUM IN THE THEORY OF STRUCTURES\*

By H. S. RICHMOND,† Esq.

WITH DISCUSSION BY MESSRS. JACOB FELD, F. B. SEELY, W. J. PUTNAM, AND  
W. L. SCHWALBE, NORMAN LITCHFIELD, E. R. HILL, O. G. JULIAN AND  
GEORGE R. RICH, JOHN I. PARCEL, S. TIMOSHENKO, AND H. S. RICHMOND.

#### SYNOPSIS

The standard specifications and formulas used in structural design, were devised to meet the problems encountered in ordinary bridge and building construction. They are well adapted to this purpose and have been found convenient and practical. When, however, an attempt is made to treat certain special problems, the limitations of these standard formulas become apparent. For instance, in the reinforcement of existing structures, an investigation of their strength depends on a rational analysis of their loads, stresses, and strains, and the design of their reinforcement must be based on such analysis, rather than on any empirical formulas.

Another class of structure which demands special treatment is that used in railroad electrification work for the support of transmission wires, trolley catenary wiring, outdoor sub-station wiring, and switching. For some years, the writer has been actively engaged in the design of such structures, and has found it entirely practical to use bents which, while thoroughly braced, neither follow the usual design nor stay within the limits set up in some of the conventional rules.

As a general rule members have been of simple and compact form and of a smooth surface, because, from the standpoint of maintenance, it is important

\* Published in January, 1929, *Proceedings*.

† With Gibbs & Hill, Cons. Engrs., New York, N. Y.

to avoid lattice-bars and other intricate details. This is especially true of structures such as catenary-supporting bridges which span the railroad tracks and are exposed to exhaust gases from steam locomotive stacks.

This has finally led to the adoption of what is virtually a single-member structure; that is, two legs and one cross-beam or wire-span, instead of square latticed columns and a cross-box girder, or four-post structure. The entire structure lies almost within one vertical plane, with a minimum of lateral bracing. Consequently, the fundamental mechanical principles applying to light and slender members must be carefully analyzed in the development of a safe and economical design.

In addition to economy, structures so designed have the advantage (when used for supporting wires which are strung under considerable tension) that, in the event of a failure of one or more wires, the structure flexes a considerable amount without destructive effect, distributing the emergency load among a number of bridges.

Light structures of the type used for cross-country transmission towers, etc., are quite generally built of standard rolled sections, with slender members of thin material, and must necessarily have many unsymmetrical and eccentric connections and few rivets or bolts. In addition to the specified loads which they are designed to carry, such structures must sustain other loadings, such as their own weight, wind pressure, the weight of a man climbing the tower, etc. If standard formulas are used in the design, a member would be obtained unquestionably strong enough so that it would not be necessary to consider these secondary loadings, but the design would be uneconomical. When it is understood that the cost of transporting these towers to the site and erecting them may amount to a considerable addition to the cost of their purchase, it will be found profitable to apply an analytical treatment, especially where there is much duplication of type.

The foregoing applies chiefly to structures having light members. Quite different considerations apply to heavy structural members, for which the engineer is justified in giving a very careful study to the economics of design with a view of obtaining a member of more nearly ideal proportions. For example, in a cantilever bridge of great span, the dead load is often much greater than the live load. The saving of a pound weight of steel at a point in mid-span will reduce the dead load and save many pounds elsewhere in the structure. In such a case the use of high-strength alloys appeals to the imagination, but in utilizing such alloys, it is necessary to consider that the elastic modulus of steels has not kept pace with their elastic limit and ultimate strength. If a higher compressive stress is to be used, especial care must be given to the consideration of elastic stability or resistance to various kinds of crippling. A long column may fail by bowing or by a wrinkling of the plates and flanges which form its section. The make-up of a column is governed by a balancing of these various points of consideration, and the use of a steel other than the standard involves a fresh analytical treatment.

A thorough study of the column should include that of the resistance of its elements to failure by any modes which may be classified under the head-

ing of neutral elastic equilibrium. Its web-plates must not be thin enough to fail by wrinkling; its flanges must not crimp; and if it is a single-angle member it must have sufficient torsional rigidity to prevent failure by twisting.

This principle of elastic equilibrium is given consideration in structural design and special attention is given to its consideration in connection with the design of columns, to which a great amount of study has been devoted and on which subject the literature is voluminous.

While the column has been thus honored, other structural members, such as beams, have been given less consideration. The writer published a small pamphlet in 1912, entitled "The Lateral Deflection of Beams", in which he set forth the results of some experiences with model beams and offered an analytical treatment of the problem of the elastic equilibrium of beams. This, with the exception of a study by Dr. S. Timoshenko,\* is, in so far as he knows, the only analytical treatment of this problem.

Two distinct classes of beams were recognized, the flanged beam without torsional resistance and the beam of compact form, but with torsional rigidity. Subsequently, the theorems were extended to apply to a flanged beam having torsional resistance, and to include channel-shaped as well as symmetrical sections. Tests of small wooden model beams showed a satisfactory conformity with the theorem for the class tested, namely, the beam with considerable torsional resistance.

#### NOTATION

The following notation has been used in the paper:

- $a$  = distance (measured in the plane of the web) of the point of application of the load above the center of the beam.
- $-a$  = distance (measured in the plane of the web) of the point of application of the load below the center of the beam.
- $b$  = distance from center to center of channel or **I**-beam flanges.
- $f$  = fiber stress.
- $h$  = distance of the fiber,  $f$ , from an axis that is perpendicular to the web, through its center.
- $k_1$  = lateral curvature of the upper flange of a beam.
- $k_2$  = lateral curvature of the lower flange of a beam.
- $n$  = eccentricity of the applied load (see Fig. 4).
- $r$  = modulus of rigidity =  $\frac{Q}{\alpha}$ .
- $S$  = shear.
- $x$  = abscissa of a point on a beam, measured in a horizontal plane from the  $Y$ -axis.
- $y$  = ordinate of a point, the abscissa of which is  $x$ .
- $z$  = abscissa of a point, the ordinate of which is  $h$ .
- $A, B, C$ , and  $D$  = arbitrary constants.
- $E$  = modulus of elasticity.
- $E_s$  = shearing modulus of elasticity.
- $\bar{I}$  = moment of inertia about the originally horizontal gravity axis.
- $I'$  = least moment of inertia.
- $I_A$  = moment of inertia (about a horizontal axis) of a half section of a beam.

\* "Beams Without Lateral Support," *Transactions, Am. Soc. C. E.*, Vol. LXXXVII (1924), p. 1247.

$I_1$  = moment of inertia of the section about its originally vertical gravity axis.

$$I_3 = \frac{I_1}{1 - \frac{I_1}{I}}$$

$I_2$  = moment of inertia of the upper half section of a beam about its originally vertical axis through the center of the web.

$J$  = factor expressing the capacity of any cross-section to resist torsion.

$$K = \text{factor} = TL^2 = \frac{PL^2}{\sqrt{EI_3E_sJ}}$$

$L$  = length of a cantilever beam or column; or one-half the length of a beam supported at each end.

$M$  = applied bending moment in a beam and parallel to the web.

$M_2$  = bending moment in a beam induced by torsion, and perpendicular to the web.

$M_3$  = bending moment in the flanges of a beam induced by torsion, and parallel to the web;  $+M_3$  applies to upper flange, and  $-M_3$  to lower flange.

$M_t$  = lateral bending moment in the upper flange of a beam.

$M_b$  = lateral bending moment in the lower flange of a beam.

$$N = \text{factor} = \frac{a}{L} \sqrt{\frac{EI_3}{E_sJ}}$$

$P$  = compressive load or the load necessary for neutral elastic equilibrium.

$Q$  = torque due to the applied load,  $P$ .

$R$  = factor.

$$T = \text{factor such that } T^2 = \frac{P^2}{EI_3E_sJ}$$

$U = \iint hz \, dh \, dz$  for the upper half section referred to the central point of the web.

$\alpha = \frac{Q}{r}$  = angle of deflection of the web due to torque,  $Q$  (see Fig. 3).

$\delta$ ,  $\varepsilon$ , and  $\lambda$  = factors.

$\Delta$  = horizontal displacement of a load,  $P$ , producing torsion in a beam.

#### DEFINITIONS

The term, "elastic equilibrium", as herein used, is to be understood as meaning the state of an elastic body (under a condition of stress resulting from the application of an external loading) with respect to its ability to resist excessive deformation or change of form initiated by a second, or disturbing, force temporarily applied. A body is in stable equilibrium when it has a tendency to regain its original form on removal of the disturbing force.

Likewise, neutral elastic equilibrium exists when the body has an equal tendency to regain its original form, to remain in its deformed condition, or to increase its deformation after removal of the disturbing force.

The "pin-ended" Euler column furnishes a familiar example illustrating this principle. In this case the column is in neutral equilibrium when  $P = \frac{\pi^2 EI}{L^2}$ .

If  $P$  is less than this amount, the column is in stable equilibrium and if it is greater, the column is in unstable equilibrium.

Consider a horizontal shaft of length,  $L$  (Fig. 1(a)), fixed at one end (the other end supported but free to rotate), and carrying a rigid arm extending vertically upward and sustaining a load acting vertically downward at its upper extremity. Suppose that the shaft undergoes a torsional deflection,  $\alpha$ , from any cause, so that the arm at the end assumes an inclined position as shown in Fig. 1(b). From Fig. 1,

$$Q = P \Delta = P a \alpha \dots \dots \dots (1)$$

and since, by definition,  $\alpha = \frac{Q}{r}$ ,

$$P = \frac{r}{a} \dots \dots \dots (2)$$

which is the relation sought.

Let  $J$  equal a factor expressing the capacity of any cross-section to resist torsion, so that  $\alpha = \frac{Q L}{E_s J}$ ; then  $r = \frac{E_s J}{L}$ , and,

$$P = \frac{E_s J}{a L} \dots \dots \dots (3)$$

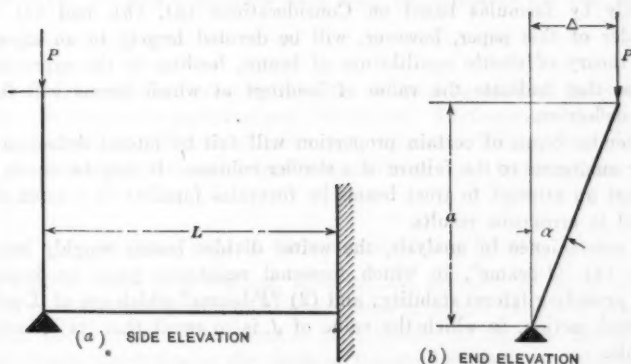

FIG. 1.

In practice, all structures must meet the condition of stable elastic equilibrium and their loadings must not approach too closely the loadings which would result in neutral elastic equilibrium. Even so, account must be taken of the results of deformation under load, as affecting stress conditions. This can be accomplished in two ways: (1) The problem of the particular structural member, which is in a state of deformation and, at the same time, is in stable elastic equilibrium, may be analyzed; or (2) the designer's judgment may be governed by the following considerations:

(a) A member subject to deformation due to any system of loading (the primary loading), will in general be less well adapted to resist the effects of another system, (the secondary loading), than if the first system of loading did not exist.

(b) If the primary system of loading does not exist, then the entire strength of the member can be devoted to the resistance of the secondary system.

(c) If the primary system of loading is such as to place the member in a state of neutral elastic equilibrium, then the member has generally no strength to resist the secondary system, but is, so to speak, in a state of ruin or uselessness as a structural member.

Between the limits of no primary load and a primary load resulting in neutral elastic equilibrium, it may be shown that for some members, loaded in a certain way, the load-resisting function of the member as regards the secondary system is approximately proportional to 1 minus the ratio of the primary load or system to a similar load or system which would result in a condition of neutral elastic equilibrium. This relation forms the basis of some useful formulas.

In the absence of analysis, certain problems may be treated in this manner, but it should be noted that the relation is by no means generally applicable and must be used judiciously.

Columns having considerable eccentricity of loading and members subject to combined bending and compression may be treated conveniently and rationally by formulas based on Considerations (a), (b), and (c). The remainder of this paper, however, will be devoted largely to an exposition of the theory of elastic equilibrium of beams, leading to the expression of formulas that indicate the value of loadings at which beams will fail by lateral deflection.

A slender beam of certain proportion will fail by lateral deflection in a manner analogous to the failure of a slender column. It may be shown, however, that an attempt to treat beams by formulas familiar in column design will lead to erroneous results.

For convenience in analysis, the writer divides beams roughly into two classes: (1) "*J*-beams", in which torsional resistance plays an important part in providing lateral stability; and (2) "*F*-beams" which are of *I*-section, or channel section, in which the value of *J* is so small that its influence is negligible.

Many beams do not conform to these pure types, but share the characteristics of each. Channel-shaped beams are a peculiar type and their analysis is extended.

#### PROPER USE OF CHANNEL MEMBERS AS BEAMS

In a channel consider a system of external forces transverse to its length, acting in the plane of the web and perpendicular to the axis of the channel. The resulting bending will produce longitudinal tensile and compressive stresses in the flanges, but these stresses will be greater at the heel than at the toe of the flange. It is easy to imagine this, since the stresses result from the shear in the web which acts directly on the heel and not on the center of the flange as in the case of *I*-beams.

In the analysis it is assumed that the fiber stress in any given cross-section of the channel varies uniformly from heel to heel of the two flanges and also

from heel to toe of each flange. This is more conservative than the usual assumption that the stress varies uniformly throughout the section and in proportion to the distance of the point considered from an axis of the section. The analysis shows the latter assumption to be erroneous as applied to the channel.

If the influence of  $J$  is neglected, then knowing the bending moment applied in a direction parallel to the web, it would be simple to compute the fiber stresses in the flange, and the stress at the toe would be of opposite sign to that at the heel. The influence of  $J$ , however, is to make the unit stress more nearly equal, throughout the section of the flange, especially as the beam increases in length. On the other hand, as the beam becomes very long, the slenderness effect becomes of greater importance and must be considered in the design.

It is possible to apply the external loads so as to make the distribution of flange stress uniform from heel to toe, and in this case the fiber stress at any point would be governed by the formula,  $f = \frac{M h}{2 I_h}$ .

This ideal position of the loading system is that of a plane which lies parallel to the web and a distance back from the center of the web equal to  $\frac{U b}{2 I_h}$ , as shown in Fig. 2.

Safe design will then provide that this relation be adhered to closely, or else that the stresses be analyzed and considered. Furthermore, the condition of neutral elastic equilibrium should not be allowed. This applies only to a beam which is not restrained laterally so as to prevent torsional and lateral deformation.

#### NEUTRAL ELASTIC EQUILIBRIUM OF THE $J$ -BEAM

As treated under this heading,  $J$ -beams are assumed to be of uniform, compact cross-section, symmetrical about each principal axis, and capable of acting in pure torsion. The beam is more slender as regards that principal axis of inertia which lies in the plane of the applied loading. It is assumed that the cross-sectional form of the beam is conserved under conditions of stress and that there is a property adhering to the central axis of the beam which represents its ability to resist torsional deformation and which is symbolized by the letter,  $J$ .

In Fig. 3, let the curved line represent the horizontal projection of the central axis of a cantilever beam which has been deflected laterally.

At its right end, it is fixed, its axis is horizontal, and the two axes of symmetry of its cross-section are horizontal and vertical, respectively. Its moment of inertia about the horizontal axis is the greater. The beam is weightless and carries a load,  $P$ , acting vertically downward, and applied at a point, a distance,  $a$ , above the central axis of the beam at its left end. The beam suffers both bending and torsional strains, and is in a state of neutral elastic equilibrium.

At any section,  $x, y$ , its normally vertical axis is inclined an angle,  $\alpha$ , with the vertical. It is required to find an expression for  $P$ , the load necessary to produce neutral elastic equilibrium. The origin of co-ordinates is taken at the horizontal projection of the point of loading. On the left of Fig. 3 are shown an end view and two cross-sections. As plotted in the diagram,  $\alpha$  and  $\frac{dy^2}{dx^2}$  are negative and  $\frac{d\alpha}{dx}, \frac{dy}{dx}$ , and  $y$  are positive.

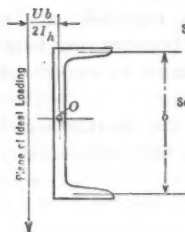

FIG. 2.

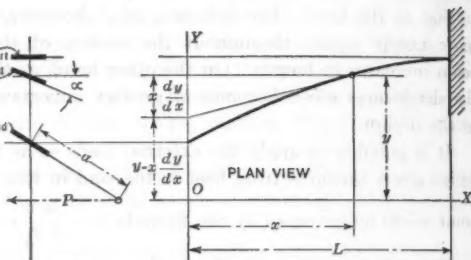

FIG. 3.

Let  $J$  be a function of the section representing its ability to resist torsional deformation, and of such a value that, disregarding the resistance of the flanges,

$$d\alpha = \frac{Q dx}{E_s J} \dots \dots \dots (4)$$

The bending moment at any point is  $M = Px$ . The torque,  $Q$ , at any point is equal to the load,  $P$ , times the distance from its line of action to a tangent to the central axis of the beam at the point considered; that is (see Fig. 3):

$$Q = P \left( y - x \frac{dy}{dx} \right) \dots \dots \dots (5)$$

The component of the bending moment in a direction perpendicular to its originally vertical axis is  $Px \sin \alpha$  and, in a direction at right angles to this direction, is  $Px \cos \alpha$ .

The components of the curvature in each direction are  $\frac{Px \sin \alpha}{E I_1}$  and  $\frac{Px \cos \alpha}{E I}$ , respectively.

The curvature of the horizontal projection of the axis is obtained by multiplying these expressions by the cosine and sine, respectively, of the angle of inclination, and taking the difference of the results, or

$$\frac{d^2 y}{dx^2} = \frac{Px \sin \alpha \cos \alpha}{E I_1} - \frac{Px \cos \alpha \sin \alpha}{E I}$$

or, since  $\alpha$  is small,

$$\frac{d^2 y}{dx^2} = \frac{P}{E} \left( \frac{1}{I_1} - \frac{1}{I} \right) x \alpha = \frac{P}{E I_3} x \alpha \dots \dots \dots (6)$$

From the law of torsional deflection,

$$\frac{d\alpha}{dx} = \frac{P}{E_s J} \left( y - x \frac{dy}{dx} \right) \dots \dots \dots (7)$$

Solving for  $\alpha$  in Equation (6),

$$\alpha = \frac{E I_3}{P} \frac{1}{x} \frac{d^2 y}{dx^2} \dots \dots \dots (8)$$

Differentiating Equation (8),

$$\frac{d\alpha}{dx} = \frac{E I_3}{P} \frac{1}{x} \frac{d^3 y}{dx^3} - \frac{E I_3}{P} \frac{1}{x^2} \frac{d^2 y}{dx^2} \dots \dots \dots (9)$$

Equating Equations (7) and (9), clearing of fractions and substituting

$$T^2 \text{ for its equivalent, } \frac{P^2}{E I_3 E_s J},$$

$$x \frac{d^3 y}{dx^3} - \frac{d^2 y}{dx^2} + T^2 x^3 \frac{dy}{dx} - T^2 x^2 y = 0 \dots \dots \dots (10)$$

The solution of Equation (10) is,

$$y = A \left( 1 + \frac{T^2 x^4}{12} - \frac{T^4 x^8}{4 \times 5 \times 7 \times 8} + \frac{T^6 x^{12}}{4 \times 5 \times 8 \times 9 \times 11 \times 12} - \dots \right) \\ + Bx + C \left( x^3 - \frac{T^2 x^7}{2 \times 6 \times 7} + \frac{T^4 x^{11}}{2 \times 7 \times 8 \times 10 \times 11} \right. \\ \left. - \frac{T^6 x^{15}}{2 \times 7 \times 8 \times 11 \times 12 \times 14 \times 15} + \dots \right) \dots \dots \dots (11)$$

Differentiating Equation (11) successively,

$$\frac{d^2 y}{dx^2} = A \left( T^2 x^2 - \frac{T^4 x^6}{20} + \frac{T^6 x^{10}}{1440} - \dots \right) \\ + C \left( 6x - \frac{T^2 x^5}{2} + \frac{T^4 x^9}{112} - \frac{T^6 x^{13}}{14784} + \dots \right) \dots \dots \dots (12)$$

From the condition,  $y = -a\alpha$ , when  $x = 0$ , and from Equations (11), (8), and (12),

$$A = -a\alpha = -\frac{6 E I_3 a C}{P} \dots \dots \dots (13)$$

From the condition,  $\alpha = 0$  when  $x = L$ , and from Equations (8) and (12),

$$0 = \frac{E I_3 A}{P L^3} \left( K^2 - \frac{K^4}{20} + \frac{K^6}{1440} - \dots \right) \\ + \frac{E I_3 C}{P} \left( 6 - \frac{K^2}{2} + \frac{K^4}{112} - \frac{K^6}{14784} + \dots \right) \dots \dots \dots (14)$$

Eliminating  $A$  and  $C$  between Equations (13) and (14),

$$0 = -\frac{6 E I_3 a}{P L^3} \left( K^2 - \frac{K^4}{20} + \frac{K^6}{1440} - \dots \right) \\ + \left( 6 - \frac{K^2}{2} + \frac{K^4}{112} - \frac{K^6}{14784} + \dots \right) \dots \dots \dots (15)$$

Since  $N = \frac{a}{L} \sqrt{\frac{E I_3}{E_s J}}$ ,  $P = T \sqrt{E I_3 E_s J}$ , and  $T L^2 = K$ , therefore,

$$\frac{E I_3 a}{P L^3} = \frac{E I_3 a}{T L^3 \sqrt{E I_3 E_s J}} = \frac{a}{T L^3 \sqrt{E_s J}} = \frac{a}{L K \sqrt{E_s J}} = \frac{N}{K}$$

Substituting these values in Equation (15),

$$0 = -6N \left( K - \frac{K^3}{20} + \frac{K^5}{1440} - \dots \right) + \left( 6 - \frac{K^2}{2} + \frac{K^4}{112} - \frac{K^6}{14784} + \dots \right) \dots \dots \dots (16)$$

$$N = \frac{6 - \frac{K^2}{2} + \frac{K^4}{112} - \frac{K^6}{14784} + \dots}{6 \left( K - \frac{K^3}{20} + \frac{K^5}{1440} - \dots \right)} \dots \dots \dots (17)$$

$$N = \frac{1}{K} - \frac{K}{30} - \frac{11K^3}{12600} - \dots \dots \dots (18)$$

Equation (18) holds for both positive and negative values of  $N$ .  $K$  occurs only in the odd powers; therefore, changing the sign of  $K$  changes the sign of  $N$  without otherwise affecting its value.

When  $N = 0$ , the numerator of the right-hand member of Equation (17) becomes 0, and the lowest root of  $K^2$  is 16.11, or,

$$K = TL^2 = \frac{PL^2}{\sqrt{EI_3 E_s J}} = \pm 4.014$$

or,

$$PL^2 = 4.014 \sqrt{EI_3 E_s J}$$

When  $N = -\infty$ , the denominator of the right-hand member of Equation (17) is 0; then,

$$K = +5.6$$

or,

$$PL^2 = 5.6 \sqrt{EI_3 E_s J}$$

For large negative values of  $N$ ,  $K$  approaches 5.6 and for large positive values of  $N$ ,  $K$  approaches  $\frac{1}{N}$ , or  $\frac{PL^2}{\sqrt{EI_3 E_s J}}$  approaches  $\frac{L}{a} \sqrt{\frac{E_s J}{EI_3}}$ , or  $P$  approaches  $\frac{E_s J}{aL}$ . Compare this with the value of  $P$  in Equation (3). The simple beam may be treated in a similar manner.

#### NEUTRAL ELASTIC EQUILIBRIUM OF THE FLANGED BEAM

In this case an I-beam having no torsional resistance is assumed. The resistance of the flanges to lateral flexure is assumed to be located at their centers.

Let the cantilever I-beam shown in Fig. 4 be assumed as fixed at the right end, both flanges being restrained at this end against lateral rotation. The beam is shown in a deflected position. Its originally vertical web is tilted at the end as shown. It supports a load,  $P$ , at the end, applied a distance,  $a$ , above the center of the beam, and a distance,  $n$ , horizontally from the center line of the web.

At any point  $(x, y)$ , the beam is under the following conditions of stress: A moment,  $M_s$ , in the upper flange and  $-M_s$  in the lower; a moment,  $M_2$ , in the beam and perpendicular to the web; and a moment,  $M$ , in the beam and parallel to the web.

From Fig. 4,  $y = \frac{y_1 + y_2}{2}$ ,  $\alpha = \frac{y_1 - y_2}{b}$ ;  $\frac{d\alpha}{dx} = \frac{1}{b} \left( \frac{dy_1}{dx} - \frac{dy_2}{dx} \right)$ ;  $M_1 = Px$ ; and  $M_2 = Px \alpha = M\alpha$ . Then,

$$\frac{dM_s}{dx} = \frac{P}{b} \left( x \frac{dy_1}{dx} - y_2 \right) \dots \dots \dots (19)$$

$$\frac{dM_b}{dx} = \frac{P}{b} \left( -x \frac{dy_2}{dx} + y_1 \right) \dots \dots \dots (20)$$

$$\begin{aligned} \frac{dM_s}{dx} - \frac{dM_b}{dx} &= \frac{P}{2b} \left[ x \left( \frac{dy_1}{dx} + \frac{dy_2}{dx} \right) - (y_2 + y_1) \right] \\ &= \frac{P}{b} \left( x \frac{dy}{dx} - y \right) \dots \dots \dots (21) \end{aligned}$$

$$\frac{d^2\alpha}{dx^2} = \frac{k_1 - k_2}{b} = -\frac{2M_s}{EbI_z}, \text{ or, } M_s = \frac{EbI_z}{2} \frac{d^2\alpha}{dx^2} \dots \dots \dots (22)$$

$$\frac{dM_s}{dx} = \frac{EbI_z}{2} \frac{d^3\alpha}{dx^3} \dots \dots \dots (23)$$

$$\frac{d^2M_s}{dx^2} = \frac{EbI_z}{2} \frac{d^4\alpha}{dx^4} = \frac{P}{b} \frac{d^2y}{dx^2} \dots \dots \dots (24)$$

$$\frac{d^2y}{dx^2} = \frac{Px\alpha}{2EI_z} - \frac{Px\alpha}{2EI_h} = \frac{Px\alpha}{2E} \left[ \frac{1}{I_z} - \frac{1}{I_h} \right] \dots \dots \dots (25)$$

$$\frac{EbI_z}{2} \frac{d^4\alpha}{dx^4} = \frac{P^2x^2\alpha}{2Eb} \left[ \frac{1}{I_z} - \frac{1}{I_h} \right] \dots \dots \dots (26)$$

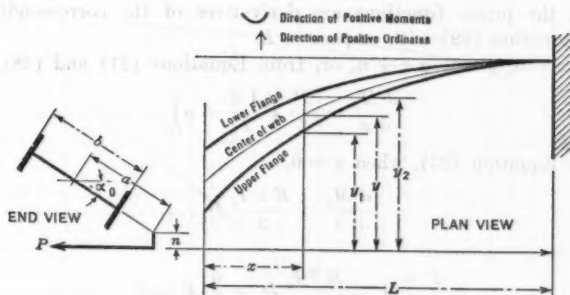

FIG. 4.

or,

$$\frac{d^4\alpha}{dx^4} - R^2x^2\alpha = 0 \dots \dots \dots (27)$$

in which,

$$R^2 = \frac{P^2}{E^2 b^2 I_z} \left[ \frac{1}{I_z} - \frac{1}{I_h} \right]$$

The solution of Equation (27) is,

$$\begin{aligned} \alpha = & A \left[ \frac{1}{2} + \frac{(R x^3)^2}{6} + \frac{56 (R x^3)^4}{12} + \frac{10\,192 (R x^3)^6}{18} + \dots \right] \\ & + B x \left[ \frac{1}{6} + \frac{(R x^3)^2}{7} + \frac{72 (R x^3)^4}{13} + \frac{15\,120 (R x^3)^6}{19} + \dots \right] \\ & + C x^2 \left[ \frac{1}{2} + \frac{12 (R x^3)^2}{8} + \frac{1\,080 (R x^3)^4}{14} + \frac{259\,200 (R x^3)^6}{20} + \dots \right] \\ & + D x^3 \left[ \frac{1}{6} + \frac{20 (R x^3)^2}{9} + \frac{2\,200 (R x^3)^4}{15} + \frac{598\,400 (R x^3)^6}{21} + \dots \right] \dots (28) \end{aligned}$$

When  $x = 0$ ,  $\frac{d^2 \alpha}{dx^2} = 0$  and, therefore,  $C = 0$ ; when  $x = L$ ,  $\alpha = 0$ ; so that,

$0 = A \varepsilon + B \lambda + D \delta$ , in which,

$$\varepsilon = \left[ \frac{1}{2} + \frac{(R L^3)^2}{6} + \frac{56 (R L^3)^4}{12} + \dots \right]$$

$$\lambda = L \left[ \frac{1}{6} + \frac{(R L^3)^2}{7} + \frac{72 (R L^3)^4}{13} + \dots \right]$$

and

$$\delta = L^3 \left[ \frac{1}{6} + \frac{20 (R L^3)^2}{9} + \frac{2\,200 (R L^3)^4}{15} + \dots \right] \dots (29)$$

Furthermore, when  $x = L$ ,  $\frac{d \alpha}{dx} = 0$ , and,

$$0 = A \varepsilon' + B \lambda' + D \delta' \dots (30)$$

in which, the prime functions are derivatives of the corresponding functions in Equation (29) with respect to  $L$ .

When  $x = 0$ ,  $y = -a \alpha + n$ , or, from Equations (21) and (28),

$$\frac{d M_3}{dx} = \frac{P}{b} \left( \frac{A a}{2} - n \right) \dots (31)$$

also, from Equation (23), when  $x = 0$ ,

$$\frac{d M_3}{dx} = \frac{E b I_z}{2} D \dots (32)$$

whence,

$$\frac{P a}{2 b} A - \frac{E b I_z}{2} D - \frac{n}{b} P = 0 \dots (33)$$

Eliminating  $B$  and  $D$  from Equations (29), (30), and (33):

$$A \left[ 1 + \frac{E b^2 I_z (\varepsilon \lambda' - \lambda \varepsilon')}{P a (\delta \lambda' - \lambda \delta')} \right] - \frac{2 n}{a} = 0 \dots (34)$$

If  $n = 0$  and  $A$  is not zero, the beam is in neutral elastic equilibrium.

The development of Equations (1) to (34) indicates in a general way, the treatment of the "J-beam" and the "F-beam". Analyses have been made of the cases of the simple beam with a concentrated load at the center of the span and a theorem has been developed covering the case of the flanged beam complicated by the existence of the  $J$ -property. The treatment has also been broadened to include the unsymmetrical or channel-shaped section.

The results of analyses are shown in Figs. 5, 6, and 7. Fig. 5 illustrates the mode of failure by neutral elastic equilibrium of a flanged beam (or ideal "F-beam"; either a channel or symmetrical section). By means of Fig. 5(b), the load of neutral elastic equilibrium may be determined. Failure by neutral elastic equilibrium can occur only if the load is applied within the plane

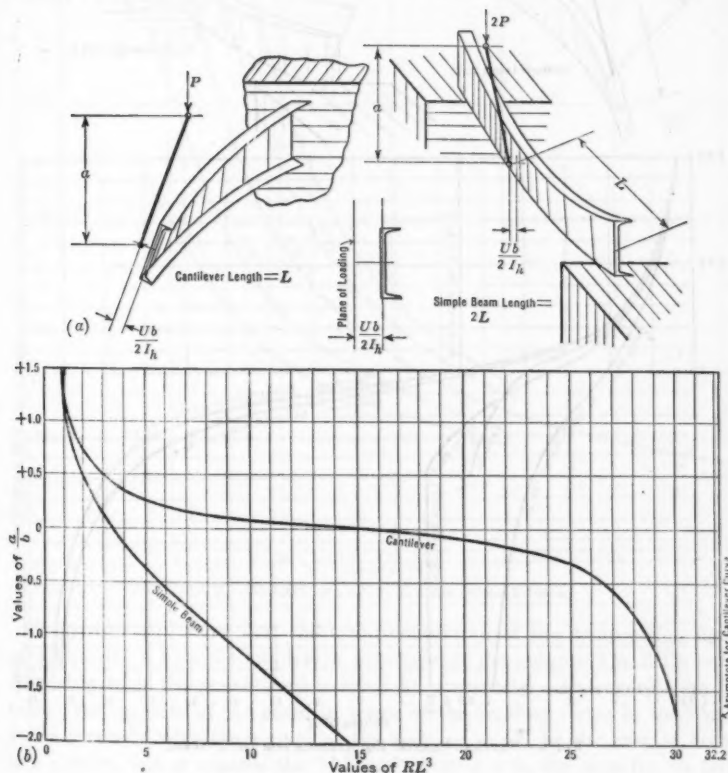

FIG. 5.—NEUTRAL ELASTIC EQUILIBRIUM FOR THE F-BEAM

of the center of the web if a symmetrical section, or within a plane at a distance,  $\frac{U b}{2 I_h}$ , back of the center of the web in the case of the channel-shaped section.

The factor,  $R$ , is expressed by the relation:

$$R^2 = \frac{2 I_h P^2}{E^2 b^2 (I_h I_z - U^2)} \left[ \frac{1}{I'} - \frac{I_z}{2 (I_h I_z - U^2)} + \frac{U^2}{2 I_h (I_h I_z - U^2)} \right] \dots (35)$$

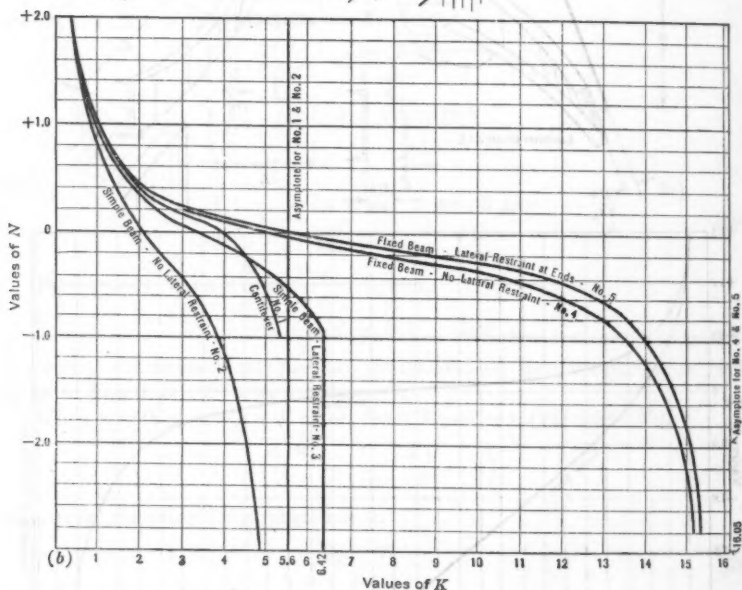

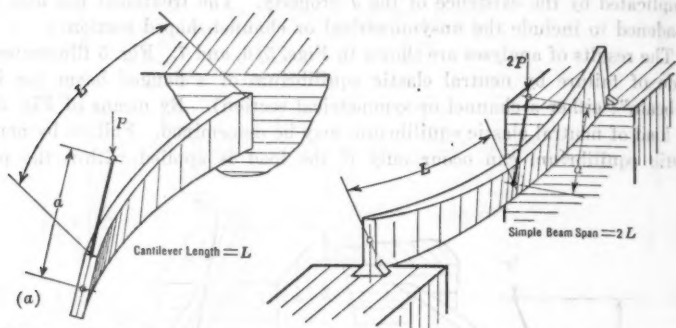

FIG. 6.—NEUTRAL ELASTIC EQUILIBRIUM FOR THE J-BEAM.

Similarly, Fig. 6 illustrates the mode of failure of the "J-beam" and Fig. 6(b) is a chart for determining the load of neutral elastic equilibrium.

Fig. 7 indicates the capacity of the standard 12-in., 31.5-lb. steel I-beam as a simple beam supported at each end and carrying a concentrated load at the middle of the span. The beam is treated as a flanged beam having

torsional rigidity. Its capacity is expressed in terms of maximum fiber stress in the flange at the middle of the span when in the state of neutral elastic equilibrium.

These diagrams must not be applied to the commercial rolled sections which have a large torsional resistance property.

Table 1 gives computed properties of some standard beams and channels. The derivation of the values of the function,  $J$ , is based on results of tests of small steel beams which were made by the writer at the time of his early research in this line.

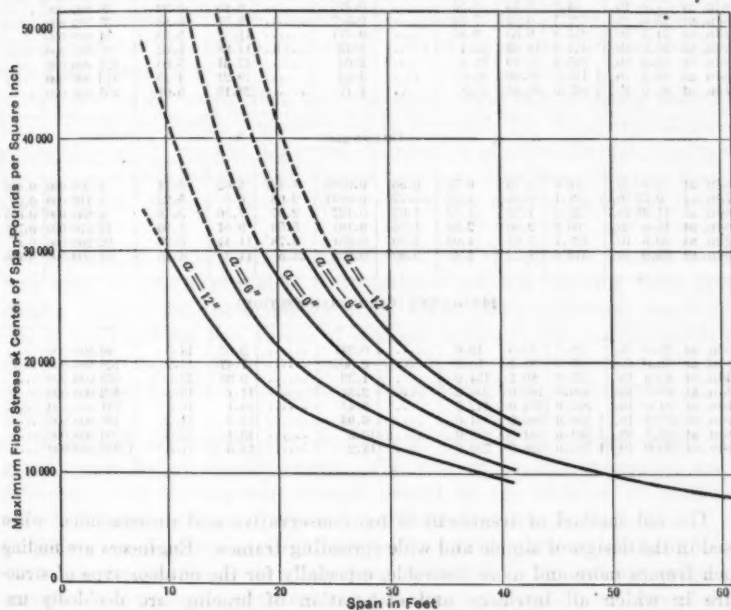

FIG. 7.—CAPACITY OF A 12-IN., 31.5-LB. STEEL I-BEAM.

Comparison will show that the usual conception of the compression flange of a beam as a member similar in principle to the column has little correspondence with the conclusions arrived at previously. As regards the "F-beam", the capacity of the beam in terms of the bending stress in the flanges varies inversely with the square of the span as would be the case if viewed as a column, but as regards the "J-beam" when  $\alpha = 0$ , the capacity, in terms of the bending stress, varies inversely with the first power of the span.

The importance of the torsional resistance function is emphasized and its effect is very important in the use of the standard rolled sections. The tremendous advantage of the box-section, such as is often used in crane girders, becomes apparent and usually removes such girders from all need of serious consideration of failure by neutral elastic equilibrium.

The old method of treatment is too conservative and uneconomical when used in the design of simple and wide spreading frames. Engineers are finding such frames more and more desirable, especially for the outdoor type of structure in which all intricacy and elaboration of bracing are decidedly undesirable from the standpoint of maintenance, and it is hoped that the sketchy treatment offered will lead the way to further study of the subject along these lines.

## DISCUSSION

JACOB FELD,\* ASSOC. M. AM. SOC. C. E. (by letter).—The author opens up a subject which can fill many volumes, and which is the very basis of structural design, and then discusses in detail one phase of the subject, namely, the true action of two types of structural members acting as beams.

The great majority of present-day designs are based on formulas which are known to be purely approximate. The unknown as well as the omitted factors in determining maximum stress, are provided for by the use of a unit stress which is admittedly much lower than that at which members may fail. This method, of course, cannot be classed as the scientific procedure and has as its virtue only one fact, that a very small percentage of structures so designed have been known to fail.

It seems to the writer that three questions must be completely answered before a scientific design procedure can be expected: (1) What type of stress causes failure; (2) what is the actual distribution of stress through a section; and (3) what re-distribution of stresses occurs in a section when one fiber is stressed beyond its elastic limit? The writer makes no attempt to discuss these points.

Of course, it is fairly simple to determine all the possible loading conditions and, if time is available, to investigate stresses resulting from every possible loading; but the maximum stress which exists under any one condition of loads and the true excess of strength before failure occurs cannot be determined so easily. If failure has occurred, as in a test specimen, the type of stress causing failure often can be determined from an inspection of the fracture.

In general, the actual stresses, both theoretical and experimental, are greater than the apparent stresses. The true or equivalent stresses are a refinement over the apparent stresses caused by the addition of combined normal and shear stresses as opposed to normal stresses only.

Experimental determination of stresses in various members acting in bending has shown greater stresses than those calculated by the ordinary empirical methods. However, the measured values agree closely with those computed by the ordinary elastic theory if due allowance is made for lateral strain (Poisson's ratio).†

In dealing with beams under bending and torsion the author has introduced a subject in which the ordinary analysis gives results that do not agree with experimental data. It is only necessary to point out the great variation between analytical and experimental results for the effective polar moment of inertias as tabulated in a report of tests on the torsional strength of steel I-sections.‡

The effect of torsion on beams in ordinary building construction, although never considered in the average design, is marked by unsightly results in many

\* Cons. Engr., New York, N. Y.

† "The Strength of T-Beams and Girders," by Herbert F. Moore and W. M. Wilson, Bulletin No. 86, Eng. Experiment Station, Univ. of Illinois, 1916.

‡ Bulletin 4, Univ. of Toronto, 1924.

structures. This is especially apparent in spandrel beams in concrete structures which very often show cracks on the exterior face at approximately the quarter points of the span. Similar torsional strains are visible on steel buildings, in which case the brick or stone facing shows open joints.

However, in the type of frames for which the author develops his theory, the effect of torsion due to eccentricity of loading can be included in the analysis. It must be remembered, however, that experimental results also show a variation of shear stress across the depth of the web, the shearing stress being much greater in that part of the web nearest the loaded flange than near the unloaded flange. Therefore, if a beam first has an unequal unit shear stress in the web area, even with axial load, the condition of neutral elastic equilibrium used by the author as a criterion for the strength of a beam, must take into account the combination of shear and tension or compression at the junction of the web and flange areas near the loaded flange.\*

With reference to the author's discussion of the proper use of channel members as beams, it is proper that several contributions to the subject be enumerated. In a thesis presented at the University of Zurich, in 1920, H. Schwyzer proved mathematically that, in order to produce bending without twisting, a channel section must be loaded by forces parallel to the web and

a distance,  $\frac{3b}{6 + \frac{F_1}{F_2}}$ , from the back of the channel. The factor,  $b$ , is the width

of the flange,  $F_1$  is the area of the web, and  $F_2$  is the area of one flange.

A detailed method for the calculation of torsional stresses has been developed by Dr. A. Eggenschwyler.† Other contributions to the subject are those of Maillart‡ and Zimmerman.§ These men have checked their analyses against the experimental work of Bach who found among other things that the longitudinal stress at the connection of the web and flange of channel under load is 36% greater on the compression side, and 53% greater on the tension side, than the values given by the bending formula.

If the author suggests that structures be designed for the maximum allowable stress without a factor of safety, he must give methods of analysis which will determine the maximum existing stress under any given loads. He is to be commended for his addition to the ultimate goal of all design analysis.

F. B. SEELY,|| W. J. PUTNAM,|| and W. L. SCHWALBE,|| Esqs. (by letter).—The author points out that when a channel is used as a beam without lateral restraint the stresses set up in it will not be in accordance with the simple flexure formula,  $f = \frac{Mh}{2I_h}$ , unless the "position of the loading system

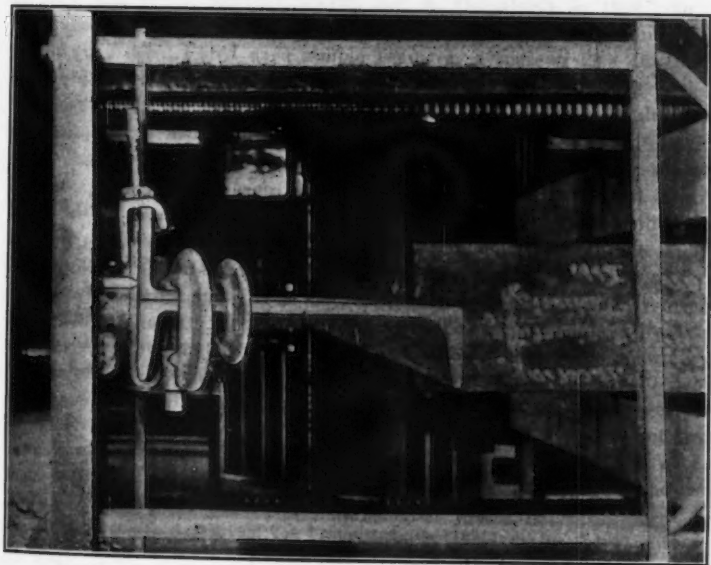

FIG. 8.—VIEW OF CHANNEL WITH LOAD APPLIED THROUGH SHEAR-CENTER AT END OF CANTILEVER.

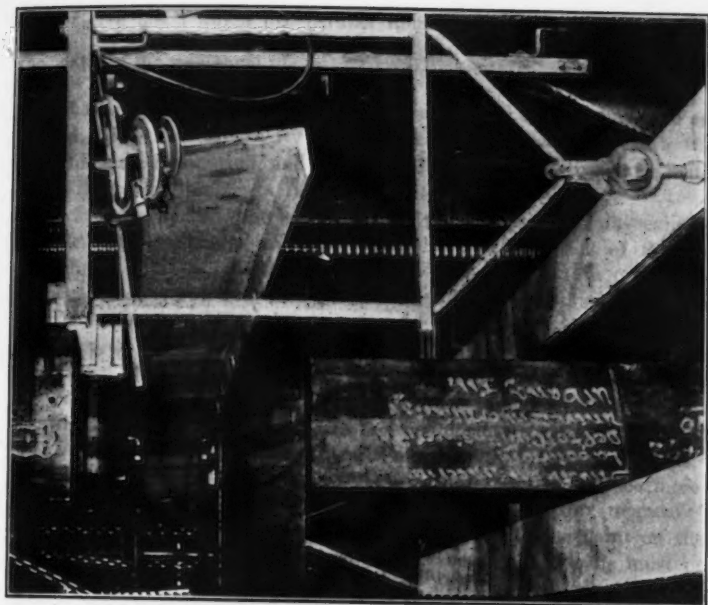

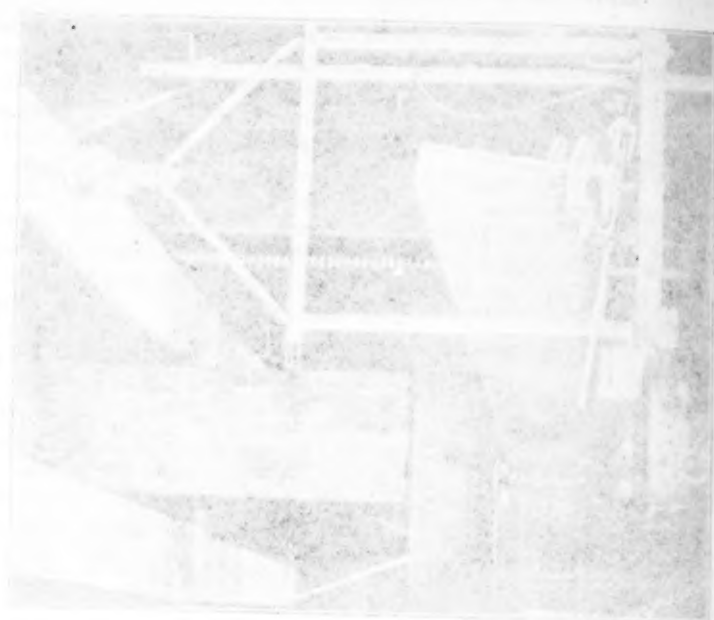

FIG. 9.—VIEW OF CHANNEL WITH LOAD APPLIED AT POINT ON FLANGE DIRECTLY ABOVE CENTER OF GRAVITY OF END SECTION WHEN SECTION IS NOT TWISTED.

is that of a plane which lies parallel to the web and a distance back from the center of the web equal to  $\frac{U b}{2 I_h}$ ."

It has been very widely assumed, however, that the loads should be applied through the center of gravity of the sections in order to cause a channel to bend without twisting and to produce stresses in accordance with the simple flexure formula.

It may be worth while, therefore, to present experimental evidence of the fact that a channel must be loaded back of the back of the channel (not through the center of gravity of the cross-sections) in order to cause bending, without twisting, as is assumed in the simple theory of beams.

The writers have made bending tests\* of a number of rolled steel channels, varying in depth from 4 to 15 in., in which the positions of the loads that caused bending in accordance with the flexure formula were determined. The main purpose of the tests, however, was to determine the additional longitudinal stress in a channel beam when loaded so that twisting accompanies bending. This additional longitudinal stress, for some channels, when the load acts through the center of gravity of the section may be more than one-half the maximum stress caused by the vertical bending moment.

The name, "shear-center", has been used to denote the point on the axis of symmetry of the channel through which the plane of loads must pass to produce simple bending (without twisting), and its location and significance seem to have been brought first to the attention of engineers by R. Maillart† in 1921, and by A. Eggenschwyler‡ and A. Ostenfeld§ in 1924. In 1925, K. Hubert|| obtained experimental results on a rolled steel channel 10.3 in. (26.14 cm.) deep, tested as a simple beam on a span of 20.8 ft. (5.8 m.), and subjected to a concentrated load of 5 500 lb. (2 500 kg.) at mid-span; the position of the "shear-center," as found from the test results, was in substantial agreement with the calculated position.

In order to determine the "shear-centers" of the channels tested at the University of Illinois, each channel was tested as a horizontal cantilever beam with a vertical load consisting of a suspended weight applied at the free end. Some of the smaller channels were embedded at one end in a large cube of concrete, and this cube was held on the weighing table of a testing machine by applying a load to the top face of the cube by means of the movable head of the testing machine. The large channels were tested as double cantilevers. In Fig. 8, a 15-in., 33.9-lb. channel is shown with a load of 5 600 lb. applied through the "shear-center" at the end of a 10-ft. cantilever. In Fig. 9, the same load is applied at a point on the flange directly above the center of gravity of the end section when the section is not twisted. The beam was balanced on a knife-edge on the weighing table of a testing machine and equal weights were applied to the two free ends. The central

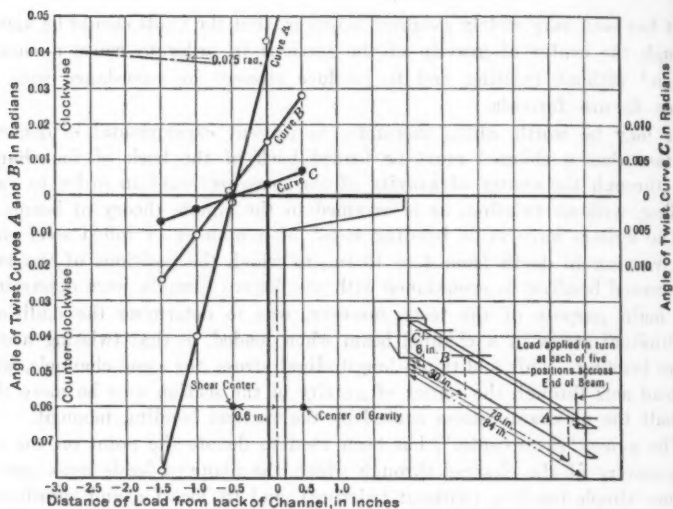

FIG. 10.—LOCATION OF SHEAR-CENTER FOR 6-INCH, 8.2-POUND CHANNEL.

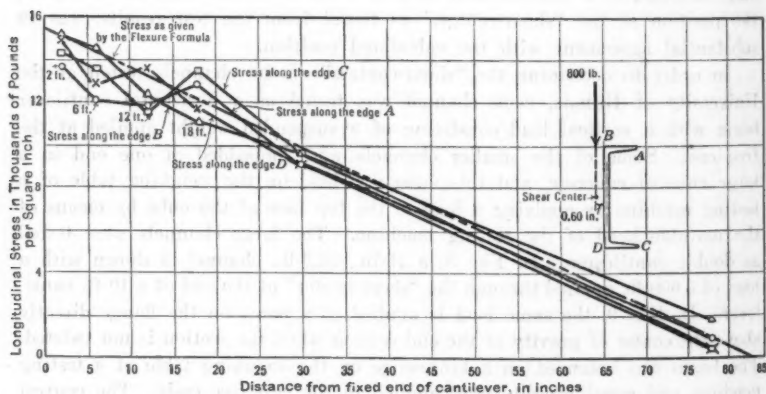

FIG. 11.—LONGITUDINAL STRESS IN 6-INCH, 8.2-POUND CHANNEL WITH LOAD OF 800 POUNDS APPLIED THROUGH THE SHEAR-CENTER AT END OF CANTILEVER HAVING A LENGTH OF 84 INCHES.

section of the channel was held fixed in position by a light load applied through the movable head of the testing machine to the top flange, and by small horizontal jacks on each side of the top and bottom flanges. In addition, the outstanding flanges at the central section were supported by a vertical stiffener extending between the flanges.

The angle of twist was measured at six or seven sections along the length of the beam for each of several lateral positions of the load at the end. The load was applied at two or three points on each side of the back. An angle was clamped to the back at the free end of the beam, so that the load could be applied back of the back of the channel. (See Fig. 8.)

The angle of twist was measured by means of a level bar used on a 20-in. gauge length. For this purpose bars slightly more than 20 in. long were clamped to the top flange of the channel at several sections along the length of the beam, and the change in inclination of these bars was measured on a 20-in. gauge length; the change in elevation of one end of the gauge length with respect to the other was measured to 0.001 in. by adjusting a micrometer screw at one end of the level bar. The bubble in the level bar was a 20-sec. bubble, which was amply sensitive.

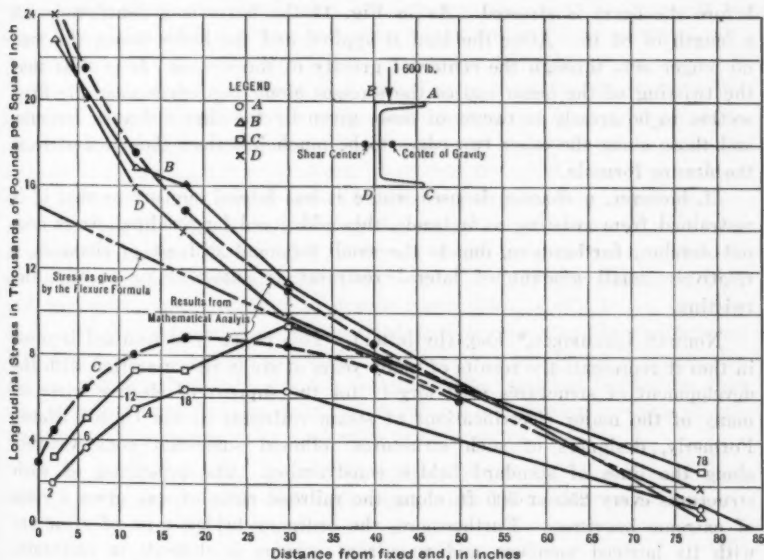

FIG. 12.—EXPERIMENTAL VALUES OF LONGITUDINAL STRESS IN A 6-INCH, 15-POUND SHIP CHANNEL.

The values of the angles of twist at three sections for five different lateral positions of the load on a 6-in., 8.2-lb. channel are given in Fig. 10. (One point on Curve A, at  $\pm 0.5$  in. = 0.0735 radians, has been omitted.) The diagram shows clearly that this channel beam twists, as it bends, when the load is applied at any lateral position, except that at the distance of

0.60 + in., approximately, from the center of the web. The calculated value for the distance of this "shear-center" from the center of the web, according to the expression,  $\frac{U b}{2 I_h}$ , is 0.618 in. A satisfactory agreement between experimental and calculated results was obtained for the other channels tested.

In order to determine the longitudinal stresses in the channel beam, the strains along each of the four edges were measured with a 2-in. strain-gauge at several sections. A value of 30 000 000 lb. per sq. in. was used for the modulus of elasticity in converting strains to stresses. Readings of the gauge could be repeated within a maximum error of  $\pm 1\,000$  lb. per sq. in.

Fig. 11 shows the experimental values of the longitudinal stresses in the 6-in., 8.2-lb. channel beam when the load of 800 lb. is applied through the "shear-center" as determined from Fig. 10. It is evident that the stresses are in substantial agreement with those given by the simple flexure formula.

Fig. 12 shows the experimental values of the longitudinal stresses in a 6-in., 15-lb. ship channel when the vertical load of 1 600 lb. is applied at the point on the flange that is directly above the center of gravity of the section before the beam is stressed. As in Fig. 11 the beam is a cantilever with a length of 84 in. After the load is applied and the beam twists, the load no longer acts through the center of gravity of the section. It is clear that the twisting of the beam causes the stresses along two edges near the fixed section to be greatly in excess of those given by the simple flexure formula, and those along the other two edges to be much less than those found from the flexure formula.

If, however, a channel is used where it has lateral support so that it is restrained from twisting as it bends, this additional longitudinal stress does not develop; furthermore, due to the small torsional stiffness of channels, a relatively small amount of lateral restraint is sufficient to prevent the twisting.

NORMAN LITCHFIELD,\* Esq. (by letter).—This paper is of unusual interest in that it represents the results of many years of study in connection with the development of structures used largely for the support of electric wires on many of the major electrifications of steam railroads in the United States. Formerly, designers of such structures followed somewhat conservatively along the lines of standard bridge construction. The repetition of such structures every 250 or 300 ft. along the railroad right of way gives a vista of extreme heaviness. Furthermore, the ordinary bridge type of structure with its latticed members and re-entrant corners is difficult to maintain, especially on roads that operate a combination of electric and steam service, a condition which has obtained on a great many lines. These pockets collect cinders and corrosion is very rapid.

The structures that Mr. Richmond has aided in developing are light in appearance, but a careful study of the designs, the mathematics of which are developed in the paper, will indicate that they are thoroughly sound. More-

\* With Gibbs & Hill, Cons. Engrs., New York, N. Y.

over, many years' experience has shown that they are entirely satisfactory from all standpoints, including safety, durability, and economical maintenance.

The subject which the author presents so well is one of increasing interest to railroad companies as congestion on many lines is gradually forcing more extended consideration of electrification. There has been an attempt to write into some specifications for structures of this character certain provisions based on the accepted practice of bridge design. Should it be necessary to follow these in exact conformity, a considerable hardship would be put upon the railroads that are using electric traction, because they would be forced to erect uneconomical structures which are also difficult to maintain. The writer believes Mr. Richmond's paper will be received with considerable interest by all structural engineers who face the problem of the support of electric wires.

E. R. HILL,\* M. AM. SOC. C. E. (by letter).—Structures designed in accordance with the principles set forth in this paper have been used in connection with railroad electrification and power transmission for many years. They are relatively light, and, although flexible, possess ample strength under service and emergency conditions. It is noteworthy that of thousands of structures designed in this way and erected over the main-line tracks of railroads, there has been no case of failure or evidence of undue strain.

For the extensive electrification of main-line railroads the design of structures for supporting the trolley wires and transmission and signal circuits assumes a very important place. Such structures should involve minimum first cost and maintenance expense consistent with the satisfactory performance of the service required, and because of their extensive use they should be neat and attractive in appearance, avoiding the suggestion of a mass of steel over or along the tracks. A clear view of signals should be maintained. There is also a great duplication of structures of the same design, or similarity of type, and engineers can well afford to devote much detail study to an accurate analysis of the loads which must be carried, both normally and in emergencies. Where such determinations are made Mr. Richmond has found it practicable and entirely permissible to abandon certain of the empirical limitations that are generally imposed in the design of structures and develop methods of calculation and design especially applicable to these structures.

O. G. JULIAN,† M. AM. SOC. C. E., and GEORGE R. RICH,‡ ASSOC. M. AM. SOC. C. E. (by letter).—The well known and widely used reduction formula,

$$\frac{M}{S} < \frac{f}{1 + \left(\frac{L}{b}\right)^2 \frac{1}{k}} \dots\dots\dots (36)$$

merely considers the unsupported length of the compression flange as a column. The same buckling resistance is assigned to all beams having a given width of flange, irrespective of the "shape factor" (that is, the relation that the stiffness

\* Cons. Engr. (Gibbs & Hill), New York, N. Y.

† Catenary Engr., Jackson & Moreland, Hoboken, N. J.

‡ Engr., Hydr. Div., Stone & Webster Eng. Corporation, Boston, Mass.

of the member about the axis parallel to bending bears to its stiffness about the axis normal to bending), or the factor of torsional rigidity of the section. The author's rational analysis clearly indicates that the flexural rigidity about both axes and also the torsional rigidity are vital factors in resisting this type of failure.

The critical buckling load for beams of narrow rectangular cross-section and also for I-beams in which the flexural rigidity about the axis normal to the plane of loading is great in comparison with that about the axis parallel to the plane of loading, has been determined analytically for a wide range of loads and terminal conditions by Professor S. Timoshenko\* by considering the changes in potential energy of the elastic system. The writers have attempted to extend Professor Timoshenko's analysis so as to include H-beams, built-up girders, and trusses, loaded either parallel or normal to the major axis, and to develop practical working formulas for such members which would not penalize them unduly as appears to be done by the formulas in common use. The values so obtained for critical loads check the author's values fairly closely.

According to Professor Timoshenko's theory† as understood by the writers, it is required to evaluate the following changes in potential energy, or work done, at the instant buckling and twisting occurs:

- $V_1$ , due to bending about the axis normal to the plane of loading;
- $V_2$ , due to the bending of each flange or chord about the axis parallel to the plane of loading;
- $V_3$ , due to twisting of the section; and,
- $V_4$ , due to the movement of the loads in their plane of application.

In so far as buckling and twisting are concerned, as long as  $V_1 + V_2 + V_3 > V_4$ , the member is in "stable elastic equilibrium" and as load is added it will finally fail when the  $\frac{M}{S}$  stress exceeds the yield point of the material.

When  $V_1 + V_2 + V_3 = V_4$ , "neutral elastic equilibrium" exists, and as further increments of load are added, the potential energy of the elastic system is decreased and the member may fail by buckling or twisting.

In that which follows, a cantilever beam subjected to a concentrated load in the plane of one principal axis has been selected for study. However, the method appears to be general and applicable in the analysis of members subjected to various loads and types of end restraint.

Using the author's nomenclature, except as noted, and if  $W$  = work done,  $f$  = fiber stress in general, and  $\lambda$  = change in length,

$$W = \frac{1}{2} \int f d A \lambda \dots\dots\dots (37)$$

which, provided the elastic limit of the material has not been exceeded, becomes (prior to buckling):

$$W = \frac{1}{2} \int_0^L \frac{M^2 dx}{E I} \dots\dots\dots (38)$$

\* "Beams Without Lateral Support," *Transactions, Am. Soc. C. E.*, Vol. LXXXVII (1924), p. 1247.

† *Loc. cit.*, p. 1257.

or, for beams of constant cross-section and homogeneous material,

$$W = \frac{P^2}{2EI} \int_0^L x^2 dx \dots \dots \dots (39)$$

As buckling and twisting occur the load,  $P$ , may be resolved into components normal and parallel to the original axis of loading, as indicated in Fig. 13 (c). Then,

$$W = \frac{P^2}{2EI} \int_0^L (1 - \alpha^2) x^2 dx \dots \dots \dots (40)$$

and by subtracting Equation (39) from Equation (40),

$$V_1 = - \frac{P^2}{2EI} \int_0^L x^2 \alpha^2 dx \dots \dots \dots (41)$$

Similarly,

$$V_2 = \frac{P^2}{2EI'} \int_0^L x^2 \alpha^2 dx \dots \dots \dots (42)$$

or,

$$V_2 = \frac{EI'}{2} \int_0^L \left( \frac{d^2 y}{dx^2} \right)^2 dx \dots \dots \dots (43)$$

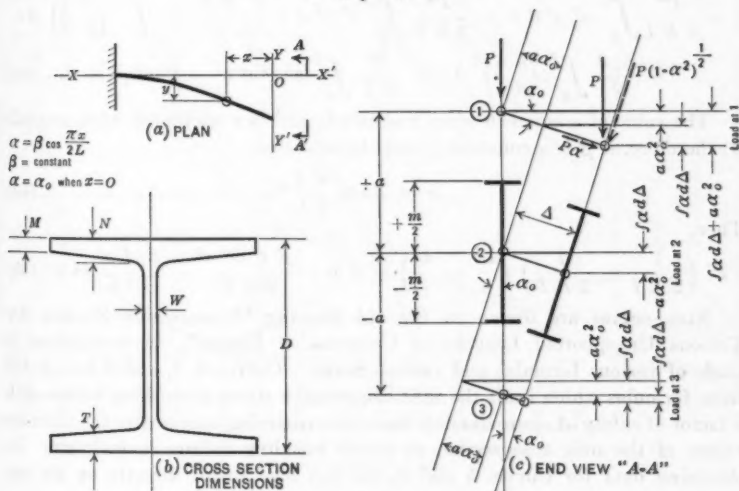

FIG. 13.—THE EFFECT OF BENDING AND TWISTING.

Considering the work done on the flanges separately, it is possible to replace

$y$  by  $y + \frac{m\alpha}{2}$  for the upper flange and by  $y - \frac{m\alpha}{2}$  for the lower flange. Then,

$$V_2 = \frac{P^2}{2EI'} \int_0^L x^2 \alpha^2 dx + \frac{EI'}{8m^2} \int_0^L \left( \frac{d^2 \alpha}{dx^2} \right)^2 dx \dots \dots \dots (44)$$

The work done in twisting a member may be expressed by,

$$V_3 = \frac{1}{2} \int Q d\alpha \dots \dots \dots (45)$$

but, in general, and as given by the author,

$$\alpha = \frac{Qx}{E_s J} \dots \dots \dots (46)$$

Then,

$$V_3 = \frac{E_s J}{2} \int_0^L \left( \frac{d\alpha}{dx} \right)^2 dx \dots \dots \dots (47)$$

Referring to Fig. 13 (c), it may be seen that,

$$V_4 = P a \alpha_0^2 + P \int \alpha d\Delta \dots \dots \dots (48)$$

but,

$$d\Delta = \frac{P}{E I'} \alpha x^2 dx \dots \dots \dots (49)$$

Then,

$$V_4 = P a \alpha_0^2 + \frac{P^2}{E I'} \int_0^L x^2 \alpha^2 dx \dots \dots \dots (50)$$

For the system to be in "neutral elastic equilibrium",

$$\begin{aligned} -\frac{P^2}{2 E I} \int_0^L x^2 \alpha^2 dx + \frac{P^2}{2 E I'} \int_0^L x^2 \alpha^2 dx + \frac{E I'}{8} m^2 \int_0^L \left( \frac{d^2 \alpha}{dx^2} \right)^2 dx \\ + \frac{E_s J}{2} \int_0^L \left( \frac{d\alpha}{dx} \right)^2 dx - \frac{P^2}{E I'} \int_0^L x^2 \alpha^2 dx - P a \alpha_0^2 = 0 \dots (51) \end{aligned}$$

The value of  $\alpha$  equals 0 when  $x$  equals  $L$ , and is a maximum when  $x$  equals 0; therefore, if  $\beta$  is a constant, it may be said that,

$$\alpha = \beta \cos \frac{\pi x}{2L} \dots \dots \dots (52)$$

Then,

$$P^2 \left( \frac{1}{2 E I} + \frac{1}{2 E I'} \right) \left( \frac{L^3}{6} - \frac{L^3}{\pi^2} \right) + P a - \frac{E I' m^2 \pi^4}{256 L^3} - \frac{E_s J \pi^2}{16 L} = 0 \dots (53)$$

Nine curves are drawn in Fig. 14 showing "Compression Stresses for Various Unsupported Lengths of Compression Flange". A comparison is made of various formulas and various beams. Curves 6, 7, and 8 are plotted from formulas which limit the unit compressive stress to working values with a factor of safety of approximately two; the remaining curves give the ultimate values of the unit compression at which buckling failure is incipient. In obtaining data for Curves 5 and 9, the test load rested directly on the top flange of the beam corresponding to a value of  $a = + \frac{m}{2}$ . In Curves 1, 2, 3, 4, 6, and 7, the value of  $a$  was assumed equal to 0; that is, the load was applied at the center of the web. Equation (53) was used to calculate Curves 2 and 4, the values of  $J$  being obtained from the formula proposed by Mr. William B. Campbell:†

$$J = 0.4 D W^3 + 0.1 (N + M)^3 (T - W) \dots \dots \dots (54)$$

\* "Beams Without Lateral Support," *Transactions, Am. Soc. C. E.*, Vol. LXXXVII (1924), p 1248.

† *Engineering News-Record*, October 11, 1928, p. 542.

in which,  $D$ ,  $W$ ,  $N$ ,  $M$ , and  $T$  are as shown in Fig. 13 (b). The numerical values of  $J$  for the curves in Fig. 14 are as follows:

Curve No.	Value of $J$ .
1	2.31
2	2.53
3	0.295
4	0.322

There is substantial agreement between values of  $J$  obtained by Equation (54) and those given in Table 1. Both the author and Mr. Campbell predicted their values on tests of  $\Gamma$ -beams. It is doubtful whether the results should be extended to include  $H$ -beams in which the comparatively heavy flanges carry a greater proportion of the torsional stress. Experimental data on the torsional resistance of  $H$ -sections seem to be entirely lacking.

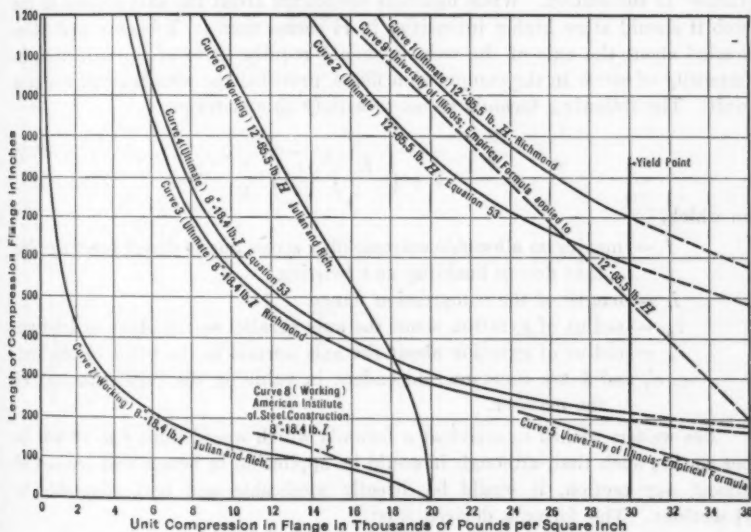

FIG. 14.—COMPRESSIVE STRESSES FOR VARIOUS UNSUPPORTED LENGTHS OF COMPRESSION FLANGE.

As successive increments of load are applied to a beam in bending about the axis normal to the web, the plane form of flexure remains stable up to a certain point; that is, if an accidental lateral force were to disturb the beam, on removal of the force the beam would return to the original plane. As the load is further increased, a sudden lateral deflection occurs, accompanied by torsion. In other words, on application of the last load increment the potential energy of the elastic system decreased, because the last load increment caused a relatively great increase of the work done by the additional dropping of the load as measured by Equation (50). The beam seeks relief by rotation of the section toward a more favorable position as regards lateral components of the loading.

As successive increments of load are applied to the same beam, but in bending about the axis of the web, the plane form of bending remains stable provided the component parts of the beam act as a unit. Failure will finally occur when the yield point of the material is exceeded, because the section is already in the position which affords maximum relief from buckling and twisting and could not possibly rotate toward a more stable position as regards lateral components of the loading.

When tubes and similar sections are subjected to bending no reduction formula for unit compression in the extreme fiber is necessary, because buckling will not occur unless torsional rotation can move the section to a more favorable position.

The author's analysis indicates that an efficient working formula for limiting stress intensity in the compression flange should evaluate the "shape factor" of the section. When members are loaded about the axis normal to the web it should allow higher intensities in **H**-beams than in **I**-beams, and when loaded about the axis of the web, it should require little or no reduction in intensity of stress in the compression fibers, provided the member will act as a unit. The following formula seems to satisfy this criterion:

$$\frac{M}{S} < \frac{f}{1 + \left(\frac{L}{c' r_p}\right)^2 \left(\frac{r_n}{r_p}\right)^2 \frac{c}{k}} \dots\dots\dots (55)$$

in which,

$f$  = maximum allowable extreme fiber stress due to direct bending plus that due to buckling and twisting.

$L$  = length of the compression flange.

$r_p$  = radius of gyration about the axis parallel to the plane of loading.

$r_n$  = radius of gyration about the axis normal to the plane of loading.

$c$ ,  $c'$ , and  $k$  are constants, dependent in value on the "shape factor" of the member.

The writers wished to arrive at a formula which would limit  $f$  to 20 000 lb. per sq. in., such that, although it would be applicable to beams and trusses of almost any section, it would be directly applicable and best adaptable to **H**-sections. The formula derived was:

$$\frac{M}{S} < \frac{20\,000}{1 + \frac{\left(\frac{L}{4 r_p}\right)^2 \left(\frac{r_n}{r_p}\right)^2 \frac{1}{3}}{8\,000}} \dots\dots\dots (56)$$

For **H**-sections having "shape factors" similar to that of a 12-in., 65.5-lb. **H**-beam and loaded parallel to the web, Equation (56) becomes:

$$\frac{M}{S} < \frac{20\,000}{1 + \left(\frac{L}{b}\right)^2 \frac{1}{8\,000}} \dots\dots\dots (57)$$

in which,  $b$  = breadth of the flange. If the loading is normal to the web, it becomes practically,  $\frac{M}{S} < 20\,000$ .

For I-beams having "shape factors" similar to that of an 8-in., 18-lb. I-beam and loaded parallel to the web, Equation (56) becomes:

$$\frac{M}{S} < \frac{20\,000}{1 + \left(\frac{L}{b}\right)^2 \frac{1}{1\,100}} \dots\dots\dots (58)$$

In Fig. 15, the denominator of Equation (56) has been plotted against  $L$  for various sections. The one exception to this is for the curve marked "American Institute of Steel Construction", for which the abscissas are deter-

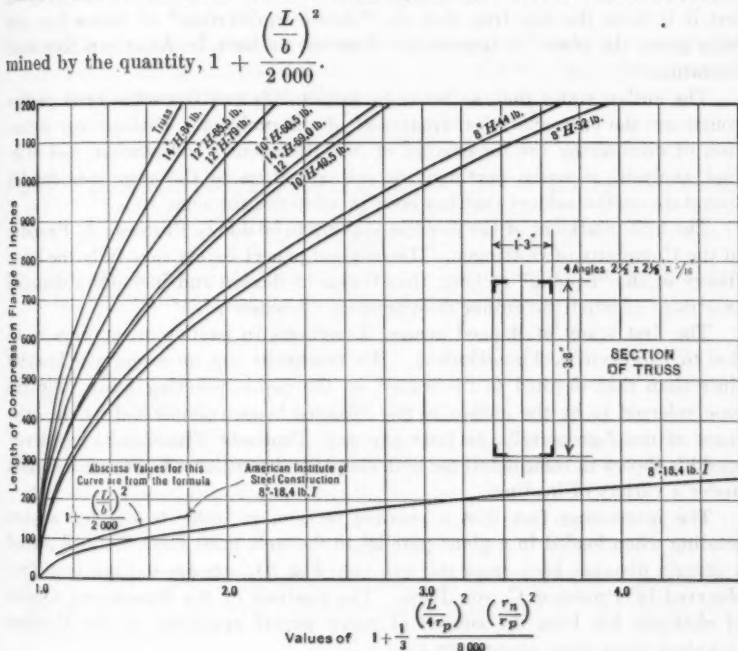

FIG. 15.

The writers were able to find very little test data on side buckling of the compression flange and torsional resistance of such sections as H-columns. Curve 5 of Fig. 14 has been plotted from tests made at the University of Illinois\* of I-beams loaded on the top flange. The empirical formula thus derived was:

$$\frac{M}{S} = 40\,000 - \frac{60\,L}{r_p} \dots\dots\dots (59)$$

So far as the writers know, similar tests have not been made on H-sections. It is felt that such tests would confirm the author's analytical findings.

The writers wish to express their appreciation of this splendid and timely paper. Structural engineers engaged on railway electrification would owe the

\* "Tests of I-Beams in Flexure," by Prof. Herbert F. Moore, Bulletin No. 68, Univ. of Illinois Eng. Experiment Station.

author an additional debt of gratitude if he would publish his method of evaluating the resistance of beam sections when subjected to a torsional load, such as that encountered due to "broken wire" loadings.

JOHN I. PARCEL,\* M. AM. SOC. C. E. (by letter).—This excellent paper is a timely contribution to the theory of structures. It is very true, as the author notes, that the buckling of beams has received far less attention than the buckling of columns. There are doubtless good reasons why the latter should have taken a more prominent place in the literature of the subject, but it is none the less true that the "elastic equilibrium" of beams has not been given the place its importance deserves, at least in American technical literature.

The author states that, so far as he knows, this and two other brief papers constitute the only analytical treatment of the problem. Without any intention of minimizing the importance of Mr. Richmond's independent and original analysis, it seems pertinent to call attention to the very considerable literature on the subject that has been in existence for some time.

The first treatment of the problem appears to be due to Professor L. Prandtl, of the University of Göttingen. His original paper† covers very fully the basic theory of the "tipping" of long, thin beams in flexure and includes a detailed treatment of what the author designates as "*J*-beams".

The first study of flanged beams, *I*-sections in particular, appears to be due to Professor S. Timoshenko.‡ His treatment was on essentially broader lines than that devoted to "*F*-beams" in the paper, covering quite fully the case referred to by the author as the "flanged beam complicated by the existence of the *J*-property". In later papers,§ Professor Timoshenko has developed his theory in some detail for both simple and cantilever beams of *I*-section under a variety of loadings.

The interesting fact that a channel section, in order to develop a pure bending when loaded in a plane parallel to the web, must have the load placed a certain distance back from the web (see Fig. 5), appears to have been first observed by Professor C. von Bach. The analysis of the flexure and torsion of channels has been the subject of many papers appearing in the German technical press since about 1920.||

Although the author presents some very interesting and useful tables and graphs, the prime object of his paper seems to be the presentation of a fundamental method for the rational analysis of the problem of the stability of a narrow beam subjected to flexure. In view of this fact, the presentation of a somewhat different method of approach leading to the same results may be of some interest.

|| See paper by Professor L. Föppl, *Der Bauingenieur*, Heft 12, 1925, p. 455, et seq., in which a considerable bibliography is given.

The writer assumes Equations (4) to (7), inclusive, as the basic formulas, except that the right side of Equations (4), (6), and (7) is assumed to be negative. The author notes that in a flanged beam fixed at one end and carrying a concentrated load at the other, the principal torsional resistance is furnished by a lateral bending moment in the flanges,  $\pm M_s$ . Assuming that all distortions are small enough to justify the application of the theory of elasticity, it is possible to write, with sufficient exactness:

$$\eta = \frac{b}{2} \alpha \dots \dots \dots (60)^*$$

in which,  $\eta$  = the linear displacement of the center line of the flanges in a direction normal to the plane of the web, due to the twisting effect alone; and from the ordinary theory of bending,

$$\pm M_s = E I_f \frac{d^2 \eta}{dx^2} \dots \dots \dots (61)$$

if  $I_f$  = moment of inertia of one flange in the plane of bending. Furthermore,

$$\pm \frac{d M_s}{dx} = E I_f \frac{d^3 \eta}{dx^3} = \frac{b}{2} E I_f \frac{d^3 \alpha}{dx^3} = V \dots \dots \dots (62)$$

The pair of oppositely directed shears in the top and bottom flanges, due to the lateral bending moment,  $M_s$ , effectively constitute a couple:

$$V b = b \frac{d M_s}{dx} = \frac{b^2}{2} E I_f \frac{d^3 \alpha}{dx^3} = K \frac{d^3 \alpha}{dx^3} \dots \dots \dots (63)$$

if  $K = \frac{b^2}{2} E I_f$

If, in addition to the resistance to twist furnished by the lateral bending of the flanges, the beam also develops a purely torsional resistance, it follows that, from Equations (4), (5), and (63):

$$Q = P \left( y - x \frac{dy}{dx} \right) = K \frac{d^3 \alpha}{dx^3} - C \frac{d \alpha}{dx} \dots \dots \dots (64)$$

if  $C = E_s J$ . Since the torque increases as  $\alpha$  decreases, a negative sign is placed before the last term. Differentiating Equation (64) and taking account of Equation (6):

$$K \frac{d^4 \alpha}{dx^4} - C \frac{d^2 \alpha}{dx^2} - \frac{P^2 x^2}{E} \left( \frac{1}{I_1} - \frac{1}{I} \right) \alpha = 0 \dots \dots \dots (65)$$

which is the differential equation of elastic equilibrium of the cantilever subjected to a load,  $P$ , at the free end and slightly bent and twisted.

If the beam is incapable of developing a purely torsional resistance,  $C$  is equal to zero and, since,  $I_1 = 2 I_z$ ;  $I = 2 I_h$ , and  $I_f = I_z$  (approximately):

$$\frac{d^4 \alpha}{dx^4} - R^2 x^2 \alpha = 0 \dots \dots \dots (66)$$

in which,

$$R^2 = \frac{P^2}{E^2 b^2 I_z} \left[ \frac{1}{I_z} - \frac{1}{I_h} \right]$$

which is Equation (27) for the "F-beam".

\* This is essentially the same as the author's equations, top of p. 855.

If, on the other hand, the beam is of such a form that the contribution of the lateral bending of the flange to the twisting resistance is negligible,  $K$  is equal to zero, and the differential equation of elastic equilibrium for the  $J$ -beam is:\*

$$\frac{d^2 \alpha}{dx^2} + N^2 x^2 \alpha = 0 \dots \dots \dots (67)$$

if,

$$N^2 = \frac{P^2}{E E_s J} \left( \frac{1}{I_1} - \frac{1}{I} \right).$$

A primitive of this differential equation may be found in terms of Bessel's functions,† or it may be integrated by means of a simple power series in the same manner as the author has integrated Equations (10) and (27). As an example of method, it may be interesting to sketch the process (for this rather simple case) in more detail than is given in the paper.

Assume that  $\alpha$  can be expressed in a converging infinite series in ascending powers of  $x$ , thus:  $\alpha = A_0 + A_1 x + A_2 x^2 + A_3 x^3 + \dots$ . Then,

$$\frac{d^2 \alpha}{dx^2} = 2 A_2 + 2 \times 3 A_3 x + 3 \times 4 A_4 x^2 \dots$$

Equation (67) then gives,

$$2 A_2 + 2 \times 3 A_3 x + 3 \times 4 A_4 x^2 + \dots + N^2 A_0 x^2 + N^2 A_1 x^3 + N^2 A_2 x^4 + \dots = 0 \dots \dots \dots (68)$$

If Equation (68) is to hold for all values of  $x$ , the method of undetermined coefficients requires that:  $A_2 = A_3 = 0$ ;  $A_4 = \frac{-N^2 A_0}{3 \times 4}$ ;  $A_5 = \frac{-N^2 A_1}{4 \times 5}$ ;  $A_6 = A_7 = 0$ ; and, in general,  $A_n = \frac{-N^2 A_{n-4}}{n(n-1)}$ .

All coefficients are thus expressed in terms of the two arbitrary factors,  $A_0$  and  $A_1$ , which are the constants of integration for the second-order differential equation, and then:

$$\alpha = A_0 \left( 1 - \frac{N^2 x^4}{3 \times 4} + \frac{N^4 x^8}{3 \times 4 \times 7 \times 8} - \dots \right) + A_1 x \left( 1 - \frac{N^2 x^4}{4 \times 5} + \frac{N^4 x^8}{4 \times 5 \times 8 \times 9} - \dots \right) \dots \dots \dots (69)$$

If it is desired to obtain the expression for the horizontal displacement,  $y$ , this may readily be done by means of Equation (7), thus:

$$E_s J \frac{d \alpha}{dx} = -P \left( y - x \frac{dy}{dx} \right) = -P x^2 \frac{d}{dx} \left( \frac{y}{x} \right)$$

from which,

$$\frac{1}{x^2} \frac{d \alpha}{dx} = -\frac{P}{C} \frac{d}{dx} \left( \frac{y}{x} \right), \text{ and } -y = \frac{C}{P} x \int \frac{1}{x^2} \frac{d \alpha}{dx} dx + B x \dots (70)$$

in which,  $B$  is a new integration constant.

\* The preceding analysis is essentially the same as that presented by A. and L. Föppl. "Drang und Zwang," First Edition, Vol. II, p. 350 *et seq.*

† See A. E. H. Love, "Mathematical Theory of Elasticity," 1920 Edition, pp. 425-427.

If the value of  $\alpha$  from Equation (69) is substituted in Equation (70);

$$-y = Bx + A_0' \left( -x^3 + \frac{N^2 x^7}{2 \times 6 \times 7} - \frac{N^4 x^{11}}{2 \times 7 \times 8 \times 10 \times 11} + \dots \right) + A_1' \left( -1 - \frac{N^2 x^4}{3 \times 4} + \frac{N^4 x^8}{4 \times 5 \times 7 \times 8} - \dots \right) \dots \dots \dots (71)$$

in which,  $A_0' = \frac{1}{6} \frac{C N^2}{P} A_1$  and  $A_1' = \frac{C}{P} A_1$ . Equation (71) is substantially identical with Equation (11).

From the relations arising in the evaluation of the constants, the author arrives at a value for the lowest critical load of,

$$P_k = 4.014 \sqrt{\frac{E I_3 E_s J}{L^4}}$$

Professor Prandtl has determined a value of,

$$P_k = 4.0126 \sqrt{\frac{E I_1 E_s J}{L^4}}$$

Noting that  $I_3 = \frac{I_1}{1 - \frac{I_1}{I}}$ , and that  $\frac{I_1}{I}$  is always negligibly small in any

case in which the "tipping" action of the beam is of any practical importance, the correspondence between the two results is practically exact.

The author states that he has extended his analysis to cover the case of flanged beams having an appreciable true torsional resistance, although this analysis is not included in the paper. It may be noted that the differential Equation (65) which applies to this case, may be integrated in precisely the same manner as the author has in Equations (10) and (27). The solution has been completely described by Professor Timoshenko,\* who has also provided tables for use in the numerical application of his results. It should be observed that these tables are only intended for the case in which the load is assumed to be applied at the center of gravity of the cross-section ( $n = 0$ ;  $a = 0$  in the author's notation). Fig. 5 (b) is the only solution the writer has seen which takes into account the effect of the application of the load at other points than the centroid.

It is interesting to compare the critical load derived by Professor Timoshenko for a given case with that obtained from the author's curve. In the example under consideration,† the cantilever is a plate-girder section, with approximately the following properties: Span, 16 ft., 5 in.; depth, 1 ft., 7½ in.;  $I = 670$ ;  $I_1 = 6.8$ ; and the section is made up of 2½ by ⅞-in. angles and 19½ by ⅞-in. web.

† "Einige Stabilitäts Probleme der Elastizitätstheorie," *Zeitschrift f. Math. u. Phys.*, 1910, Vol. 58, p. 372.

Then, from Fig. 5 (b),

$$a = 0, R L^3 = 15 = (\text{approximately}) \frac{P L^3}{E b \frac{I_1}{2}}$$

and,

$$P = \frac{15 \times 29\,000\,000 \times 19.5 \times 3.4}{197 \times 197 \times 197} = 3\,790 \text{ lb.}$$

The corresponding value obtained by applying Professor Timoshenko's tables is 3 840 lb. This indicates that the effect of the torsional resistance in a girder of such dimensions as the one considered is very slight compared to the resistance furnished by the lateral bending of the flanges, and since this is fairly evident from general considerations, the close correspondence of the two values constitutes a good check on the analysis.

S. TIMOSHENKO,\* Esq. (by letter).—The author raises an important point in showing the necessity for investigations into the elastic stability of structures. This becomes especially important in light structures containing slender members, such as are used in railroad electrification. In such cases, a failure of the structure may occur, due to instability rather than to high stresses. Increasing the strength of the steel used does not increase safety in such cases, because the critical load for a slender member depends on the modulus of elasticity of the material, and not on its strength.

As an important example of elastic instability, the author discusses the problem of sidewise buckling of beams loaded in the plane of maximum rigidity. Two extreme conditions are considered: (1) Beams in which torsional resistance plays an important part in providing lateral stability; and (2) beams in which torsional resistance is due to bending of the flanges only. The first condition is fulfilled to a great extent in the case of beams of narrow rectangular cross-section. This problem has been discussed by L. Prandtl† and A. G. M. Michell.‡ Both arrived at the same equation for a cantilever as that given by the author, namely:

$$P = \frac{4.014 \sqrt{B C}}{L^2} \dots \dots \dots (72)$$

in which,  $B$  is the flexural rigidity of the beam in a lateral direction; and  $C$  is the torsional rigidity of the beam. In the case of an I-beam, the problem becomes more complicated because not only torsional rigidity of the beam, but also the resistance of the flanges to bending, must be considered. The writer§ has shown that instead of Equation (72), the following equation must be used:

$$P_c = \frac{K \sqrt{B C}}{L^2} \dots \dots \dots (73)$$

\* Prof. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

† "Kipperscheinungen," Dissertation, München, 1899.

‡ *Philosophical Magazine*, Vol. 48, 1899.

§ See *Bulletin*, Polytechnical Inst. at St. Petersburg, 1905-06; see, also, *Zeitschrift für Mathematik und Physik*, 1910, and *Annales des Ponts et Chaussées*, 1913.

in which,  $K$  is a numerical factor depending on the proportions of the beam. Some values of this factor for various values of the ratio,  $\frac{L^2}{a^2} = \frac{4 C L^2}{B d^2}$ , are as given in Table 2.

TABLE 2.—NUMERICAL VALUES OF THE FACTOR,  $K$ , IN EQUATION (73).

$\frac{L^2}{a^2}$	$K$	$\frac{L^2}{a^2}$	$K$
0.1	44.3	10	7.58
1	15.7	12	7.20
2	12.2	14	6.96
3	10.7	16	6.73
4	9.76	24	6.19
6	8.69	32	5.87
8	8.03	40	5.64

The factor,  $d$ , refers to the over-all depth of the beam. For greater values of  $\frac{L^2}{a^2}$ , the factor,  $K$ , can be calculated from the following approximate equation:

$$K = \frac{4.01}{(L-a)^2} \dots \dots \dots (74)$$

It may be seen that, as the ratio,  $\frac{L^2}{a^2}$ , increases, the factor,  $K$ , approaches 4.01, and Equation (73) coincides with Equation (72). This means that for long I-beams the bending of the flanges becomes of secondary importance. The author also gives without derivation some numerical results for a 12-in., 31.5-lb., steel I-beam supported at the ends and loaded at the middle. These results are in satisfactory agreement with results given by the writer.\* For example, when  $L = 20$  ft. and  $a = 0$  (that is, the point of application of the load coincides with the centroid of the cross-section), the writer obtains†  $f = 27\,000$  lb. per sq. in. This agrees with the ordinate in Fig. 7. It should be noted that the author determines the torsional rigidity by tests of small steel beams, although this quantity can be calculated with sufficient accuracy by using one of two approximate formulas proposed by the writer.‡

In conclusion, it should be noted that the question of the stability of a given configuration is connected with the investigation of the energy of the system in this configuration. The configuration is stable provided the corresponding energy is a minimum. On this basis of considering the energy of the system an approximate method for calculating the critical values of loads has been developed in a paper by the writer published elsewhere in this volume.

The method proved very handy for approximate solutions of stability problems, and in the case of sidewise buckling of beams it is simpler than the method used by the author, which is based on the investigation of the corresponding differential equation of equilibrium.

\* Transactions, Am. Soc. C. E., Vol. 87 (1924), p. 1247.

† Loc. cit., Table 5, p. 1255.

‡ Loc. cit., p. 1249.

Furthermore, by using the energy method, problems can be discussed in which a member is subjected simultaneously to the "primary loading", and to a "secondary loading", and it can be proved that, in general, a member subject to deformation by the primary loading will not be so well adapted to resist the effects of secondary loading as if the first system of loading did not exist. Applying the method to struts submitted to axial compression (the primary loading), and lateral loading (the secondary loading), it can be proved that when all the lateral forces are in the same direction the "load-resisting function of the member as regards the secondary system is approximately proportional to 1 minus the ratio of the primary load or system to a similar load or system which would result in a condition of neutral elastic equilibrium."

The problem of determining the center of twist in bending of non-symmetrical profiles, which is raised by the author (Fig. 5) in discussing bending of channel members, is also of practical importance, and has been extensively discussed in recent European literature.\* The case of a cantilever in which the cross-section is a sector of a circle, or is bounded by two concentric arcs and two radii, is discussed in detail by M. Seegar and K. Pearson.† The case in which the section is an isosceles triangle is treated by the writer.‡ The problem of determining the center of twist in the general case of a non-symmetrical profile can also be solved with sufficient accuracy, provided the thickness of the material is so small that the distribution of the shearing stress over it can be taken as uniform. This problem has been discussed in recent engineering literature by several authors.§

H. S. RICHMOND,|| Esq. (by letter).—One of the discussers, Mr. Feld, brings forward three questions having to do with stress distribution which he states the writer makes no attempt to discuss. The treatment of this subject in detail lies outside the scope of the paper. As indicated by Professor Timoshenko, it is assumed in treating problems in elastic stability that failure is to occur, not through over-stress, but by excessive distortion below the yield point. The analyses are based upon relations prevailing below the elastic limit.

Recognition, however, is given in the paper to the weakening effect of a load similar to the crippling load, but less in value; but the designer must work out the stress relations in the particular design, making proper application of the theorems.

The writer's values for the torsional resistance functions of **I** and **H**-sections are only tentative. In theoretical studies, it should be recognized that this function not only varies from the polar moment of inertia, but that for these types of section, it actually has no relation thereto.

|| With Gibbs & Hill, Cons. Engrs., New York, N. Y.

The discussion by Messrs. Seely, Putnam, and Schwalbe is exceedingly interesting in illustration of the experimental determination of the "shear-center" in channels. The writer has not seen any discussion of this principle in the standard works on structural mechanics. Students have been free to arrive at all sorts of erroneous conclusions as to the action of channels as flexural members.

Messrs. Julian and Rich have made an interesting analysis and have prepared a working formula which, for the practical range which lies safely within the limit of the curve for the crippling load and for low slenderness ratios, meets an arbitrarily assigned working stress. It is to be noted that their formula, Equation (53), is based upon the condition,  $a = 0$ , and that their working formula assumes this; therefore, care should be taken to see whether that condition prevails. In many problems, this is an important consideration.

It would be possible to derive a working formula for any given class and use of beam; the writer, however, would prefer not to crystallize the theorems into working formulas at this time, but would express the hope that the principles brought into consideration might receive further study and in due course be given recognition in the drafting of codes of design, especially where light and open-work types of construction are concerned.

The writer is obligated to Mr. Parcel and other commentators for citations of analyses by previous investigators, showing points of correspondence with his own work.

### PUMPED-STORAGE HYDRO-ELECTRIC PLANTS\*

By WILLIAM W. K. FREEMAN,† Assoc. M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. JOHN R. FREEMAN, H. ALDEN FOSTER, OREN REED,  
PAUL L. HESLOP, A. H. MARKWART, AND WILLIAM W. K. FREEMAN.

#### SYNOPSIS

The Rocky River hydro-electric development, recently completed near New Milford, Conn., is the first modern plant in America to pump water into a reservoir with off-peak power, in order to produce on-peak power later. In connection with this project, a search of engineering literature was made for data on similar plants built elsewhere. The number of such plants was discovered to be forty-two. Ten other plants have been proposed in Europe (including one 600 000-kw. installation) and thirty-six in America. The rapid increase in size of units and total installations and the number of plants built in Europe in the past few years, when considered with the building of the first large plant in the United States, make it appear that America is on the threshold of a new phase in hydro-electric development.

The principle of operation of such plants is therefore explained, with a discussion of their economic justification; a summary is given to point out the extremes in physical features and the advanced stage of development of this type of hydro-electric development; and brief descriptions of the most interesting pumped-storage plants are included, particularly of those which are adaptations of existing developments. Their fundamental cycle of operation is discussed in the Appendix.

#### I.—GENERAL DESCRIPTION

*Growth and Size.*—An increasing number of American hydraulic engineers are becoming interested in the type of hydro-electric development in which

\* Published in November, 1928, *Proceedings*.

† Asst. Engr., New England Power Constr. Co., Boston, Mass.

water is pumped into a reservoir with off-peak energy in order to produce on-peak energy later. Few of them, however, know that this has been done for nearly half a century; that forty-two plants have been built to date (Fig. 1); that twenty-one of them have been built within the past five years; and that their evolution has progressed to the point where 34 000-h.p. pumps are being installed and a total pumping capacity of 250 000 kw. has been seriously proposed (see Tables 1 and 2). Ten more plants have been proposed in Europe, where practically all this development has taken place. In the United States, however, the first modern plant of this type has recently been completed by the Connecticut Light and Power Company on Rocky River, near Milford, Conn., although thirty-six more plants have been proposed, among them being one to pump 5 000 sec.-ft. against a 90-ft. head over a divide.

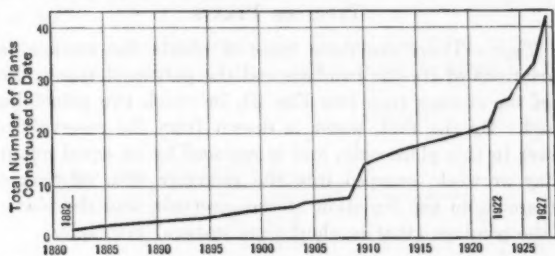

FIG. 1.—HYDRO-ELECTRIC PLANTS WITH STORAGE RESERVOIRS FILLED BY PUMPING.

Those who are in close touch with the situation regard the Rocky River development as the first of a large number of such plants in this country. The inevitable human inertia due to a conservative attitude toward the transplanting of a European idea to American soil has now been overcome and with the building of the first large plant in the United States the development should be rapid. It is timely therefore to explain the principles of operation and to show the wide range of conditions for which these plants have been built, as well as to stress their advanced stage of evolution.

"Hydraulic accumulator" is a name that has been given such plants, ill-advisedly, in the writer's opinion, because a hydraulic accumulator is a system used principally in rolling mills for supplying jacks with water under high pressure. A preferable term is, therefore, the more graphic "pumped-storage hydro-electric plant".

#### PRINCIPLE OF OPERATION

The principle on which these plants operate is that of building a storage reservoir where the natural conditions are favorable for the economic storage and utilization of water even if the natural inflow into the reservoir is negligible, provided there exists, a short distance away and at a lower level, a supply from which water can be pumped into the reservoir. This pumping is done with low-cost off-peak energy generated at steam plants or run-of-stream plants, in order later to obtain high-value peak energy from the storage reservoir. The process of using power to pump water into a reservoir and

drawing it out again to obtain power would be uneconomical except for the fact that electric energy must be produced at the time the consumer requires it. The marginal cost of off-peak energy from steam turbo-generators which would be idle or partly loaded if it were not for the pumping load of a pumped-storage plant, is quite low; and the marginal cost of off-peak energy from water which would otherwise be wasted over the dams of run-of-stream plants (called "surplus hydro-electric energy") is practically zero. These conditions tend to make it economical to use this equipment (which would otherwise be wholly or partly idle, but on which nevertheless the fixed charges would be continuing), to pump water into a reservoir to produce power later when required, the arrangement resembling an electric storage battery in its operation.

#### TYPES OF PLANTS

*Storage Type.*—There are three types of plants, the storage development and two variations of it—the pondage and the part-head types. Rocky River is a plant of the storage type (see Fig. 2), in which two principles of operation are used. By the first, water is drawn from the reservoir to generate on-peak power in this plant only, and is replaced by an equal quantity within the same day or week, pumped into the reservoir with off-peak power. In this case, there is no net depletion of the reservoir, and the plant is said to operate on the pondage (that is, short-time storage) principle.

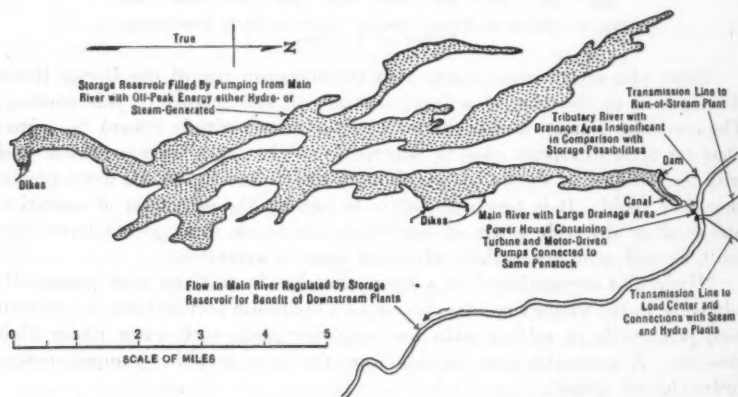

FIG. 2.—TYPICAL PUMPED-STORAGE HYDRO-ELECTRIC PLANT, ROCKY RIVER, NEAR NEW MILFORD, CONN.

The second is the flow-regulation principle in which water is drawn from the reservoir not only to produce power at this plant, but also to increase the low-water flow in the main river for the benefit of down-stream plants. This operation differs from that common to all storage reservoirs only in the fact that the reservoir is filled by pumping because the natural inflow is too small.

*Pondage Type.*—Nearly four times as many pondage plants as storage plants have been built. In this type only short-time storage is economical and the feature of releasing water to regulate the flow of the river below the

reservoir, as described for the storage type, is entirely absent. Some have pumps of enormous size; as, for instance, the Hengstey plant now under construction, which has 34 000-h.p. pumps. Among the developments of medium size are some reservoirs formed by dikes on hillsides, while a few of them are so small that they are made of reinforced concrete.

A number of the plants of this type have two reservoirs, one forming the forebay of the plant and the other the tail-race. In this case the only additional water used, once the lower reservoir is filled, is that required to replace leakage and evaporation. This type of plant extends the possibilities of hydro-electric development to locations where it has never been considered, because practically no natural flow of water is necessary. It requires only suitable natural or artificial pools at different elevations, with the proper hydraulic works.

*Part-Head Type.*—As illustrated in Fig. 3, the third or part-head type pumps water against a certain head to make it available through a higher head.

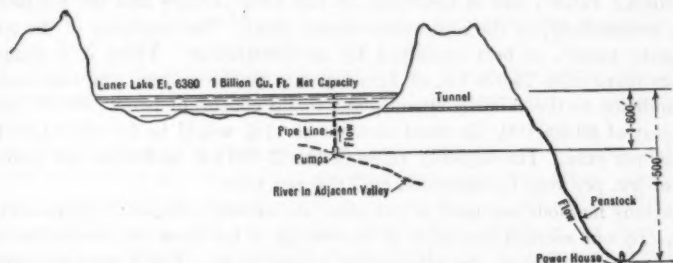

FIG. 3.—TYPICAL PART-HEAD PLANT AT LÜNER LAKE, AUSTRIA.

A common form of part-head development is one in which water is pumped into the penstock from a lake, or other source of supply, and from there it flows up into the main reservoir. The only American plant built prior to Rocky River on which data have been found, is one of this type. In addition to the Mill Creek plant, pumping is utilized at the Thousand Springs, Lake Waha, and Bear Lake developments in Idaho, but these are not true pumped-storage plants, because at Thousand Springs the pumping is done continuously and there is no storage of water during off-peak periods; and at the other two the water is pumped out of a reservoir which is filled by natural inflow, instead of into a reservoir deficient in natural inflow.

#### ECONOMIC JUSTIFICATION

Allusion has been made to the economics of pumped-storage plants. To discuss this question let it be assumed that, due to the growth of its load, a certain company requires additional firm capacity which can be supplied by the enlargement of its steam plant or by the addition of a pumped-storage plant to its hydro-electric system, in which there are some run-of-stream plants. The net value of the hydro-electric plant, therefore, is determined in the following manner. Hydraulic computations for a certain installed capacity show:

- (1) The increase in the firm capacity of the system due to the building of the pumped-storage plant;
- (2) The increase in the primary energy;
- (3) The decrease in the secondary energy produced by the hydro-electric system due to storing water during periods of higher flow; and
- (4) The secondary energy used for pumping.

It is considered properly conservative to assume that all pumping both for pondage and for storage will be done by steam-generated off-peak energy (although a part of it may be done by water otherwise wasted over the dams of run-of-stream plants). It is likewise conservative to omit the saving due to the plant's production of secondary energy except from the natural inflow into the reservoir, as discussed in the Appendix.

The value of the hydro-electric plant is the sum of its "capacity value" plus its "energy value", and is measured by the fixed charges and the production costs, respectively, at the alternative steam plant. The meaning of the term, "capacity value", is best explained by an illustration. Thus, if a pumped-storage plant adds 75 000 kw. of firm capacity to the system, and the alternative addition to the existing steam plant would consist of two 40 000-kw. units at a cost of \$9 600 000, the fixed charges at 11% would be \$1 060 000, or \$13 per kw. per year. The capacity value of the 75 000-kw. hydro-electric plant at \$13 per kw. per year is, therefore, \$975 000 per year.

Various methods are used to calculate the energy value of a hydro-electric plant. By one method the value of the energy is taken as the production cost of the same energy at the alternative steam plant. For a pumped-storage plant the energy value is found by subtracting from the value of the primary energy, the sum of the values of the decrease in secondary energy due to storing water plus the secondary energy used for pumping.

Against the capacity value plus the energy value of the hydro-electric plant, are set the fixed charges on the investment in the pumped-storage plant plus its production costs. The difference represents the annual saving through the building of the pumped-storage plant instead of an addition to the steam plant, or *vice versa*. In addition to these items there are also frequently others, such as fixed charges on the unused capacities of the alternative installations before they are fully loaded; investment and operating costs of transmission lines; relative reliability; and the addition of an independent source of supply. Some of these may easily be evaluated; while others cannot be evaluated, but should be considered.

As may readily be seen for any specific case, the economic justification of the pumped-storage plant lies in its capacity value even more than in the difference in production cost between off-peak and on-peak steam-generated energy.

#### GENERAL ECONOMIC CONSIDERATIONS

The writer hesitates to try to formulate general statements as to what conditions make plants of the three different types economical because of the

infinite variations there can be in topography, market, competing power, and surplus power for pumping, all of which influence vitally the economy of any project.

In general, however, it may be said that the conditions that make ordinary hydro-electric plants feasible make pumped-storage plants feasible; for example, low investment cost per kilowatt of firm capacity; high cost of competing fuels; large and concentrated system loads, etc. Although the pumped-storage plant labors under the disadvantages of the added cost of the pumping equipment and operation, it has certain compensating advantages over ordinary storage plants, some of which may be enumerated as follows:

1.—It is comparatively independent of rainfall and drainage area—although, of course, a high average annual rainfall on a large drainage area means less pumping.

2.—In more settled areas the land and other damages are apt to cost less for a given reservoir capacity because the plant is on a tributary instead of on the main river.

3.—Since, for a given reservoir capacity, the drainage area is smaller, the provision for floods is less expensive, if not absent.

4.—The plant that pumps from a large river, or from a pool, is valuable as a reserve plant because water released in an emergency can be replaced by pumping.

5.—Finally, among the most important advantages is the low cost of adding pumping and power equipment to an existing development to obtain more firm or reserve power. Three examples of such plants are given in Part II and it is the writer's opinion that considerable activity will be shown in the United States in the adaptation of existing plants to the pumped-storage principle; the adaptation of one plant has already been seriously proposed.

How far these favorable features outweigh the added investment and operating cost depends on local conditions.

#### SUMMARY OF DATA

There are six storage plants, twenty-one pondage plants, seven part-head plants, and eight plants not classified as to type due to the scarcity of data on them. The following summary of the outstanding features of the plants built to date (1927) or under construction (see Table 1) is based on incomplete data and is, therefore, necessarily approximate:

Salient feature.	Location.
Earliest, 1882 (hydro-mechanical until 1891).	Zurich, Switzerland.
Largest reservoir, net capacity, 6 000 000 000 cu. ft. at present; 7 000 000 000 cu. ft. ultimately	Rocky River, Connecticut.
Smallest reservoir, capacity, 200 000 cu. ft.	Tübingen, Brunnenmühle, and Zweribach, Germany.
Highest head in full-head development, 2 900 ft.	Tremorgio, Switzerland.
Lowest head, 80 ft.	Cornabbia, Italy.
Highest reservoir elevation, 7 710 ft.	Rhône Valley, Switzerland.
Lowest reservoir elevation, 430 ft.	Rocky River, Connecticut.

#### PROPOSED PLANTS

The biggest project on which data have been published is that for which a grant has been applied by the Rhine-Westphalia Electric System and the General Electric Company (see Table 2). They propose ultimately to build a 600 000-kw. plant on the Our River, in Germany, with a main dam 350 ft. high, which alone will have 920 000 cu. yd. of concrete. With this large volume of concrete is to be compared the 660 000 cu. yd. at Conowingo, Md., a run-of-stream plant with an ultimate installation of 396 000 kw. At the Our River development there are three rivers, on one of which there is a reservoir with a capacity of 3 000 000 000 cu. ft. for the Stolzenberg plant which operates under a 330-ft. head. Into this reservoir the Sauer River will be diverted and here will be installed, in the power-house, pumps with an ultimate capacity of 250 000 kw. to fill the main reservoir of 28 000 000 000 cu. ft. on the Our River. The plant will replace the 25% reserve capacity of the companies' existing steam plants which will be used 6 000 instead of 3 000 hours per year, and it will produce 500 000 000 kw-hr. per year, of which one-third will be from the natural run-off and the remainder from pumped-storage. Most of the energy for pumping will be produced at steam stations.

A development of the magnitude of the Our River project indicates what, in time, may be expected in this country. An old report on Rocky River considered a 2 100-kw. installation to use the natural flow of the river, while the ultimate proposed now is twenty-three times as great, due to the utilization of the large reservoir for pumped-storage. It has been said of Rocky River that each time a greater installation of pumps was investigated the development looked more favorable, and the pumping capacity is now double that originally authorized. If this example is typical of other locations the present estimates of the country's potential water power will have to be increased many times, and the strides made in the last few years in Europe, lead to the conclusion that the development of the pumped-storage hydro-electric plant in the United States will go forward at a swift pace.

#### II.—DESCRIPTION OF PLANTS

A brief description of the most important plants will illustrate the application of the principles discussed.

*Mill Creek No. 2, Murray, Utah.*—This small part-head plant, built in 1913, is the first American installation on which data have been found. The striking statement has been published\* that the entire cost of the pumping features added to a high-head development (\$5 500), was less than the value of the additional saleable energy produced annually.

\* *Engineering Record*, March 15, 1913.

\* Motor-kilowatts.

† Generator-kilowatts.

The main development consists of a 20-ft. dam forming a reservoir with a capacity of 300 000 cu. ft., from which the water is led by a 2.5-ft. pipe line, 27 200 ft. long, to a power-house. Two 1 300-h.p. turbines are installed at this power-house for a head of 1 030 ft. One-half mile below the dam are a number of springs with a total flow of 3 to 4.5 sec-ft., and a 4-ft. dam has been built to collect their discharge. A 100-h.p. pump, delivering 3.5 sec-ft., and operated automatically by a float-switch, pumps water against a head of 140 ft. through a 12-in. pipe into the main pipe line on the hillside above.

The operation of this plant is not entirely on the pumped-storage principle because the pumping is controlled by a float-switch and is not exclusively off-peak. At the Lake Fully plant, in Switzerland, also, the water from the pump flows up or down the penstock, depending on the load on the turbines.

*Tübingen, Germany.*—The reservoir for this plant, which was built in 1922, is of reinforced concrete. It is one of three which are smaller than any of the others, containing only 200 000 cu. ft., or 2 000 000 gal. The pool is 20 ft. deep and only 144 by 82 ft. in plan. Rocky River has a capacity 30 000 times as great. The reservoir is set upon a hill 370 ft. above the Neckar River, where the power-house is located, and is filled in 16 to 20 hours through a 15-in. pipe, 2 000 ft. long. In the power-house is a unit typical of present European practice even for the largest plants. It consists of a dynamo with a horizontal shaft, on one end of which is a turbine, and on the other end, a pump, the dynamo acting as a motor or as a generator as occasion demands. At Tübingen, the turbine is rated at 290 h.p. and the pump at 190 h.p., delivering 3 sec-ft. Additional pumping capacity is supplied by a pump delivering 0.9 sec-ft.

The smallness of this reservoir, taken in conjunction with those at Brunnenmühle and Zveribach, which are equally small, seems to indicate that while economic conditions are not the same in America as in Europe, it might pay some of the smaller companies in this country, when they need a few hundred kilowatts of firm capacity, to look around their hills and brooks to see whether there is not some particularly favorable location worth investigating for pumped-storage.

*Schwarzenbach, near Forbach, Baden, Germany.*—The adaptation of an existing hydro-electric plant to secure additional firm power makes this plant unusual. Previous to 1923 the Murg plant had been built for a head of 490 ft., with a forebay of a capacity of 10 000 000 cu. ft., an 11-ft. tunnel, 18 000 ft. long, and two penstocks, 1 000 ft. long, supplying five 7 000-h.p. turbines. For the Schwarzenbach plant these penstocks have been tapped at the bottom and water is drawn from them and pumped to a reservoir 730 ft. above the forebay of the Murg plant, or 1 220 ft. above the old tail-water level. This reservoir has a present capacity of 500 000 000 cu. ft. (600 000 000 cu. ft. in the future) for a draw-down of 130 ft. and is filled through a 6-ft. penstock, 2 600 ft. long, by two combination units, each of which has two pumps connected by gears to the main shaft. The two pumps of each unit together are rated at 10 000 h.p. and deliver 110 cu. ft. per sec. with an efficiency of 85%, the highest in Europe, while the turbines are of 27 000 h.p.

*Tremorgio, Tessin, Switzerland.*—This plant is an excellent example of the addition of pumping equipment at an existing development to add to its value.

Its reservoir was originally formed for pure storage by damming a natural lake and raising its surface to Elevation 6 000. Later, a 5-ft. tunnel, 600 ft. long, was driven to tap the lake and secure a capacity of 300 000 000 cu. ft. for a draw-down of 90 ft. From the tunnel a penstock 5 100 ft. long and 2.3 ft. in diameter, with provision for a second, leads to a 12 000-h.p. turbine under 2 900-ft. head in the power-house which is located on the Tessin River. This head is the highest in a full-head development. In 1926 two pumps with a total capacity of 13 000 h.p. were added, making it a pumped-storage plant. An unusual feature of this development is the tapping of the penstock to supply water to several towns.

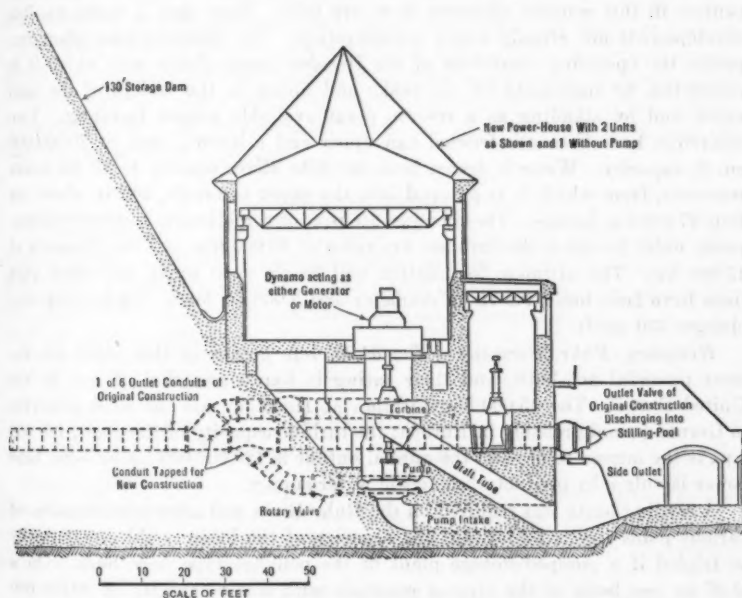

FIG. 4.—ADAPTATION OF STORAGE AND POWER PLANT TO THE PUMPED-STORAGE PRINCIPLE.

*Hemfurth, Prussia, Germany.*—This is a unique addition of pumping and power equipment to an existing development. The original construction consisted of a 130-ft. storage dam with 15 000 kw. installed in the power-house and six outlet conduits discharging through needle-valves into a stilling pool. This has been transformed into a pumped-storage plant (Fig. 4\*) by tapping two of the conduits and connecting each of them by branches to a turbine-dynamo-pump unit in a second power-house. A dam has been built down stream to form a pool from which the pumps can draw water, with a fluctuation of 7 ft. in the water level.

\* From *Elektrotechnische Zeitschrift*, June 30, 1927, p. 946.

The pumps in this development have the greatest discharge of any so far built (480 sec.-ft.), although their rating of 8 400 h.p. does not approach a record. The turbines are of 7 900 h.p., and the generators are rated at 6 000 kw. In addition to the two combination units there is a third unit with the pump omitted. The units are unusual in the fact that the shaft is vertical. If the plant had been designed originally as a pumped-storage plant it is possible that it could have been designed for greater hydraulic efficiency, but as an example of the application of the pumped-storage principle to a plant already constructed, it is highly interesting.

*Niederwartha, near Dresden, Germany.*—This is the type of plant which, in the writer's opinion, is likely to become common near metropolitan load centers in this country wherever there are hills. More than a dozen possible developments are already under consideration. The Niederwartha plant improves the operating conditions of the Dresden steam plants with which it is connected, by smoothing off the peaks and filling in the valleys of the load curve and by standing as a reserve plant available almost instantly. Two reservoirs have been constructed (an upper and a lower), each of 70 000 000 cu. ft. capacity. Water is drawn from the Elbe River near-by to fill the lower reservoir, from which it is pumped into the upper reservoir, 460 ft. above, by four 27 000-h.p. pumps. These pumps are part of combination turbine-dynamo-pump units in which the turbines are rated at 30 000 h.p. and the dynamos at 15 000 kw. The ultimate installation will be six such units, and three pipe lines have been built, 9.2 ft. in diameter and 3 000 ft. long. Each pump discharges 350 sec.-ft.

*Hengstey, Ruhr, Germany.*—The 34 000-h.p. pumps at this plant are the most powerful yet built, and their rating is four times that of any in the United States. The 45 000-h.p. turbines at Hengstey are the most powerful in Germany, and probably in Europe; the turbine capacity of the plant, 180 000 h.p., is the largest total; and the annual output is 120 000 000 kw-hr.—yet here power is only a by-product of domestic water supply.

A settling basin was required on the Ruhr River and after consideration of various plans it was found that the capacity of the basin could economically be tripled if a pumped-storage plant of the pondage type were built. On a bluff on one bank of the river a reservoir with a net capacity of 40 000 000 cu. ft. for 45-ft. draw-down is being constructed by building an oval dike, and this reservoir is being connected with the power-house on the river by four 8.2-ft. penstocks, 1 000 ft. long. In the power-house are three combination turbine-dynamo-pump units and a fourth unit with the pump omitted. The head is 520 ft. and each pump discharges at the rate of 420 sec.-ft. The sedimentation basin, which has a gross capacity of 100 000 000 cu. ft., is formed by a dam at which there is a run-of-stream plant developing a 15-ft. head. The lowering of the water level in the basin due to the draft to fill the upper reservoir, is 2.3 ft.

*Rocky River, near New Milford, Conn.*—This development has four outstanding features: (1) It is the first modern plant in America; (2) its reservoir is the largest of all, having a net capacity of 6 000 000 000 cu. ft. for a 30-ft. draw-down with an ultimate capacity of 7 000 000 000 cu. ft. when raised

5 ft.; (3) its elevation of 430 ft. above sea level is the lowest; and (4) its pumps have the highest efficiency, 87% being guaranteed. The lowness of the elevation of the reservoir indicates that pumped-storage is not limited to mountainous country where there is a large output from each cubic foot of water stored. As indicated in Fig. 2, Rocky River is a small tributary of the Housatonic River entering a mile above New Milford. Fig. 5\* is a photograph made during the filling of the reservoir. The dam is of earth. The pumps are at the right end of the power-house. The water is led from the reservoir by a canal 3 200 ft. long and 45 ft. deep, and a 15-ft. pipe line, 1 900 ft. long, to a power-house which contains one 24 000-kw. generator and two 8 100-h.p. pumps, each delivering 250 sec.-ft. Provision has been made for a second generator. The head is 230 ft. and the drainage area, 40 sq. miles, while the drainage area of the Housatonic at the power-house is 1 037 sq. miles. With two run-of-stream plants in the system the addition of firm capacity to the system by the building of the Rocky River plant will be 40 000 kw. and the additional output will be 80 000 000 kw-hr. Its regulating effect on the river will also make possible otherwise uneconomical projects.

#### ACKNOWLEDGMENTS

Thanks are due L. D. Gilfillan, Assoc. M. Am. Soc. C. E., for many discussions of the principles of operation with the writer, and to him and to Mr. M. S. Weil for valuable criticism. The writer wishes especially to express his deep appreciation of the criticism given by Joel D. Justin, M. Am. Soc. C. E., which has been invaluable.

### APPENDIX

#### METHODS OF OPERATION

Power is produced from a plant of the storage type like Rocky River by the following six methods. It must be remembered, however, that only average monthly flows are considered in this discussion, variations within the months being ignored.

*1.—Pondage.*—Starting with full reservoir at the end of the spring freshet season, the plant is held in reserve and is idle except as explained in Sections 3 to 6. The plants of the combined steam and hydro-electric system are to be operated so as to obtain the maximum possible firm capacity from the water available. This capacity has been determined by a trial-and-error computation, in which it has been discovered that when the average monthly flow of the main river at the power-house of the pumped-storage plant has fallen to a certain quantity, it is necessary to operate the generator in the pumped-storage plant in order to maintain the firm capacity of the hydro-electric system. The unit, therefore, is operated, but all water released during the on-peak hours of the day is replaced by water pumped up into the reservoir by steam-generated power during the off-peak hours of the night and on Sunday. The firm hydro-electric capacity is thus maintained without any

\* Copyrighted by Aero Service Corporation.

net depletion of the reservoir and the flow of the river is unaffected by the storage reservoir.

2.—*Flow Regulation*.—When the flow of the river falls still lower, the firm capacity of the hydro-electric plants of the system is maintained at the amount determined by the computation mentioned previously, by releasing water from the reservoir to be added to the flow of the river for the benefit of the plants down stream as well as to produce power at the pumped-storage plant. This water is in addition to that which is released during the day to be pumped up again during the night (see Section 1 of this Appendix).

3.—*Secondary Energy from Natural Inflow*.—As the flow of the main river increases after the low-flow period the flow-regulation operation and the pondage operation of the plant are successively stopped. When the flow increases so that the pumps can draw from the river without decreasing the firm capacity by withholding water from the down-stream plants, the reservoir is refilled by pumping. Finally, when the reservoir is full the natural inflow is used to produce secondary energy and prevent the reservoir from overflowing; but otherwise the plant is idle, except as indicated by Sections 4, 5, and 6, until the next decrease in the flow of the main river, when the cycle is repeated.

In tabular form this fundamental cycle is as follows:

Flow of Main River Decreasing:

- (a) Full reservoir.
- (b) Secondary energy from natural inflow into full reservoir.
- (c) Pondage operation with full reservoir.
- (d) Pondage and flow-regulation operation drawing down reservoir with increasing rapidity.

Flow of Main River Increasing:

- (d) (*Continued*) Pondage and flow-regulation operation drawing down reservoir with decreasing rapidity.
- (e) Pondage operation with reservoir drawn down.
- (f) Plant idle with reservoir drawn down.
- (g) Refilling reservoir.
- (a) Full reservoir again.

This cycle is reversed if at any point the tendency of the stream flow changes; that is, if in the idle period, (f), the flow decreases instead of increases, the pondage operation of Period (e) is resumed, followed by Period (d) until the flow again increases, when the operation goes forward on the cycle through Periods (e), (f), and (g).

The maximum firm capacity of the hydro-electric system is maintained by operation on this cycle, but under certain conditions this operation of the plant may be supplemented as described under Sections 4, 5, and 6.

4.—*Secondary Energy with Surplus Hydro-Electric Energy*.—If the plant is operated on the fundamental cycle, Sections 1 to 3, there are some parts of Period (b) when the reservoir is full and the plant is producing secondary energy from the natural inflow only, while water is being wasted over the dams of run-of-stream plants at night and on Sunday, the units being only partly loaded. Under these conditions coal can be saved at steam plants by drawing on the reservoir during the peak hours and refilling it by pumping with surplus

FIG. 5.—ROCKY RIVER DEVELOPMENT FROM A RETOUCHE PHOTOGRAPH MADE DURING THE FILLING OF THE RESERVOIR.

hydro-electric energy during the off-peak hours. This secondary energy from water which is replaced by pumping is in addition to the secondary energy from the natural inflow when the reservoir is full, as described under Section 3.

5.—*Secondary Energy Instead of High-Cost Steam.*—Again, if the plant is operated on the fundamental cycle, there may be times in Period (b) (while the reservoir is full) when for a few hours it may be necessary to start and operate another boiler or turbine in a steam plant. The unit cost of the energy produced is very high and, as shown in the following example, it may pay to operate the pumped-storage plant for short-time storage of secondary energy.

Assume the on-peak cost of steam-generated power under the condition described to be 8 mills and the off-peak cost, 4 mills, both at the station bus. Alternative means of supplying an additional load of short duration, with the run-of-stream plants already using all the available water and one steam turbine fully loaded, are to start either a second steam turbine or the pumped-storage plant, replacing the water used shortly afterward. Energy from either plant is delivered at the same sub-station, high-tension bus, at which point the costs may be compared.

*Example.*—The cost of steam-generated energy may be analyzed as follows:

Efficiencies:	Percentage.
Steam station step-up transformers.....	98
Relatively short transmission line to load center.....	95
Resultant.....	93

The cost at the steam station switchboard is 8 mills per kw-hr., and at the sub-station, high-tension bus, 8.6 mills per kw-hr. delivered. This cost per kilowatt-hour delivered compares with the cost of pumped-storage hydro-electric energy as follows:

Efficiencies:	Percentage.
Steam station step-up transformers.....	98
Relatively long transmission line to pumped-storage plant.	90
Hydro-electric plant step-down transformers.....	98
Pump motor fully loaded.....	96
Pump fully loaded.....	87
Penstock to reservoir lightly loaded.....	99

After an interval of time between off-peak and on-peak:

Penstock from reservoir partly loaded.....	98
Turbine partly loaded.....	89
Generator partly loaded.....	96
Hydro-electric plant step-up transformers.....	98
Relatively short transmission line to load center.....	95
Resultant.....	56

The cost at the steam-station switchboard is 4 mills per kw-hr., and at the sub-station, high-tension bus, 7.2 mills per kw-hr. delivered. The saving from pumped-storage instead of steam-generated energy is 1.4 mills per kw-hr., or 16 per cent. The ratio of the resultant efficiencies is 0.60.

The extent of this use of the pumped-storage plant changes with the system load, available units, cost of energy, and stream flow, and it is ignored in the financial statement of the value of the plant.

6.—*Break-Down Power.*—In an emergency the hydro-electric unit, if not already generating power, can be placed in operation in a few minutes. The difference, however, between the pumped-storage plant where the tail-race is a pool, and any other hydro-electric plant, is that this emergency use is not dependent on the stream-flow conditions, for the water can be retained in the pool and pumped back into the reservoir, while in other plants after the water is once released it is gone. This pumping, and pumping for pondage, are limited to the flow of the main river if there is no pool forming the tail-race.

For a plant to have definite reserve value which can be included in the financial statement there must be a big river or pool forming the tail-race and balanced generating and pumping equipment provided for operation outside the fundamental cycle.

In case there is no after-bay and the pumping is limited to the flow in the main river, the production of secondary energy at any time except when the reservoir is full, as discussed under Sections 4, 5, and 6, may jeopardize the filling of the reservoir before the next low-water period and may lower the firm capacity of the hydro-electric system.

## DISCUSSION

JOHN R. FREEMAN,\* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The use of pumped storage on a very large scale was suggested about 1900 by the late Julius M. Howells, M. Am. Soc. C. E., as an important part of a development of 50 000 to 100 000 h.p. from the Feather River over a transmission line about 200 miles in length, of the Western Power Company of California.

Mr. Howells was an engineer of unusual creative imagination, as was proved by his pioneer work in the construction of large earth dams by the hydraulic-fill method. It has long been a matter of deep regret to the writer that Mr. Howells did not receive the credit due him for his inventive genius in being the first to apply the methods developed in the hydraulic mines of California to the building of large earth dams. This method has now become so well established under such widespread application that it has ceased to be thought of as an invention which required great courage, as well as technical skill in its methods, by an engineer who made use of it in important structures. The writer firmly believes that Mr. Howells was entitled to the credit for that invention.

If his associates or financial backers had possessed equal confidence and courage, Mr. Howells, long ago, would have demonstrated this method of pumped storage for electric developments on a grand scale. At the beginning of this century the United States was in the early stages of large scale hydro-electric development, and it was not then so easy to find either capital for building great plants, or customers to absorb their product.

In brief, Mr. Howells' project was to transmit the electric current at a constant 24-hour, 7-day rate to a point about 15 miles from San Francisco, Calif., thereby obtaining the greatest possible economy in the use of a transmission line nearly 200 miles in length, and to utilize all surplus power in off-peak hours for pumping the water into a reservoir about 750 ft. above sea level and  $\frac{1}{2}$  sq. mile in area, in the valley on the northeasterly slope of Mt. Tamalpais.

Mr. Howells' preliminary estimates assumed that the combined efficiencies of motor and pump would be about 70% during the storage period and that in the period of return the combined efficiency of the Pelton wheel and generator would also be about 70%, or that, as a whole, about 50% of the power expended in pumping would be returned.

This pumped-storage station also was to be largely relied on to take the place of the steam reserve station near the terminus, which, in those days, was considered an essential part of any long-distance transmission through rough country.

It was a fascinating proposition, but 20 or 25 years ago the time was not ripe for it. Moreover, at that time, the efficiency of multi-stage centrifugal pumps, and of impulse wheels of the Pelton type, had not become so highly developed as in recent years.

H. ALDEN FOSTER,† ASSOC. M. AM. SOC. C. E. (by letter).—An interesting example of the use of pumped storage was involved in a hydro-electric pro-

\* Consulting Hydraulic Engr., Providence, R. I.

† With Parsons, Klapp, Brinckerhoff & Douglas, New York, N. Y.

ject on which the writer recently made some extended studies. Since the problems treated were rather unique, it is believed that the methods used in solving them may be of interest. The writer does not claim any credit for originating the general scheme of development described.

Fig. 6 is a map and profile of the project. The river flows around a large bend, *ACE*, in a distance of about 14 miles. The total fall from *A* to *E* is 420 ft., as indicated on the profile. Several plans were proposed for the development of this head, one of which consisted of building a dam across the river at *C*, to raise the water level to Elevation 1300. At this elevation, the water would overflow the main river valley into the water-shed of the creek flowing from *D* to *E*. A second dam, therefore, was located at *D*. The resulting reservoir had a flow line at Elevation 1300 (Fig. 6 (*a*)). From *D* to *E* it was proposed to build a tunnel, which would deliver the water to a power-house at *E*, where the full head of 420 ft. could be utilized.

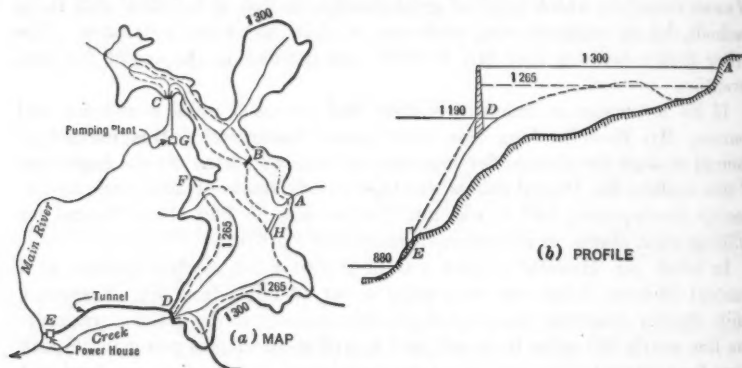

FIG. 6.

The reservoir itself was to be used to regulate the flow of the river down stream from *E*. Its use, however, was complicated by the fact that, when the water was drawn down below Elevation 1265, the lake would divide into two parts, as indicated by the flow line shown in heavy broken lines on the map. The water flowing into the reservoir from above *A* was diverted into that part which was directly tributary to the tunnel, through the canal, *H*, by a weir constructed across the river at *B*, the crest of this weir being at Elevation 1265. The only way in which the water in that part of the reservoir between *B* and *C* could be diverted to the tunnel (when the reservoir was drawn down below Elevation 1265) was by pumping. This was arranged by locating a pumping plant at *G*, which received the water through the pipe line, *GC*, and discharged into the other part of the reservoir at *F*. The available storage was thus divided into three parts, as shown diagrammatically in Fig. 7 (*a*):

*Section I.*—The storage capacity above Elevation 1265: This part of the total capacity can be drawn upon whenever the reservoir surface is above Elevation 1265.

*Section II.*—The part of the reservoir capacity below Elevation 1265 and directly tributary to the tunnel: This volume of stored water can be drawn upon whenever the reservoir surface is below Elevation 1265. The minimum draw-down is to Elevation 1190 (see Fig. 6 (b)).

*Section III.*—The part of the reservoir below Elevation 1265, and lying between the weir, *B*, and the dam at *C*: This volume of storage is available when the reservoir surface is below Elevation 1265; but it cannot be used by the power-house unless it is pumped into Section II (Fig. 7 (a)).

The pumping plant would operate against a static head varying from zero to 65 ft., plus a friction head based on the size of pipe line adopted and varying with the actual rate of discharge, with a maximum total head of about 80 ft. The water so pumped was available for power under a static head of between 310 and 385 ft., depending on the actual level of the water surface in Section II.

In order to determine the capacity for which the pumping plant should be designed, a mass curve (Fig. 7 (b)) of the unregulated stream flow was prepared, covering the driest period in the available records. At the left of this diagram, a vertical line, *ca*, shows the three parts of the total storage, as already explained. A straight line, *ab*, is drawn tangent to the lowest hollow of the mass curve, the slope of this line being 1400 cu. ft. per sec. This represents the maximum rate of flow that can be maintained in the river below the power-house if the total capacity of the reservoir can be utilized.

There are four methods of operation illustrated by Fig. 7 (b): (1) Pump water from Section III to Section II after Section I has been discharged; (2) without pumping, draw water from Section I at the rate of 1400 cu. ft. per sec. and then from Section II at 1200 cu. ft. per sec.; (3) without pumping, draw water from Sections I and II at the rate of 1400 cu. ft. per sec.; and (4) without pumping, draw water from Sections I and II at the rate of 1372 cu. ft. per sec.

By Method (1) the pumps would be operated at their full capacity at all times when Storage II is below Elevation 1265, in order to secure the greatest possible benefit from the pumps by increasing the operating head at the power-house. The sequence of operation as shown by the mass curve is to use Storage I from *c* to *d*, and Storages II and III together, from *d* to *b*. This section of the mass curve is shown at an enlarged scale in Fig. 7 (c). At *b*, lay off Storages II and I vertically upward to the point, *f*. From *e*, at a distance, *l*, above *d*, draw a straight line to the point, *f*. Then, the slope of *ef* will give the maximum rate at which water can be drawn through the tunnel during low-water stages without using Storage III. The difference between the slopes of *ef* and *ce* will give the minimum discharge at which the pumping plant must operate in order to transfer all of Storage III into Storage II during the period of time, *db*, when Storage II is being drawn upon by the power-house. The slope of *ef* is 1200 cu. ft. per sec.; hence, the pumping plant must be designed for an average continuous capacity of 200 cu. ft. per sec. Evidently, with this method of operation, the power-house will have a con-

tinuous available draft of 1400 cu. ft. per sec., and the three parts of the reservoir will be completely emptied at the end of the dry period.

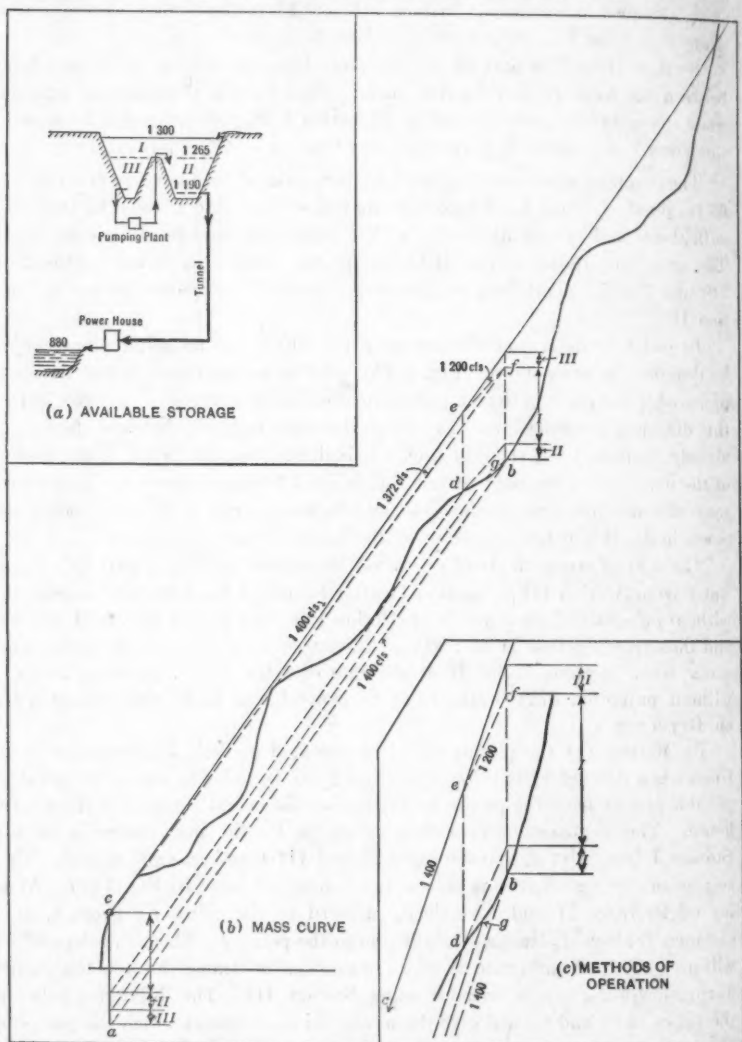

FIG. 7.

By Method (2), with no pumping plant provided, the flow through the tunnel is reduced to 1200 cu. ft. per sec. whenever the reservoir surface is drawn down below Elevation 1265. Storage II will then be entirely consumed by the end of the dry period, as in the case of Method (1). The primary flow

at the power-house is thus reduced from 1400 to 1200 cu. ft. per sec., by omitting the pumping plant. The flow in the river below the power-house, however, can be maintained at 1400 cu. ft. per sec. at all times by discharging 200 cu. ft. per sec. through the dam at *C* (Fig. 6) during the time period, *d b*. The average flow through the power-house is about 1382 cu. ft. per sec.

By Method (3), the flow through the tunnel is maintained at 1400 cu. ft. per sec. during the dry period until Storages I and II are all consumed (Point *g* on the mass curve). From *g* to *b*, the tunnel flow will be reduced to the natural stream flow entering the reservoir. The flow in the river below the power-house can be maintained at 1400 cu. ft. per sec. during this period by discharging sufficient water through the dam at *C*.

By Method (4) the discharge through the tunnel is maintained at 1372 cu. ft. per sec. at all times (slope of line, *cf*, Fig. 7 (*b*)), and no water is discharged through the dam at *C*; hence, the regulated flow in the river below the power-house is reduced from 1400 to 1372 cu. ft. per sec.

Under the first three methods, Storage III would be used during the dry period; but under Method (4), Storage III would never be used.

The relative advantages of Methods (2), (3), and (4), are not dependent on the pumping plant; they are mentioned chiefly to illustrate an interesting use of the mass diagram. Having determined which of these methods of operation is the most desirable, the economic justification of the pumping plant may be examined by the following procedure:

(a) Compute the annual fixed charges and average annual operating expense for the pumping plant.

(b) Compute the increase in firm capacity and average annual output, at the power-house, *E*, and at any other power-houses farther down the river, which may be obtained by the use of the pumping plant.

(c) Compute the kilowatt capacity required for the pumping-plant motors, and the average annual kilowatt-hours consumed in pumping.

(d) The difference between the capacity and energy increases of Procedure (b) and those required in Procedure (c) will represent the net increase of firm capacity and the kilowatt-hour output obtained by using the pumping plant. If the annual value of these increases is greater than the total annual cost of the pumping plant, the construction of the plant will be justified.

It will be seen that this problem is a special case of the "part-head" type of plant discussed by the author.

OREN REED,\* ASSOC. M. AM. SOC. C. E. (by letter).—With favorable topography and a low-head water supply the European expedient of pumping water into a storage reservoir for use at times of peak loads, as described by the author, may be very economical and may often have a decided advantage over a steam plant designed for similar service. The most costly demand on the electrical industry is to supply the power for the peak load, which lasts, on an average, only a few hours. Great strides have been made to meet this demand by providing storage hydro-electric plants as near the

\* Care, San Joaquin Light & Power Corp., Fresno, Calif.

load centers as possible. This storage, in many cases, is maintained partly or entirely by pumping.

The rate of flow of some streams is similar to the power demand. This is not the case, however, in the central part of Europe, particularly in Northern Italy and Switzerland, and a proportionally greater value attaches to stored water. In these regions the head developed is usually very high, with a correspondingly small drainage area. The demand for power has greatly increased there in recent years and, on account of the high price of coal, this demand is being supplied largely by water-power plants. The streams are fed by melting snow and glaciers, and, therefore, they have their maximum flow in summer and minimum flow in winter. The present power demand, on the other hand, is greatest in winter, due to the lighting and heating load.

In the development of storage reservoirs, therefore, particular attention has been given to the possibility of supplementing the stream flow. Often plants of this type are operated only during the winter months while stream-flow plants of the same, or interconnected, system carry the summer load. As a result, it has been found to be economical to pump water from intermediate catchment basins into the primary reservoir in cases where storage is most valuable or where the release from storage is to be used through a high-head plant or a series of plants.

Because of the cheapness of brown coal in Germany, it is not economical to build hydro-electric plants, except for very favorable projects. A number of pumped-storage plants have been constructed to provide auxiliary power for the steam plants. The steam plant is run at a good load factor, and provides power for pumping at night and on Sundays. The stored water is then used during the periods of peak demand.

The efficiencies of motors, pumps, and hydraulic turbines have been brought to a point at which the losses in plants of this kind are not great. The over-all efficiency of the Herdecke pumped-storage plant in the Ruhr District, Germany, is between 60 and 65 per cent. The first plants of this type built in Germany had an over-all efficiency of less than 50 per cent.

Perhaps one of the greatest advantages of the hydro-electric stand-by would be the short time required to put the plant into service in an emergency. It could be started and synchronized with the system in a few minutes, whereas the best a steam plant could do would require several hours. Because of delay in heating boilers, the more important steam stand-bys are kept under steam at all times, and this necessitates a corresponding attendance and operating cost. Such cost might be eliminated entirely, and, in any case, would be less, if water power were substituted for steam in this service.

At some localities in Germany where the topography prevents the construction of pumped-storage hydro-electric plants, Diesel motor units are provided, as at Hamburg and Berlin. Such units have advantages similar to the pumped-storage plants, such as facility and quickness in starting in an emergency, and low charges when not in service.

In addition to the plants described by the author, the one at Tule River, California, and the Swiss plants at Arniberg, Palu, Cavaglia, and Muttien Lake, deserve mention.

*Tule River, California.*—The Tule River project was completed in 1914. The flow of the Middle Fork of the river is diverted by a low concrete dam into a flow-line conduit of tunnels and ditches, leading to an open forebay above the power-house. The single impulse-wheel unit operates under a static head of 1 523 ft. About  $\frac{1}{2}$  mile below the diversion dam there is a permanent spring near the course of the stream. In 1922, a 5-in. centrifugal pump driven by a 100-h.p. direct-connected, electric motor was installed to pump the flow from the spring to the flow-line conduit on the hillside above. The pump operates automatically on a float-switch to deliver 2.2 sec-ft. against a head of 175 ft. through 1 100 ft. of 12-in. redwood pipe. A second unit, which was designed for a 200-ft. head, was installed in 1924. Each pump operates almost continuously from May to January of each year. The net increase at the power house is estimated to be three times the power input to the pumps.

*Arniberg, Switzerland.\**—The Arniberg plant was completed in 1910. The flow of several small streams is diverted to a small forebay at the head of the penstock at Elevation 4 503. The penstock crosses Arni Brook at a point 307 ft. lower than the forebay pond. The discharge of this stream is pumped directly into the penstock. The power-house operates under a static head of 2 795 ft.

Neither of the plants described operates entirely on the pumped-storage principle because pumping is not off-peak. However, a valuable block of firm power is obtained, which amply justifies the use of the pumping plant.

*Palu-Cavaglia, Switzerland.*—The two plants, Palu and Cavaglia, were completed by the Brusio Power Company in 1927. The upper plant, Palu, operates from the storage in Bernina Lake, which has a useful capacity of 12 150 acre-ft. The Cavaglia plant uses the flow from the Palu Glacier, in addition to the regulated flow. A short distance below Cavaglia is the intake to the Robbia plant of the same Company, completed in 1910.

The tunnel that supplies the Palu plant leads from the south dam at Bernina Lake; it has an internal area of 31.7 sq. ft. and a length of 3 570 ft. The penstock has an internal diameter of 43.2 in. and a length of 4 130 ft. The Palu plant operates under a static head of 1 013 ft. It contains a single vertical generator of 8 000 kw., driven by two turbines on the same shaft. The main turbine is near the generator level while the auxiliary wheel utilizes the additional head of about 85 ft. between the main turbine and the equalizing pond. A plant is installed at Palu, designed for a maximum capacity of 21.2 sec-ft., to pump the summer flow from the Palu Glacier back into Bernina Lake. The flow from Bernina Lake is used in winter when the natural flow to Cavaglia and Robbia is small. The pumped storage is utilized in the three plants through a total static head of 3 703 ft. Below Robbia, there are two additional plants, Campocologno, with a head of 1 380 ft., and Poschiavino, with a 295-ft. head.

*Mutten Lake, Switzerland (Proposed).*—Mutten Lake, which is at an elevation of 8 020 ft., has a drainage area of only 1.15 sq. mile. It is pro-

\* "Guide to Swiss Hydraulic Developments," 1926, p. 85.

† *Schweizerische Wasserversorgung*, June, 1926, p. 103, and August, 1928, p. 115.

‡ *Loc. cit.*, June, 1926, p. 105.

posed to tap the lake by a 4 920-ft. tunnel to give a static head of 5 360 ft. at the proposed power house. The normal run-off from the lake is 5 070 acre-ft. per year, while the economical regulated capacity of the lake is 15 400 acre-ft. In order to supply the deficiency, it is planned to pump water from the Limmern River into Mutten Lake against a gross head of 2 425 ft. The pumping plant would have an installed capacity of 15 000 h.p. and would use, on an average, 25 650 000 kw-hr. of summer power, which would be generated by two stream-flow plants of the same system at off-peak periods.

PAUL L. HESLOP,\* M. AM. SOC. C. E. (by letter).—The author is to be complimented on the painstaking thoroughness with which he has searched for, and brought to light the salient facts on the existing and proposed pumped-storage hydro-electric plants. The data gathered here illustrate the wide variety of conditions under which engineers have considered pumped-storage plants to be worthy of construction. They are not limited to high heads. (See Table 1, No. 14, Cornabbia, 80 ft.; No. 36, Hemfurth, 130 ft.; and No. 42, Rocky River, 230 ft.) The storage capacity of the reservoir and the size of the installed machinery cover a wide range of values.

Pumped-storage plants will be justified when, and only when, ordinary storage plants are not feasible or economical in the size of installation desired. An ordinary storage plant will perform all the regulating functions that can be obtained from a pumped-storage plant, with but one exception; that exception, however, is quite worthy of note. Assume that the plant discharges into a tail-water pool in which there is a reasonable storage capacity. In event of a breakdown in a steam plant of the system the pumped-storage plant may be called upon to carry part of the system load, although the reservoir may be at a stage at which withdrawal of water is not desirable. Within the limits of the effective storage in the tail-water pool the water may be pumped back into the reservoir when the steam plant is again in service, which is virtually equivalent to delaying the steam-plant breakdown to a more favorable time. Similarly, errors in the hydraulic operation of the system may be corrected within reasonable limits by pumping back the released water. With the ordinary storage plant, water once released can never be replaced as potential energy.

Pumped-storage plants in the United States will find their greatest field for consideration in the lower reaches of the various rivers, where the industrial activity is greatest, where real estate is costly, and where the valley is likely to be built up with railroads and industrial plants, making the cost of storage on the main river prohibitive. On such a location, near an important load center, a pumped-storage plant may be used to furnish peak and reserve capacity, that is, if a suitable site can be found.

In the United States pumped-storage hydro-electric plants will often have to compete with somewhat antiquated steam plants and furnish power as cheaply as the operating cost (without fixed charges) of such plants.

The author's statement that the pumping capacity of the Rocky River plant is now double that originally authorized, has an interesting explanation.

\* Asst. Hydr. Engr., Elec. Bond & Share Co., New York, N. Y.

The additional capacity was installed to reduce the time of initial filling of the reservoir and thus shorten the period before the plant would be ready for operation.

The Rocky River pumps are of the vertical-shaft, single-inlet, single-stage, bottom-suction, volute type. Prior to the construction of these pumps, a model was built and altogether twelve different combinations of impellers and suction cones were made. The pumps are by far the highest in power of the single centrifugal units in America and are, it is believed, the largest high-head pumps of any type in the country. One cannot tell from appearances that they are not hydro-electric generating units. Each pump has a suction elbow that resembles the familiar elbow-type turbine draft-tube. Each is capable of delivering 250 cu. ft. per sec., 112 500 gal. per min., or 162 000 000 gal. per day, against an operating head of 240 ft.

A. H. MARKWART,\* M. Am. Soc. C. E. (by letter).—Any electric generating device or method which promises to be economical in power production is of peculiar interest to the electrical utilities of the country. That attitude conforms with the enlightened policy which they have adopted, of service at the lowest cost consistent with continuous operation and sound expansion to meet the demands of present and future consumers. Naturally, an increase in the number of consumers and in quantity of power used will bring about a reduction of cost to the consumer. The electric utilities, not content with this, are always on the alert to discover ways to reduce cost, and, therefore, service rates, beyond that which would be possible by the ordinary process of mass production. To this end, much thought has been given lately to the idea of carrying peak loads on capacity units which will operate at low load factors. In this way the bottom and greater portion of system loads might be carried, in the interests of economy, on base-load plants, at load factors considerably higher than system load factors.

Methods of carrying peak loads have been studied in this country and abroad. Consideration has been given to devices for generating from a secondary source, such as electric storage batteries, steam accumulators in steam-electric generating systems, and hydraulic accumulators or pumped-storage hydro-electric plants, in both steam and hydro-electric generating systems. Consideration has also been given to devices for generating from a primary source, such as steam plants in hydro-electric generating systems, and Diesel engines. Because of their high cost, electric storage batteries have not been used extensively to carry peak loads. The development of large Diesel engines for central station use has not advanced, and it does not seem likely that the Diesel engine will be widely used to carry peak loads to improve the load factor of base-load plants. Pumped-storage plants may be suitable at times; the desiderata are (1) favorable natural conditions, and (2) a low first cost.

In the light of efforts on the part of electric utilities toward increasing economy in power production, a discussion of pumped-storage plants as a means of solving peak-load problems in electric power stations, is of timely interest. The author has grouped them into three types: (1) The pondage plant; (2) the storage plant; and (3), the part-head plant.

\* Vice-Pres., Pacific Gas & Elec. Co., San Francisco, Calif.

Pumped-storage installations are not recognized as standard practice in America; however, wherever they are physically possible, further study may indicate economic feasibility. In fact, pumped-storage plants must be viewed largely with respect to their economic aspects because, aside from the pumping equipment involved, they present no technical features not present in the usual hydro-electric plant.

The economics relate wholly to the cost of power at the load factor under which such plants must supply power as compared with the cost from other plants, either steam or other hydro-electric, at the same load factor. One may say that pumped-storage plants, particularly the pondage and storage type, must be used, in effect, to supply kilowatts of peak load instead of kilowatt-hours of energy. Consequently, in any given system, they must work in the peak of its load, which contains a negligible quantity of energy, instead of in the base of its load which contains the bulk of the required energy. The part-head type may be conditioned so as to supply both peak and energy.

With the exception of the pumping equipment, the part-head plant has the physical composition of an ordinary hydro-electric plant, and under equal conditions of water supply the operation and character of power are the same. In comparing the cost of power from this type with that from an ordinary hydro-electric plant, account must be taken, not only of the fixed charges on the capital investment and the usual operation, maintenance, and depreciation costs, but due allowance must be made for the cost, if any, of off-peak energy used in pumping. This has the effect of adding capital not necessary in ordinary hydro-electric projects. When such off-peak energy is supplied from steam plants, its cost would be substantially that of the fuel not otherwise burned; if supplied by run-of-stream hydro-electric plants at off-peak times, its cost would be nothing. Under such conditions of operation gross output would be used in the analysis of power cost; but, if such a plant supplied its own power for pumping, the cost of power would be determined solely by the usual hydro-electric annual costs, provided net output was considered.

There might be conditions of limited water supply and favorable topography that would make it feasible to install part-head plants, operating on the part-time storage or the flow-regulation principles, to carry peaks only. The one would be a part-head pondage plant, using natural flow and ordinary forebay regulation instead of re-pumped water, and the other a part-head storage type, if there were other plants down stream and if the natural flow of the side stream were sufficient.

In order to view this subject in its essential aspect and to reduce the economic problem to its simplest terms, the writer proposes to confine his discussion to the pondage type or to any pumped-storage plant that operates on the short-time storage principle; that is, one that uses system off-peak energy, during low load periods, from other plants of the system, to generate on-peak energy during high load periods at the pumped-storage plant and at other plants down stream, if such exist.

The problem is similar to that which presents itself in the case of steam plants, operating at low load factors, which are used to comb the top of system

loads that have load factors considerably less than 100% in order to permit hydro-electric plants to operate on the bottom of the load at load factors considerably greater than the system load factor. Often steam power is cheaper than water power at low load factors, and *vice versa* at high load factors. When this condition occurs, there will usually be a composite economy in power production if the system load is divided into two parts, and the bottom, or high load factor, is placed on water power and the top, or low load-factor, is placed on steam. This, of course, assumes that the capital cost of hydro-electric energy is not so low as to preclude the use of any steam and that fuel is not so cheap as to preclude the use of any water-power energy.

Because of the limitation on the quantity of water used, pumped-storage plants must operate on the top or low-load factor part of the load of a given system, where the quantity of energy to be supplied is negligible. Thus, they become capacity plants and their function is to improve the load factor of the base-load plants—hydro-electric or steam, or both as the case may be—to the end that the cost of system power will be a minimum. However, because of the remarkable over-all efficiency of modern steam plants, pumped-storage plants will be of no value as an aid to composite economy in power production unless the capital cost per kilowatt of installed capacity is relatively low. It is the low capital requirement and negligible fuel consumption that justify steam plants for the top or low-load factor load in a system using base-load hydro-electric power. The two kinds of generation facilities, that is, pumped-storage, and peak-load steam plants in a water power system, have a comparable function, and may be truly said to be in economic competition when the base-load plants are operated with water power.

In places where the topography and other natural conditions are favorable it is probable that the capital cost per kilowatt of deliverable peak, at the required, very low, load factor from a pumped-storage plant, will be enough less than that from an ordinary natural-flow hydro-electric plant, with forebay and afterbay regulation as may be required for a low load factor, to justify the installation of the former provided the off-peak power for pumping is available at a low cost. Consequently, a steam plant will usually be the alternative for a pumped-storage plant in any economic comparison; and the latter will be justified if a kilowatt of power at low annual load factors can be produced from it cheaper than from a steam plant. However, cost comparisons must be predicated on a common delivery point, since the steam plant has place utility.

In passing, the steam-accumulator electric plant might be mentioned as a possible alternative for a pumped-storage hydro-electric plant wherever the system base load is carried by steam plants. In such an arrangement the boilers of the base-load plant furnish steam for the accumulators during off-peak hours and the accumulator, in turn, supplies steam to its electric generator in order to furnish a low, load factor, on-peak energy, all in the manner in which base-load plants supply off-peak energy to elevate and store water that operates pumped-storage plants over the peak. The steam accumulator is peculiarly adaptable in steam-electric generating systems; consequently, it is

improbable that it would ever be the best alternative for a pumped-storage plant in which the base load is carried on hydro-electric plants. For the purpose of a generalized economic study and to make this discussion applicable to either hydro-electric or steam-electric generating systems, the ordinary steam plant, which is suitable in either system, has been chosen as the alternative for a pumped-storage plant.

When a pumped-storage plant is being considered for a system that requires additional capacity, it should be expected to carry only that part of the peak which would bring about a nice balance of system on-peak and off-peak energy, with due regard for the over-all inefficiency of the transmission, pumping, and generating combination. The part of the peak of new load which such a plant should carry can be determined only by making an intensive study of the load curve of the system in which it will operate.

This will furnish the basic information necessary to determine the quantity of off-peak energy which is available in an existing system at various times, and the amount of on-peak energy to be supplied when different amounts of the peak are to be carried by pumped-storage plants. Likewise, it furnishes a means of measuring the annual cost of off-peak energy to be used for pumping in case fuel is used in its generation.

Two composite load curves similar to those used in other economic studies\* are submitted in this connection. One is for a system load factor of 65% (Fig. 8), such as would obtain for regional systems in California, and the other for one of 45% (Fig. 9), such as would obtain for a metropolitan system, perhaps anywhere. For convenience, these curves were based on a system load of 400 000 kw. They are, in effect, composite daily load curves, 365 of which would contain, with a great degree of accuracy, all the kilowatt-hours that would be found under 365 actual daily load curves. They are necessarily inaccurate with respect to the 400 000-kw. peak because there would not be 365 peaks of such a magnitude. There is an appearance of error in the number of kilowatt-hours lying in the peak, because there would be few such peaks, perhaps only one, in the year. The degree of error would seem to be measured by the number of kilowatt-hours in about 364 such peaks lying in that part of the load above the average annual peak; but this seeming error does not exist in the composite curves, because the method used in constructing them took into account this very thing. Thus, in effect, the curves, while not being the exact shape of daily load curves, are such that they will reflect with a high degree of accuracy the kilowatt-hours that must be produced annually for a load of 400 000 kw. at 65% annual load factor for regional power systems in the one case, and at 45% for metropolitan systems. Similarly, the curves are sufficiently accurate to ascertain the kilowatt-hours in various divisions of the load to base load and peak load and the off-peak kilowatt-hours in the base load. In Fig. 8 the dotted division line between the base-load plant and the peak-load plant is at 68.6% of the peak-load ordinate and, in Fig. 9, it is at 48.5 per cent. The energy ratio, off-peak

\* "Power in California," by A. H. Markwart, M. Am. Soc. C. E., *Journal*, Franklin Inst. Vol. 204, 1927, p. 179.

to on-peak, equals  $1\frac{1}{2} : 1$ , which is equivalent to a pumped storage over-all efficiency of 60% in both cases.

To illustrate the use of the curves: If, in Fig. 8, 100% of the peak from the base, or 400 000 kw., is carried on steam, or on hydro-electric plants capable of operating at a load factor of 100%, these plants will supply 100% of the energy lying under the load line, or 2 277 600 000 kw-hr. at the system annual load factor; and by utilizing water otherwise going to waste, in the case of hydro-electric plants, or by burning additional fuel, in the case of steam plants, they would be capable also of supplying additional energy equal to 53.85% of the required system energy, or 1 226 400 000 kw-hr.

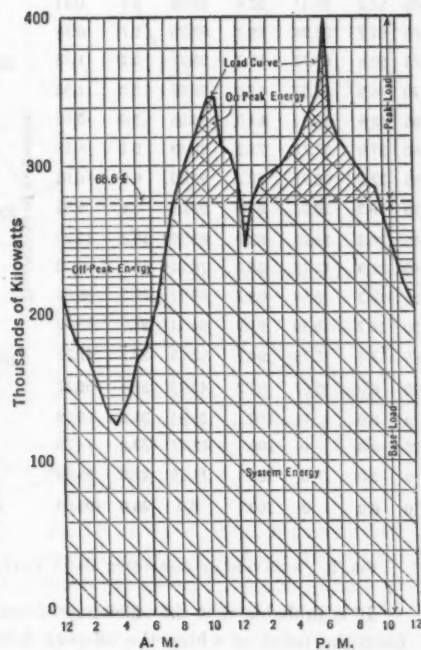

FIG. 8.—ANALYSIS OF COMPOSITE DAILY LOAD CURVE AT 65% ANNUAL LOAD FACTOR.

Similarly, if 60% of the system peak from the base, or 240 000 kw., is to be carried on like base-load hydro-electric or steam plants, and the other 40%, or 160 000 kw., is to be carried on pumped-storage hydro-electric plants, the latter would have to supply 16.37% of the system energy, or 373 000 000 kw-hr. The off-peak energy available for pumping purposes would be the equivalent of 8.77% of the system energy, or 200 000 000 kw-hr. Obviously, such division of load between the pumped-storage plants and base-load plants would not

be feasible, because the on-peak energy is less than the off-peak energy. Fig. 8 shows an approximate equality, 11.90% against 11.80%, when 65% of the load is carried on base-load plants and 35% on pumped-storage plants. This is also an unbalanced condition because there is no margin of off-peak energy to make up for the inefficiency of the pumped-storage plant combination.

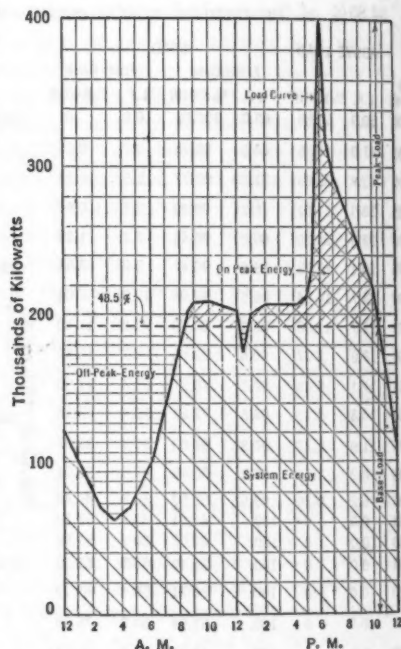

FIG. 9.—ANALYSIS OF COMPOSITE DAILY LOAD CURVE AT 45% ANNUAL LOAD FACTOR.

It is probable that the efficiency of transmission, pumping, and generation from the point at which the off-peak kilowatt-hours are available to that at which the on-peak kilowatt-hours are to be generated at the pumped-storage plants, will be about 50%, although 60% is possible. If 60% efficiency is chosen, 1 kw-hr. of generated on-peak energy would require the use for pumping, of  $1\frac{2}{3}$  kw-hr. of off-peak energy. Consequently, the balance would be found when the quotient, resulting from dividing the percentage of off-peak kilowatt-hours by the percentage of on-peak kilowatt-hours, is  $1\frac{2}{3}$ . Then all the off-peak energy would be absorbed and no waste would occur. At 65% of the peak from the base such a quotient is approximately 1.1; at 70%, it is approximately 2.1; so, it seems that the balance is between the two. It actu-

ally occurs at approximately 68.6% of the peak from the base and 31.4% of the peak from the top as determined graphically by Fig. 10 (a). With this division, the equivalent of 13.8% of the system energy would be available for pumping water to generate on-peak energy to the extent of the required 8.3% of the system energy. The load factor of the top would be 17.2 per cent.

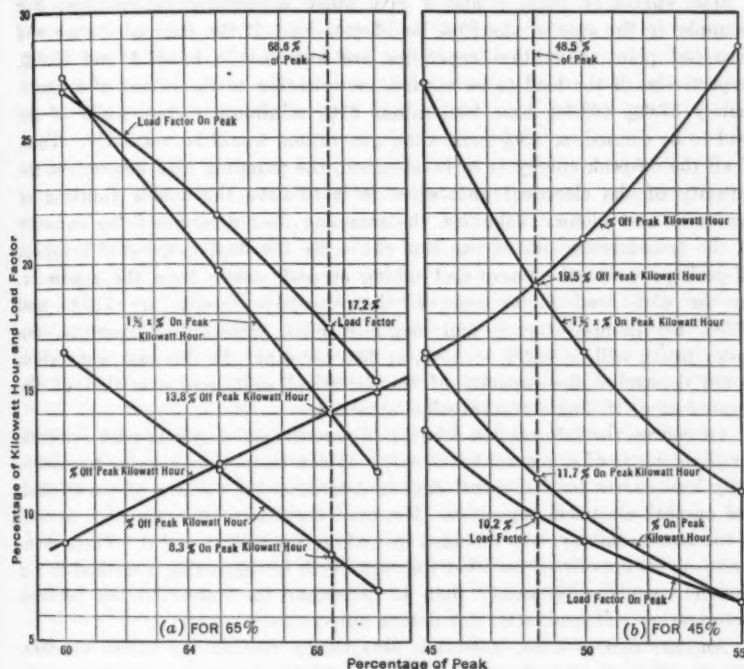

FIG. 10.—ANNUAL LOAD FACTOR SYSTEM.

A similar scrutiny of the 45% load-factor curve of Figs. 9 and 10 (b) reveals that a balance of off-peak with on-peak energy would be obtained by dividing the kilowatt load in two parts: 48.5% to base-load plant and 51.5% to pumped-storage plant. This division would cause the off-peak energy to be  $1\frac{1}{2}$  times the on-peak energy and would cause no waste of off-peak energy. There would then be available the equivalent of 19.5% of the system energy for the purpose of pumping water to generate on-peak energy to the extent of the required 11.7% of the system energy. The load factor of the top would be 10.2 per cent.

It would appear, therefore, that if 65% and 45% represent the upper and lower limits, respectively, of load factors likely to be encountered in actual systems with triangular peaks, substantially all the off-peak kilowatt-hours of base-load plants can be balanced against on-peak kilowatt-hours of pumped-storage hydro-electric plants. However, due allowance is made for the

over-all inefficiency of the pumping-storage combination when 31.4% of the peak for a 65% annual system load factor, and 51.5% of the peak for the 45% annual system load factor, are carried on pumped-storage plants. This would leave the remainder of the load in each case to be carried on water power, or steam, base-load plants.

The curves of Figs. 8 and 9 give other interesting information: For example, in the case of the 65% load-factor load, if the pumped-storage and base-load plant generation capacities are assumed to be 31.4 and 68.6%, respectively, of the load to be carried, motorization to the extent of approximately 37.6% (68.6% base load minus 31% minimum system load) of the load to be carried, or 20% more than generation, would be necessary. Thus, if all the off-peak energy is to be absorbed, the pumping load determines the capacity of the electrical unit when it is to have the double function of generator and motor. Likewise, the pumping load determines the capacity of the transmission line if one line can serve the dual purpose of bringing off-peak power to the pump and taking on-peak power from the generator. In the 45% load factor case, if the respective figures are 51.5% and 48.5% for pumped-storage and base-load plant generation capacities, the motorization will be 48.5% — 15%, or 33.5 per cent. In this case, generation would determine the capacity of the electrical unit, and also that of the transmission, if single transmission obtained.

Of course, the information relating to percentages of system peak available for pumping is of a general order only. It can be used as a guide to explore daily load curves for individual days to determine the relation of the off-peak and on-peak electrical capacities. However, the load of the minimum as well as the maximum day, was included in making up Figs. 8 and 9. These composite curves are offered for what they are worth in suggesting a method to aid economic study only, rather than to determine the exact relation between motorization and generation for design purposes.

Another fact of some interest is revealed by reading the curves together. The quantity of off-peak energy that is available for pumping under conditions of practical balance between the two kinds of energy is reduced as system load factors rise. This is indicated by the 13.8% of the system energy that is available at the low-load period in the 65% load factor case as compared to the 19.5%, with a 45% load factor. From this it would appear that pumped-storage plants are more suited to metropolitan systems which have low system load factors, than to regional systems which enjoy high load factors. Furthermore, there is that other feature, which tends to bar their general use in steam-supported regional hydro-electric systems which usually enjoy high load factors, relating to the control of the water to suit the load factor of the load.

Often it is possible to regulate the flow at the plants of regional systems that operate on stored water so that plants on streams that have no storage can carry block load. Steam plants designed to carry peaks and a number of hydro-electric plants of varying output characteristics permit this form of operation, with the result that no appreciable quantity of water is wasted

during low-load periods, if there is a proper ratio of steam to hydro-electric energy in a given situation. Some waste of water would occur if a hydro-electric development were introduced too soon or if the growth of load was less than the anticipation. Usually, however, the steam plants care for any growth in the load, and the bringing in of a new hydro-electric plant is timed in accordance with its capacity, so that it will be fully used when it takes over the load accumulated for it by the steam plants. Illustrative of this is the system of the Pacific Gas and Electric Company. It consists of thirty-two hydro-electric plants, five major steam plants, and an extensive network of power lines which serve the northern and central parts of California. The peak load and output in 1928 were 484 000 kw. and 2 545 713 564 kw-hr., respectively. This system has no off-peak hydro-electric energy and, generally, it has been possible to control the construction program so that there is substantially no off-peak energy. The spilled hydro-electric energy in the spring does not exceed 3% of the total generated output.

The system has steam energy which, under some conditions, might be available for pumping at times when the steam plants are not being operated over peaks. On the other hand, the steam plants serve the same economic purpose as pumped-storage plants and they have the additional function of supplying stand-by against a water power or transmission failure. Furthermore, they supply energy to make up the water power deficiency in years of reduced run-off (when conditions are reversed and the steam plants are operated on the base of the load and the water power plants on the peak). Therefore, they can hardly be considered as means for supplying the energy necessary to the operation of pumped-storage plants. In fact, even if the base load of this system were carried on steam plants it is highly probable that pumped-storage plants would be uneconomical because the water power sources that might be suited to such projects are at a considerable distance from the localities where steam plants are situated. However, it might be possible, in regional systems that have a metropolitan load, to utilize a pondage type of pumped-storage plant, providing a pump-storage site was available in close proximity to the steam plant in the metropolitan area, and that the economy in power production for the remainder of the regional system was not affected adversely.

The conditions that make pumped-storage hydro-electric plants economically feasible will vary in each locality; individual situations must be analyzed. The cost of peak power at the required low load factor from other available sources is the determining factor, and it is probable that usually steam power will be the alternative for pumped-storage power, with off-peak power from either steam or run-of-stream hydro-electric plants.

However, it is possible to state with approximate correctness, a general economic rule for pumped-storage hydro-electric plants under the following six premises:

- (1) The total additional load to be carried will be divided between the pumped-storage peak-load plant and the base-load plant (either run-of-stream hydro-electric or steam). Under these conditions, the base-load plant will be

of a capacity such that when operating at a load factor of 100%, it will produce off-peak energy enough to balance the on-peak energy of the pumped-storage plant without substantial waste.

(2) In an economic analysis the capital cost and fuel economy of the alternate steam plant shall be (a) that of a plant having the capacity of the pumped-storage plant, in cases where the base load can be carried on run-of-stream water power; and (b) that of a plant with a capacity equal to the total additional load to be carried, in cases where the base load must be carried on steam.

(3) The marginal cost of off-peak steam power will be for energy fuel only. (The fuel economy must be that of a base-load steam plant with a 100% load factor and a capacity equal to the difference between that of the pumped-storage plant and the total load to be added to the system, with no consideration of stand-by fuel.)

(4) The marginal cost of off-peak hydro-electric energy will be zero. (Under such an assumption it is obvious that knowledge of the capacity and capital cost of the base-load hydro-electric energy is unnecessary.)

(5) Only pumped water is available to the pumped-storage plant.

(6) Nothing except on-peak power is produced as a result of the installation of pumped-storage.

Under these six premises the economic rule would be as follows: The economic limit for capital expenditure for pumped-storage plants is the capitalized annual charges of steam plants operating under similar load conditions, as follows:

- 1.—In the event that the off-peak energy is supplied by run-of-stream hydro-electric plants the limit will be the annual cost of a kilowatt-year of equivalent steam power, capitalized at the annual percentage cost for hydro-electric plants.
- 2.—In the event that the off-peak energy is supplied by steam plants, the limit will be the annual cost of a kilowatt-year of equivalent steam power minus the annual cost of the fuel burned to supply a kilowatt of pumped-storage peak, capitalized at the annual percentage cost for hydro-electric plants.

It may be objected that these statements are mere truisms and are, therefore, of no significance, but truisms are significant if they cause the basic elements in what appears on its face to be a confused problem, to be universally recognized. Generalized statements of the elementary principles which attach to the problem under discussion are desirable in order to simplify its solution. The endeavor has been made to formulate such statements.

It is obvious that the allowable capital expenditure per unit of capacity for pumped-storage plants, for each price of fuel, will depend on the fuel economy and capital cost of the alternate steam plant, and also on the fuel economy under which the off-peak energy is generated if it is supplied from steam plants. The values of these elements, in turn, depend on the size of the plant. Consequently, economic comparisons must be made with like capacities and concomitant conditions. The capital cost per unit of capacity of steam plants and the fixed charges, that is, the interest, depreciation, taxes,

operation, and maintenance cost, and the cost of stand-by fuel, or the annual charges except for energy fuel, decrease as the capacity increases; but the fixed charges, expressed as a percentage of the capital cost, will be substantially the same for all capacities of plant, varying only slightly for different unit prices of fuel. (See Table 3.)

In the case of a small pumped-storage plant a relatively high capital expenditure per kilowatt of capacity would be justified because its alternate steam plant would have a high capital cost and a relatively low fuel economy. On the other hand, the justifiable capital expenditure per unit of pumped-storage capacity for a large plant would be relatively low because the alternate steam plant in that case would have a low capital cost and a relatively high fuel economy.

It is probable that the total operating charges on pumped-storage plants would be close to those which would obtain for ordinary hydro-electric plants, and when expressed as a percentage of the capital cost, would be substantially the same for all capacities of plants.

An economic study under the rule will be made for a range of capacities from 5 000 to 100 000 kw., assuming that the annual fixed charges for steam plants are 15.5%, 15.75%, and 16% of the capital cost for \$1.00, \$1.50, and \$2.00 oil, respectively, and that the annual fixed charge for pumped-storage plants is 10.25 per cent.

The annual fixed charge for a steam plant which is the alternate for pumped storage, operating in conjunction with base-load hydro-electric power, should be a little greater than that of the steam plant which is the alternate for pumped-storage operating in conjunction with a base-load steam plant. A little more stand-by fuel would be used in the first case, because it would be necessary to bring the alternate steam plant into operation each day from cold boilers in order to carry the load for a period of not more than two shifts, or about 16 hours. This kind of operation would be unnecessary in the latter case, because the alternate steam plant would then be a part of the larger capacity that would be required to pull the total additional load, and it would be operated continuously instead of intermittently. However, this element is disregarded in the studies, because it is more or less academic; the effect, when considered, would not have been perceptible in the final result.

The fuel economies for the chosen capacities of alternate steam plants and base-load steam plants are intended to be those which would obtain with plants designed for moderate steam pressures and elevated temperatures ranging from 400 lb. with 700° total heat for the larger plants, to 250 lb. with 650° for the smaller ones. These conditions are generally used in steam plant practice and for that reason power resulting from such plants, rather than steam power resulting from the greater economies which would obtain with plants designed for elevated pressures and corresponding temperatures, is considered the alternate for power from a pumped-storage plant. However, in places where a pumped-storage plant of very large capacity is a possibility a steam plant with a 1 200 lb. capacity may be the alternate. In that case the study might properly be based on a fuel economy of about 11 500 B. t. u. per kw-hr., as compared with 13 000 B. t. u. (which is the highest value

TABLE 3.—RELATIVE COST OF VARIOUS STEAM PLANTS.

chosen for this study), except that no material change should be made in capital cost, because the investment per unit of capacity does not change as materially with changes in pressure and temperature, as it does with a change in size. The economic position of pumped-storage capacity would be slightly modified if a British thermal unit value per kilowatt-hour, based on the greatest advancement in the art of designing steam plants, were chosen in the studies. In most individual instances, this type of alternate steam plant would probably justify a smaller capital expenditure for pumped-storage plant than the moderate pressure type.

Assume that the pumped-storage plant or its alternate steam plant will generate at 17.2% load factor in the case of the 65% load factor, and at 10.2% load factor in the 45% case. This would seem to be necessary (see Figs. 8 and 9) if the division of the load is to be such that it will bring about a balance between on-peak and off-peak kilowatt-hours after making allowance for losses. The energy requirements per kilowatt per year would be 1507 and 893 kw-hr. for on-peak generation and 2511 and 1489 kw-hr. off-peak pumping, respectively, for the two cases. The quantity of energy fuel to meet this condition of operation for the various sizes of plants, used in this study, is given in Table 4.

TABLE 4.—QUANTITY OF ENERGY FUEL REQUIRED FOR PLANTS OF VARIOUS CAPACITIES.

The economical limits of capital expenditure for pumped-storage as determined by the rule are given in Fig. 11 (a) and Fig. 11 (b). The data for the curves were determined by using the cost of power from alternate steam plants with different prices for fuel. It is assumed that the off-peak pumping energy is supplied either by run-of-stream hydro-electric plants or base-load steam plants and that the annual fixed charge for the pumped storage is 10.25 per cent.

While this study is not precise and obviously cannot cover an individual situation, it sets with sufficient accuracy the upper limit of capital expenditure for pumped-storage plants of the capacities considered when they are to operate on the top of 65% and 45% system loads having triangular peaks, if the cost of power therefrom is to be just equal to that of similar power from fuel plants. However, pumped-storage plants would not be economically attractive if the power from them was just equal in cost to alternate steam power; it would have to be considerably cheaper than steam power to offset the disadvantage which attaches to a plant that can be used only to "pull" peak loads. A steam plant can always furnish energy up to its capacity by burning sufficient fuel. Consequently, one would not build a pumped-storage plant in lieu of a steam plant unless the estimated capital cost of the pumped-storage plant was well below that which would bring an equality of cost with steam power as indicated by economic study; or unless, where base load is carried by both run-of-stream hydro-electric and steam plants, enough useful secondary power resulting from natural inflow to pumped-storage reservoir or from water pumped by surplus hydro-electric energy, was produced to reduce substantially the quantity of fuel otherwise burned in the base-load steam plants.

Savings resulting from pumped-storage operation in any individual situation may be measured by the difference between the upper limit of capital expenditure per kilowatt of pumped-storage capacity and the estimated cost per kilowatt of capacity in a given instance. For example: Consider a system that has an annual load factor of 65 per cent. Suppose that an increase of 60 000 kw. in capacity is contemplated; that a pumped storage site is available at which power can be developed at a capital cost of \$200 per kw. of peak; that the base load will be carried on hydro-electric plants; and that the current price of coal is \$6 per ton. Under such a set of conditions the 60 000 kw. of additional capacity would be divided into 18 840 kw. to pumped storage and 41 160 kw. to additional base-load water power. The former would operate at a load factor of 17.2% and the latter at 100 per cent. The upper limit of capital expenditure for off-peak energy from run-of-stream hydro-electric plants is \$253 per kw., as given by the curve for the \$6 fuel in Fig. 11 (a). Thus, the saving per kilowatt per year less than what steam peak power would cost at 17.2% load factor is 10.25% of the difference between \$253 per kw. and \$200 per kw., which is the estimated capital expenditure for the pumped storage, or \$5.43 per kw. per year. If this saving, \$102 300 annually, is sufficient to overcome the disadvantages inherent in pumped-storage plants, and not present in steam plants, the pumped-storage plant would be justified.

Similarly, with a system load factor of 45%, off-peak power from base-load steam plants and an estimated cost of \$200 per kw. for the pumped-storage plant, the additional capacity would be divided into 30 900 to pumped storage and 29 100 to base-load steam; the former would operate at a load factor of 10.2% and the latter at 100 per cent. The upper limit of capital expendi-

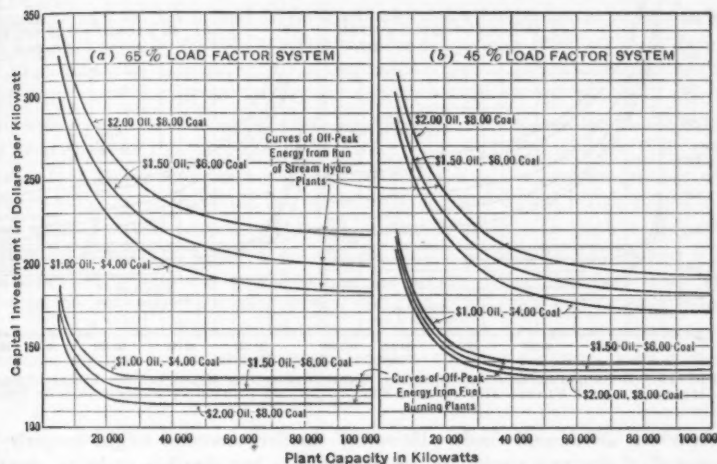

FIG. 11.—ECONOMICAL LIMIT OF CAPITAL EXPENDITURE PER KILOWATT OF INSTALLED CAPACITY.

ture as given by the \$6 coal curve, off-peak energy for steam plants, is \$140 per kw. (Fig. 11 (b)). In this case the excess cost of pumped storage over alternate steam power is 10.25% of the difference between \$200 per kw., the estimated capital cost, and \$140, the limiting capital expenditure, or \$6.15 per

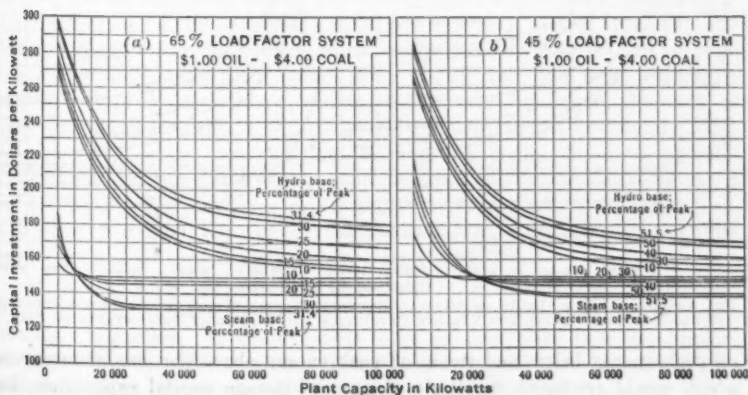

FIG. 12.—ECONOMICAL LIMIT OF CAPITAL EXPENDITURE PER KILOWATT OF PUMPED-STORAGE HYDRO-ELECTRIC PLANTS FOR VARIOUS CAPACITIES AND DIFFERENT PERCENTAGES OF PEAK.

kw. per year (\$190 000 per year). Obviously, this would be an uneconomical development.

Thus far, the discussion has dealt with the maximum amount of peak load that could be carried by pumped-storage plants in the two load-factor

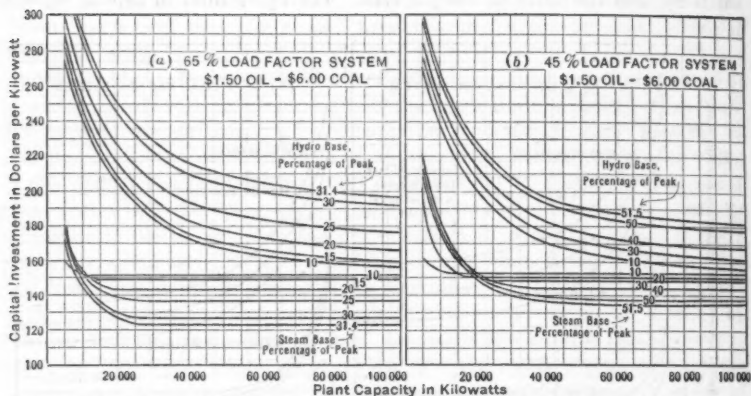

FIG. 13.—ECONOMICAL LIMIT OF CAPITAL EXPENDITURE PER KILOWATT OF PUMPED-STORAGE HYDRO-ELECTRIC PLANTS FOR VARIOUS CAPACITIES AND DIFFERENT PERCENTAGES OF PEAK.

cases on an annual basis. However, smaller amounts might properly be carried if for one reason or another it was not feasible to bring about a balance between the annual on-peak and off-peak energy of a given load to be added to a system. It is convenient to plot other curves, hydro-electric

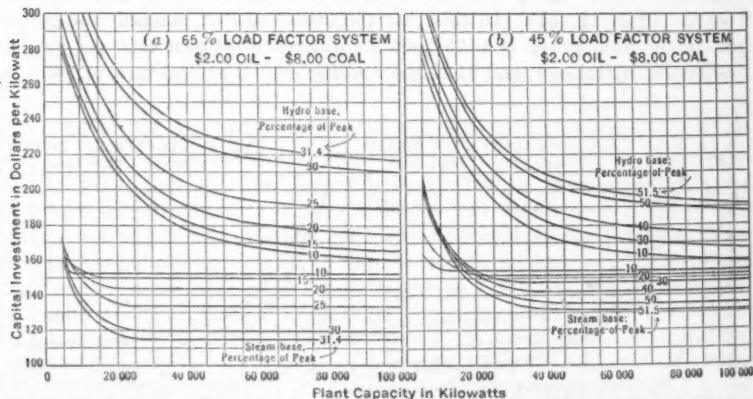

FIG. 14.—ECONOMICAL LIMIT OF CAPITAL EXPENDITURE PER KILOWATT OF PUMPED-STORAGE HYDRO-ELECTRIC PLANTS FOR VARIOUS CAPACITIES AND DIFFERENT PERCENTAGES OF PEAK.

off-peak energy below and steam off-peak energy above the maximum curves, which would represent the limit of pumped-storage capital expenditure for various percentages of the peak less than the maximum percentage at which

annual off-peak and on-peak energy balance obtains. Tabulations are not included herein in this connection, but curves are given in Figs. 12, 13, and 14, for the two load-factor cases and for the three prices of fuel. These curves can be used in a manner similar to that discussed in connection with those in Fig. 11. It must be borne in mind, however, that any "combing" of the peak with pumped storage that is less than that which would bring about a balance of the annual off-peak and on-peak kilowatt-hours would cause the base-load plant to operate at a load factor of less than 100% on some days.

Regarding this last point it is improbable that a pumped-storage base-load plant arrangement could ever be such as to permit the base-load plant to operate at an annual load factor of 100 per cent. The reason for this is that on many days of the year the daily load factor would be greater than the annual load factor and there will be a day which has a greater number of kilowatt-hours than there are in the annual composite day which might be used solely for the purpose of broad economic study. In such a day of maximum energy the division of load to peak and base as determined for the annual composite day would not be the proper division of load in order to effect for the maximum energy day, the desired on-peak and off-peak kilowatt-hour relation. This situation causes a change, perhaps slight, in the economic picture as presented, when using a composite annual load curve. Consequently, a correction must be made to cover this condition.

This is illustrated in Fig. 15, which is a representative part of a 12-month composite daily load curve covering May, June, and July, 1928. The basic data are the same as those used in Figs. 8 and 9. The January curve is the composite January day, the February curve, the composite February day, and the other curves (through May, June, July, etc., to December) are corresponding composite monthly days.

The composite load curves illustrated in this study are made by plotting the half-hourly loads for the period considered (either a year or a month) on a 24-hour base downward during the hours when the load is decreasing, and upward during the hours when the load is increasing. There were plotted 1440 ordinates for the composite curve for a 30-day month (Fig. 15) and 17520 ordinates for the composite curve for a year (Fig. 8). The composite load curve has been found more useful than the more commonly employed "load duration curve" constructed by re-assembling in the order of their decreasing magnitude, the ordinates representing the half-hourly loads for the period under consideration, because the composite curve actually looks like a load curve and closely approximates many of the daily curves; it reveals the distribution of the load throughout the day, which the "load duration curve" does not. For convenience, the ordinates of the composite monthly curves are plotted in percentage of the yearly peak.

By extending the curve in Fig. 15 to include the entire year, the day that would be likely to have the greatest number of kilowatt-hours can be determined by inspection. It would appear to be the composite June day because its peak is less than the maximum, being 95% of it, and the minimum of this composite June day is one of the highest, being 33% of the peak. As a matter of fact, a study of the actual records of the system load for 1928

reveals that the greatest number of kilowatt-hours was generated on June 13, and that the load factor for the day was 74.56 per cent. The actual half-hourly loads of that day, also expressed as percentages of the peak for 1928, were plotted adjacent to the composite June day. Areas *A* and *B*, Fig. 15, which are representative of off-peak and on-peak kilowatt-hours, respectively, for this day of maximum energy, were measured. It was found that the 1 to  $1\frac{1}{3}$  relation was established when 75.8% of the annual peak was placed on the base for this day as contrasted with the 68.6% as determined by the study of the annual composite daily load curve, characteristic of the system in question (see Figs. 8 and 9). The on-peak energy above the 75.8% line, projected across the twelve composite monthly days, is equivalent to that above the

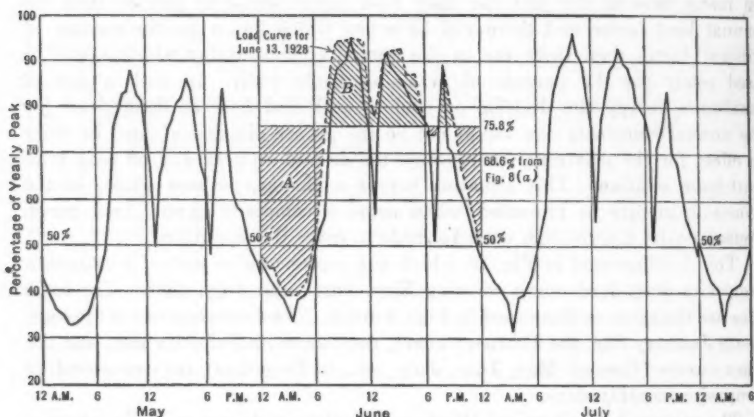

FIG. 15.—REPRESENTATIVE PART OF COMPOSITE DAILY LOAD CURVE FOR EACH MONTH.

75.8% line on the annual composite curve in Figs. 8 and 9. The load factor and percentage of kilowatt-hours from peak will be 8.4% and 3.10%, respectively. These relations are to be determined by the use of a diagram similar to that given on Fig. 10.

The additional curves in Figs. 12, 13, and 14, are particularly useful in that they afford means of determining the economic situation respecting pumped storage if a study of the load curve of an individual day indicates that more load must be carried that day on the base-load plant than is indicated by the study of the annual composite daily load curve. The necessity for considering the maximum energy day becomes apparent when it is remembered that the curves of Fig. 11 are based on a composite daily load curve for the entire year, no actual day of which will be exactly like this composite curve. Moreover, if the curves of Fig. 11 were precisely interpreted they would indicate that storage could be carried over from week to week or month to month in a given year, and this would probably not be the case in actual practice. Curves such as those in Figs. 12, 13, and 14, will then indicate what economic correction, if any, is desirable when load conditions of the

critical day and off-peak energy conversion are to be taken into account entirely on a daily basis.

To make a practical application of these curves, with reference to the example, previously used (60 000 kw. additional load): The division of load would be 24.2%, or 14 520 kw., to pumped storage, and 75.8%, or 45 480 kw., to base load. By reference to Fig. 13 (a) and the hydro-electric base-load curve for 25% of peak from the top, it will be seen that the capital expenditure for a plant of 14 520 kw. capacity should not exceed \$242 per kw. as contrasted to the \$253 per kw. given in Fig. 11 (a). Were such division of the 60 000 kw. additional load to be made, the pumped-storage plant would carry a variable peak throughout the year, operate at an annual load factor of 8.4, and supply 3.10% of the system kilowatt-hours. This detail is given to indicate a procedure which might be used to determine the capital limitations of pumped storage with greater refinement, if the maximum daily load factor is substantially more than that of the annual composite load curve which might have been used in an over-all economic study. The example chosen indicates that the limit of capital expenditure for pumped storage should be reduced about 5% less than that determined without giving consideration to the conditions which obtained for the maximum-energy and load-factor day and those which would prevail under daily instead of period carry-over storage operations.

The curves in Figs. 12, 13, and 14, reveal a number of interesting facts relating to the economics of such peak-load plants:

- 1.—Hydro-electric off-peak power warrants a larger capital expenditure than steam off-peak power.
- 2.—The limit of capital expenditure decreases:
  - (a) With increase in fuel price when off-peak power is supplied from steam plants; and
  - (b) With decrease in fuel price when off-peak power is supplied from run-of-stream hydro-electric plants.
- 3.—As the load factor decreases, the limit of capital expenditure:
  - (a) Increases when off-peak power is supplied from steam plants; and
  - (b) Decreases when off-peak power is supplied from run-of-stream hydro-electric plants.
- 4.—The limit of capital expenditure decreases with increasing plant capacity:
  - (a) With no tendency to become a constant for capacities under 100 000 kw. when off-peak power is supplied from run-of-stream hydro-electric plants, irrespective of the system load factor, the percentage of peak to be pulled, and the price of fuel;
  - (b) With a tendency to become a constant for capacities of more than from 10 000 to 55 000 kw. when off-peak power is supplied from steam plants, depending on the system load factor, the percentage of peak to be "pulled", and the price of fuel.

The economic position of pumped storage depends largely upon the efficiency of the several elements of its physical composition, and the economy of production of off-peak energy. The first point needs no discussion, but with

respect to the second some further comment is in order. The writer has assumed that the total additional load is to be carried by pumped-storage and by modern base-load plants rather than by pumped-storage and old base-load plants. This consideration is of small economic importance in cases where hydro-electric plants are used on the base, because off-peak energy from such plants is regarded as having no value; but it is a factor when the off-peak energy is supplied from old steam plants that have a low economy. Very little capital could be spent per unit of pumped-storage capacity in the latter case, because of the large amount which would be deducted under the rule to allow for the cost of the off-peak energy. This becomes apparent when it is remembered that with many old steam plants the economy is about 30 000 B.t.u. per kw-hr., and because only a few of the old installations have been replaced with modern plants with high efficiencies, the average for all plants of the country is about 20 000 B.t.u.

It is probable that the capitalized value of off-peak energy based upon such economies would reduce the capital which could be spent per unit of pumped-storage capacity, so as to make impossible the building of such plants. However, if physical conditions were so fortunate as to, make it possible to build a pumped-storage plant within a capital sum per unit of capacity that was determined on the basis of using low-economy off-peak energy, the reduction in cost per kilowatt per year (when the off-peak energy was finally supplied on a high-economy basis) would equal the difference between the low and high-economy fuel costs of off-peak energy per kilowatt per year. However, this is not likely to occur when very low-economy off-peak energy is available. For example, a fuel economy of 30 000 B.t.u. per kw-hr., with about \$4 coal, would cause the cost for off-peak energy to be about \$12 and \$7 per kw. per year, respectively, for the 65% and 45% load-factor loads, in turn requiring pumped storage, in order to compete with alternate steam, to be procurable at from \$60 to \$100 per kw. It seems improbable that pumped storage could be built at a cost of \$100 per kw., or less, when that must include all transmission, pumping, generation, and storage facilities.

Low-economy off-peak power will occasionally be used with pumped storage, despite the probability that most pumped storage is likely to be barred if off-peak energy is regularly to be supplied by old steam plants. For example, it might be quite inconvenient to build a complement of base-load steam at the time when it is most necessary to build pumped storage, which estimates showed could be physically accomplished, provided the capital allowance was established on the basis of supplying off-peak energy from a high-economy steam plant. In such a situation the pumped-storage plant might properly be constructed, and for a time operated with off-peak power from old steam plants, with no disadvantage, save that the cost of energy from the pumped-storage plant would be high during the interim pending the completion of the new steam plant. The excess in cost per kilowatt per year would equal the difference between the low and high-economy fuel costs per kilowatt-year.

The best position for pumped storage with steam-electric power is that in which the base load is carried on new high-economy steam plants. This element, that is, the efficiency of operation of the base-load plants, is not

important when the base load is carried on run-of-stream hydro-electric energy, because then, since off-peak energy is considered valueless, pumped storage would have its greatest opportunity and much of it could be built which otherwise might not be feasible where the base load is carried on steam.

Owing to the fluctuating price of fuel, judgment must be exercised in selecting the fuel cost to be used in an economic study. To be on the safe side it would be the part of wisdom, when off-peak power is to come from steam plants, to choose a long-time price of fuel of more than that which might obtain at the time a pumped-storage plant was being considered, if then the price was low; and when off-peak energy is to come from run-of-stream hydro-electric plants, one that was less than that prevailing at the time, if then the fuel price was high. This reasoning follows from the fact that a lowering of the economic limit of capital expenditure for pumped storage, in cases where off-peak energy is supplied from steam plants, comes with an increase in the price of fuel, but if the off-peak energy is supplied from run-of-stream plants, it comes with a decrease in the price.

This generalized study of the economics of pumped storage is methodical only and is intended to be suggestive rather than dogmatic. There are doubtless other ways to portray the situation, particularly if the cost of pumped storage is known. The endeavor herein has been to set up something without a knowledge of the pumped-storage capital costs. Other cost assumptions will show different generalized results. However, it is believed that the curves of capital limit indicate orders of capital cost for pumped-storage plants that cannot be materially exceeded if the resulting cost of power is to be no greater than the current value of power as established by modern, fairly high-economy steam plants. It should not be inferred that this analysis will obviate the necessity for intimate study in individual situations, but it will be helpful in identifying the pumped-storage projects which, in connection with appropriate base-load plants, are worthy of intensive study to determine the cost of mingled energy from a complement of such plants. The method may be used for the purpose of generalizing with other load factors and under the same or other assumed data.

It is apparent to those in the power industry that one must be critically discerning when a determination is to be made in the matter of future power supply. What is desired is the lowest-cost electricity, irrespective of whether it comes from hydro-electric or fuel-burning plants, or from a combination of both. All recognize that, with annual-system load factors which are always less than 100%, there will be an annual economy if the narrow peaks of the system load can be carried by plants which can be built at a very low capital cost per unit of capacity. This applies to almost any kind of a peaking plant.

The future course of power development necessary to carry total loads is, in general, not fully established. At present, steam power appears to be more or less in the ascendant because fuel is cheap and fuel economies are high. On the other hand, the abundance of cheap capital and the economic advantages which accrue by the use of high transmission voltages, causes hydro-electric energy to remain a source of power not to be overlooked, particularly when it is remembered that the price of fuel may be higher in the case of

steam power, and sufficient experience has not been accumulated to determine with certainty the cost of operation and maintenance of modern steam plants; whereas the fixed charges which make up the major costs of hydro-electric power remain fairly stationary over a relatively long period of years. Thus, the time to build hydro-electric plants is when capital is cheap and it is sound business, if capital is readily obtainable, to use hydro-electric power when its cost is equal to or less than that of steam power. However, the economic picture in the hydro-steam scene is a moving rather than a fixed one; consequently, the engineer must be cognizant of economic conditions generally, in order that he may shift from one to the other or to both of these major power sources in delving for reduced costs. Because of the rapidly changing conditions, sound economic analysis is more important in the field of electric generation than it has been heretofore. In conclusion, be it said to the credit of the civil engineer that he is getting a broad grasp of the electric industry and is being increasingly recognized by it as a factor in the field of economic energy production.

WILLIAM W. K. FREEMAN,\* Assoc. M. Am. Soc. C. E. (by letter).—In his discussion, Mr. John R. Freeman cites the proposal made by the late Julius M. Howells, M. Am. Soc. C. E., about 1905, to deliver power to San Francisco at a weekly load factor of 100% so as to cut down the investment in 200-mile transmission lines, fitting this power to the load curve through the action of a pumped-storage plant. This is one of five special applications of pumping which have been proposed to take up the slack between supply and demand. A second application is to the case of a navigable river where no pondage is permissible, in which case off-peak power may be converted into on-peak power in a similar manner. A third example is the proposed use of surplus blast-furnace or coke-oven gas to operate gas pumps of large capacity to store water in the off-peak hours.

In contrast to these cases in which power is available at a constant rate, two other special applications have been proposed to take power when it is available at variable times and deliver it to the load as required. One of these is being planned by Dexter P. Cooper, M. Am. Soc. C. E., at Haycock Harbor, Me., in connection with the Passamaquoddy Bay tidal project. The pumped-storage part of the project involves a reservoir with a net capacity of 13 000 000 000 cu. ft. for 40-ft. draw-down, with a maximum static head of 140 ft. The plant would operate on a monthly cycle, with 195 000 h.p. of pumping and 240 000 h.p. of turbine capacity. The advance beyond present record installations is shown by the proposal, among others, of one manufacturer for combination units, each unit with a turbine of 48 000 h.p. capacity and a pump of 39 000 h.p., delivering 2 700 sec-ft.

The other application is in connection with the development of wind-power plants. While no pumping feature is under consideration in the plans for the first wind-power plant, the engineers developing the plant have recognized the possibilities of a combination of wind power and pumped storage to convert off-peak into on-peak power.

\* Asst. Engr., New England Power Constr. Co., Boston, Mass.

The discussion by Mr. Foster is valuable in pointing out the use of the mass diagram (Fig. 7) in the solution of pumping problems, and because he looks upon the addition of pumping equipment as one of a number of possible methods of developing power in a certain locality, and gives a clear picture of its economics.

Mr. Reed has added descriptions of four plants to the list of those built. The writer was already indebted to him for his description of Lüner Lake and three others.\* Mr. Reed's emphasis on the stand-by feature of pumping plants in Germany is in line with the point of view in this country for some of the proposed developments. The rapid progress of interconnection in the United States, however, probably removes this development of pumping plants to a later date when the older steam plants which are now held in reserve, will have been scrapped.

Mr. Heslop also emphasizes the reserve value of pumping plants. As a matter of fact, the first use of the Rocky River Plant was as a reserve plant, because as soon as the operating engineers of The Connecticut Light and Power Company were informed that the plant was ready for limited service, even before the reservoir was filled, the operation of reserve boilers at the Devon Steam Plant was discontinued.

Mr. Markwart's discussion is exceptionally valuable because it includes curves of justifiable investment cost for plants of the pondage type. These curves can be used as guides to determine which projects are worth further investigation and which are obviously uneconomical. The writer's experience, while limited, bears out the statement that, "because of the remarkable over-all efficiency of modern steam plants, pumped-storage plants will be of no value as an aid to composite economy in power production unless the capital cost per kilowatt of installed capacity is relatively low".

The curves, Figs. 11, 12, 13, and 14, show the limiting cost to be about \$120 to \$150 per kw. for systems with base-load plants burning coal that costs, respectively, \$4 to \$8 per ton. In October, 1929, Professor Dr.-Ing. D. Thoma, Director of the Hydraulic Institute, Technische Hochschule, Munich, gave the limiting cost in Germany as \$80 per h.p., equivalent to \$113 per kw., which checks roughly Mr. Markwart's figures.

Since projects costing only \$120 to \$150 per kw. are rare, Mr. Markwart's calculations bear out the writer's opinion that pumping plants of the pondage type do not appear to be as attractive as those of the storage or part-head types, unless perhaps they are built in conjunction with existing developments. It is the storage feature of Rocky River which makes it economical in spite of the comparatively low total head through which the stored water is used; this head averages 285 ft., excluding old hydro-mechanical developments. The Rocky River plant has several other advantages, moreover, which help to make it economical; the water supply for its pumps is drawn from a drainage area of 1 037 sq. miles, and the power house is as close to the load center as is the base-load steam plant at Devon; that is, about 30 miles. Certain features of topography are also in its favor;

\* See p. 902, Reference (9).

the reservoir basin was partly swamp and abandoned farm land, and the fall of the Rocky River is largely concentrated into the mile above its mouth, so that the total volume of earth in the dam and dikes is only 750 000 cu. yd.

The exceptional value of plants of the pondage type for emergency service may in time make them more attractive, but at present capacity is "a drug on the market" in many localities because of the rapid progress of interconnection which has made many small steam plants available for stand-by service.

The writer was able to check points on Mr. Markwart's curves of justifiable investment cost by following the usual method of comparison with an alternate steam plant, as outlined by the writer and amplified by Mr. Markwart under his six premises. Mr. Markwart states that his study is methodical only, and warns against using his curves for individual situations. This warning the writer would emphasize by adding that even for a certain power system at least one change in the method of analysis appears to be necessary.

This relates to the sizes of hydro-electric and steam plants assumed to be alternative. Mr. Markwart states that,

"In the case of a small pumped-storage plant a relatively high capital expenditure per kilowatt of capacity would be justified because its alternate steam plant would have a high capital cost and a relatively low fuel economy."

Throughout his discussion of capacities, steam pressures, and fuel economy, Mr. Markwart assumes that these must be selected for a steam plant of the same size as the pumping plant under discussion. This is true only in the broadest generalization, because the selection of capacity for a pumping plant depends essentially on the topography, while selection of capacity, etc., for a steam plant depends on the characteristics of the system and the rate of growth of its load. Thus, for a system in which 50 000-kw. steam units are being installed, the capacity, steam pressure, fuel economy, operation and maintenance charges, and load factor must be that of the 50 000-kw. alternative steam unit whether the pumping plant is of 5 000 or of 200 000 kw. The difference in interest charges on unused capacity until the larger of the alternative plants is fully loaded, is applied to the construction cost in arriving at the justifiable investment.

Another change in the method of analysis which would be necessary for a particular case would be the inclusion of an increment operation and maintenance cost in addition to the coal cost given by Mr. Markwart in Table 4, in calculating the energy charges of an installation. This cost is made up of coal storage and boiler and turbine maintenance; it equals about 0.3 mill per kw-hr. in a plant of 250 000 kw. capacity, and probably more for smaller plants. A closer analysis would also require the selection of economies, as given in Table 4, not only for size of plant, but also for load factor, instead of using one figure for everything from 10 to 100% load factor.

In conclusion, there are a few matters to be mentioned to bring the subject more nearly up to date. The Rocky River pumps, which were guaranteed to have 87% efficiency, have been tested since installation and a maximum efficiency of 91.9% was obtained with both pumps running under a dynamic

head of 230 ft. This is far more than the previous maximum of 85% obtained at Schwarzenbach, Germany.

The term, "pumped-storage plant," has found a certain measure of acceptance. The ambiguous term, "hydraulic accumulator," has been observed only in a digest of a German article translated too literally. Other terms which have been proposed as a substitute for the writer's "pumped storage" (which is a free translation of "Pumpen-Speicherkraftwerk") are: (1) "Water storage battery"; (2) "hydro-regenerating plant"; and (3) "pumping plant". The first of these might be considered ambiguous because of its possible association with a wet-cell electric storage battery, and the second lacks the brevity of the third. The writer inclines to "pumping" instead of "pumped storage" because of its brevity, where it is obvious what kind of pumping plant is meant.

Three important additions to the bibliography should be noted. Joel D. Justin, M. Am. Soc. C. E., has presented a paper\* entitled, "The Rocky River Plant of the Connecticut Light and Power Company"; and Paul L. Heslop, M. Am. Soc. C. E., a paper† entitled, "A Hydro-Electric Plant That Pumps Its Own Water Supply—The Rocky River Hydro-Electric Plant." Mr. Heslop has also written an article‡ on the Rocky River pumps entitled, "Two 8100 H.P. Pumps Supply Water for Power Generation".

### THE GRAPHICAL SOLUTION OF A CORRELATION TABLE\*

By WESTON S. EVANS,† ESQ.

WITH DISCUSSION BY MESSRS. WALTER H. DUNLAP, ROBERT C. STRACHAN, S. L. MOYER, THEODORE HATCH, B. F. JAKOBSEN, AND WESTON S. EVANS.

#### INTRODUCTION

To the engineer the graphical solution of any problem is interesting and welcome. It also seems that the solution of a correlation table‡ for Pearson's product-moment coefficient is to him a thing to be avoided whenever possible; but the time is long past when statistical methods should have been accepted and earnestly put to use by the engineer.

The objects of this paper are three: First, to present a correlation table in a new light; second, to offer graphical methods which may be used for other but similar purposes; and, third, to provide a short method for obtaining means, standard deviations, and possibly correlation coefficients for those to whom computing machines are not available, but who are experienced draftsmen.

#### METHODS

The methods described apply to data consisting of two variables which bear a relationship to each other. The problem involved is to determine the degree of this relationship as measured by the correlation coefficient.

The correlation table shown in Fig. 2 was made from data consisting of the 7-day tensile ratios and the 28-day tensile ratios for mortars using 147 sands. For any sand the ratio is found by dividing its strength by that for

\* Published in January, 1929, *Proceedings*.

† Asst. Prof., Civ. Eng., Univ. of Maine, Orono, Me.

Ottawa sand made with the same cement at the same time. These ratios were multiplied by 100, thus expressing them as percentages.\*

The 7-day ratios are plotted on the horizontal axis and the 28-day ratios on the vertical axis. For convenience, the arrays are numbered consecutively from 1 to 12, beginning in the upper left-hand corner. For the present purpose the numbers in the centers of the squares must be assumed to represent units of force acting at the center of the square. The numbers at the bottom of the diagram would then represent the units of force acting vertically in the respective columns, and the numbers at the right side represent units of force acting horizontally in the respective rows.

The mean value of  $X$  and the mean value of  $Y$  must first be obtained. This is easily accomplished by applying the method for finding the resultant of any system of forces.†

The next constants sought will be the standard deviations of the  $X$  and  $Y$ -values. The standard deviation of  $Y$  ( $S. D. y$ ) is found by obtaining the summation of the products of the units of force and the squares of the distances from the mean  $Y$ -line, dividing by the number of units in the table,

and extracting the square root. To the engineer this means  $\sqrt{\frac{\sum (A y^2)}{\sum A}}$ , in

which,  $A$  may be replaced by  $n$  where  $n$  is the number in any given square, and  $y$  is the distance from the center of the row containing the square to the Mean- $Y$  line. The standard deviation of  $X$  ( $S. D. x$ ) is obtained in a similar manner.

To find the value of  $\sum (A x^2)$ , let  $O X$  be the  $X$ -axis and  $O Y$  the  $Y$ -axis (Fig. 1) and assume that the area,  $A$ , is able to exert a force of  $A$ -units parallel to either axis.

Lay off the vector, 0-1, to represent  $A$  to some given scale. Choose a point,  $p$ , any perpendicular distance, such as  $H_x$ , from 0-1 and draw 0- $p$  and 1- $p$ . Draw a line through  $A$  parallel to  $O Y$ . From any point,  $m$ , on this line, draw  $a-m$  parallel to 1- $p$ , and then  $m-b$  parallel to 0- $p$ . Now, chose a pole,  $p'$ , any perpendicular distance, such as  $H_y$ , from  $a-b$  and draw  $a-p'$  and  $b-p'$ . Draw  $f-n$  parallel to  $a-p'$  and  $n-e$  parallel to  $b-p'$ . Then,

$$A x^2 = (e-f) \times H_y \times H_x \dots \dots \dots (1)$$

The proof follows: Triangle  $p 0 1$  is similar to Triangle  $a m b$ , and Triangle  $p' a b$  is similar to Triangle  $f n e$ . In the first pair of triangles:

$$0-1 : H_x = a-b : x$$

or,

$$(0-1) \times x = H_x \times (a-b)$$

But,

$$(0-1) \times x = A \times x = H_x \times (a-b)$$

$$a-b = \frac{A \times x}{H_x}$$

\* For information concerning similar data, see, *Bulletin No. 10*, Maine Technology Experiment Station.

† See "Graphical Analysis," by William S. Wolfe, McGraw-Hill Book Co.

As shown,  $A \times x = (a-b) \times H_x$ . Then,

$$A \times x \times y = (c-d) \times H_x \times H_y \dots \dots \dots (3)$$

In the correlation table to be solved (Fig. 2), the ordinate for  $\Sigma (nxy)$  for each row may be found at once and these may be added, provided the  $H_x$  and  $H_y$  remain the same for all the rows. Then,  $\Sigma nxy$  for the the whole diagram may be found by multiplying this total ordinate by  $H_x$  and  $H_y$ , all values being measured to the proper scale.

One of the most difficult features in applying these methods to a larger problem is the choice of scales, two of which are used, namely, the scale of percentage and the scale of numbers. On Figs. 2, 4, 5, 7, 8, 10, and 11, all measurements are made to the scale of percentage, that is, a given length represents a certain percentage. In Figs. 3, 6, and 9, all measurements are made to the scale of numbers and a given length represents a number of units. Table 1 will be helpful in following the demonstration.

TABLE 1.

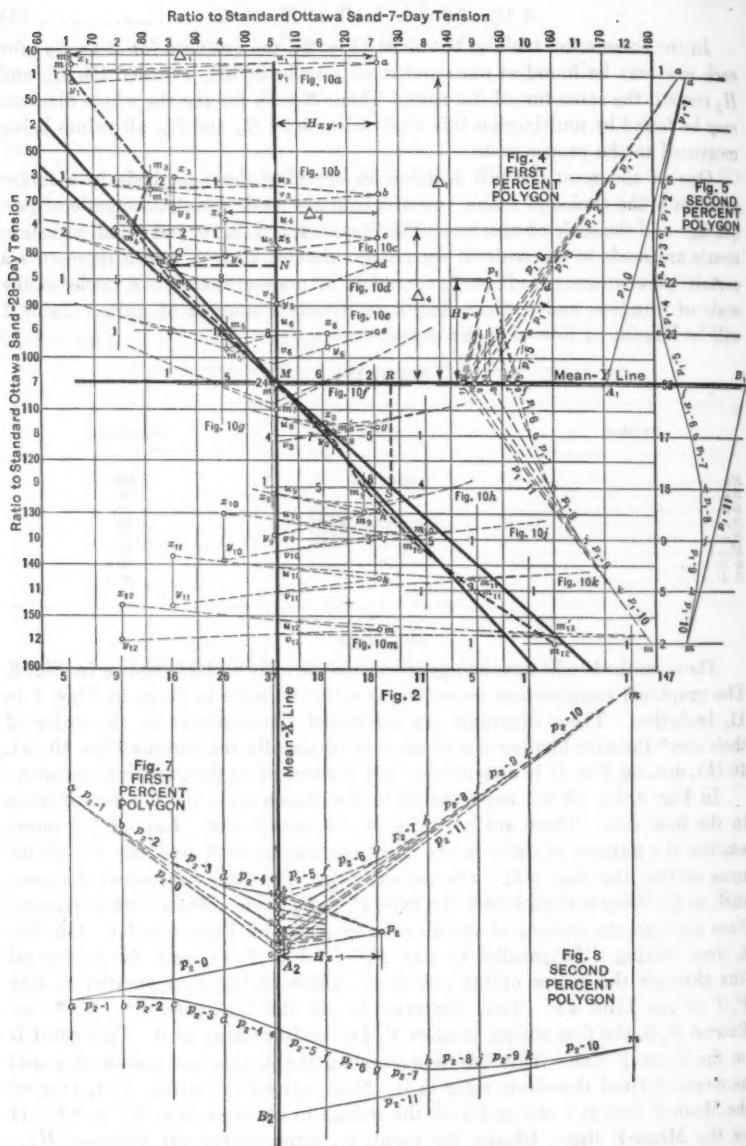

Symbol.	Scale.	Magnitude.

$H_{xy-1}$ .....	"	20
S. D. $y$ .....	"	20.0
S. D. $x$ .....	"	20.1

# SOLUTION

These methods will now be applied to the correlation table shown in Fig. 2. The graphical construction necessary to solve the table is given in Figs. 3 to 11, inclusive. These diagrams are numbered consecutively in the order of their use,\* the over-lapping one of another (especially the various Figs. 10 (a), 10 (b), etc., on Fig. 2) is unavoidable and is essential to the graphical accuracy.

In Fig. 3, lay off 0-1 representing to the chosen scale the number of units in the first row. There are no units in the second row. Lay off 1-2 representing the number of units in the third row and proceed similarly for all the rows getting the line, 0-11. Choose any point,  $P_1$ , some convenient distance, such as  $H_y$ , from 0-11 and draw the rays,  $P_1-0, P_1-1$ , etc. Next, draw horizontal lines through the centers of all the rows as shown on Figs. 4 and 5. On Fig. 4, draw String  $P_1-0$  parallel to Ray  $P_1-0$  of Fig. 3, to meet the horizontal line through the center of the row at  $a$ . Draw String  $P_1-1$  parallel to Ray  $P_1-1$  to get Line  $a-b$ . Thus continue to get the line,  $a-b-c$  \* \* \*  $m$ . Extend  $P_1-0$ , the first string, to meet  $P_1-11$ , the last string at 0. This point is on the Mean-Y line. This line now becomes the X-axis and values of  $y$  and moments derived therefrom refer to it. Next, extend the string,  $P_1-1$ , to meet the Mean-Y line at 1 and so for all the strings to get the points, 0-1-2- \* \* \* 11 on the Mean-Y line. Choose the point,  $p_1$ , some convenient distance,  $H_{y-1}$ ,

\* In actual practice Figs. 3 to 11 would best be drawn on a single sheet for graphical comparison; for convenience, they are separated here into two groups, which, however, should be considered jointly.

from this line and draw Rays  $p_1-0$ ,  $p_1-1$ , etc. In Fig. 5 draw String  $p_1-0$  parallel to Ray  $p_1-0$  of Fig. 4 and get Line  $a-A_1$ ; then, draw a string parallel to  $p_1-$  and get  $a-b$ . Continue this procedure until  $m-B$ , is obtained. The value,  $A_1-B_1$ , is used to obtain the standard deviation.

In Fig. 3, lay off  $C_1-D_1$  parallel to 0-11 and equal to  $H_{y-1}$  in Fig. 4. Through  $P_1$  draw a line,  $F_1-E_1$ , perpendicular to  $C_1-D_1$ , so that  $P_1-E_1$  is equal to  $A_1-B_1$  in Fig. 5. With  $F_1-E_1$  as a diameter, draw the semi-circle,  $F_1-G_1-E_1$ . Then, through  $P_1$  draw  $P_1-G_1$  perpendicular to  $F_1-E_1$ . This line,  $P_1-G_1$ , gives the standard deviation of  $Y$  when measured to the  $Y$ -scale on the diagram.

The proof follows: By construction, Triangle 0-11- $P_1$  is similar to Triangle  $P_1-C_1-D_1$ . Then,

$$0-11 : H_y = C_1-D_1 : F_1-P_1.$$

But 0-11 = number of individuals in the table =  $N$ ; and  $C_1-D_1 = H_{y-1}$ . Therefore,

$$N : H_y = H_{y-1} : F_1-P_1$$

or,

$$N (F_1-P_1) = H_y \times H_{y-1} \dots \dots \dots (4)$$

From Equation (1) and the theorem derived therefrom,

$$\Sigma n y^2 = (A_1 - B_1) H_y (H_{y-1})$$

in which,  $n$  is the number in any square and  $y$  is the distance from the Mean- $Y$  line to the center of this square. This is seen to be true, as the ordinate,  $A_1 - B_1$ , may be divided into a large number of smaller ordinates exactly comparable to the ordinate  $e-f$  in Equation (1). This division may be made by extending the strings in Fig. 5 to meet the Mean- $Y$  line. By construction,  $P_1 - E_1 = A_1 - B_1$ ; therefore,

$$\Sigma (n y^2) = (P_1 - E_1) H_y H_{y-1}$$

Substituting the value of  $H_y H_{y-1}$  of Equation (4),

$$\Sigma (n y^2) = (P_1 - E_1) N (F_1 - P_1)$$

or,

$$\frac{\Sigma (n y^2)}{N} = (P_1 - E_1) (F_1 - P_1)$$

But,

$$S. D. y = \sqrt{\frac{\Sigma (n y^2)}{N}} = \sqrt{(P_1 - E_1) (F_1 - P_1)}$$

From plane geometry,  $P_1 - G_1$  is a mean proportional between  $P_1 - E_1$  and  $F_1 - P_1$ . Therefore,

$$P_1 - G_1 = \sqrt{(P_1 - E_1) (F_1 - P_1)} = S. D. y$$

The mean value of  $X$  and the standard deviation of  $X$  may be obtained in the same manner using the columns instead of the rows. This construction is shown in Figs. 6, 7, and 8. Values of  $x$  refer to the Mean- $X$  line as an axis and the intersection of the Mean- $X$  and Mean- $Y$  lines, marked  $M$ , is the origin.

The value,  $\Sigma n x y$ , is known as the product of inertia, the observations being considered as having weight. This may be simplified by finding  $\Sigma n x$  for each row (Fig. 2) and multiplying it by the  $y$  for this row indicated by  $A_1$  for the first row and  $A_4$  for the fourth row. The  $y$  for other rows is not shown. In Fig. 9, lay off 0-1 to represent the number of units in the first square of the first row. There being no other units in this row, this part of Fig. 9 is now complete. Choose any point,  $a$  (Fig. 9), some convenient distance from 0-1, as  $H_{xy}$ , and draw Rays  $a-0$  and  $a-1$ . In Fig. 10 (a), assume  $m_1'$  anywhere on the center line of the first square and draw String  $m_1' - v_1$  parallel to Ray  $a-0$  of Fig. 9 and String  $m_1' - u_1$  parallel to Ray  $a-1$ . In general,  $u_1$  and  $v_1$  are the points on the Mean- $X$  line where it is intercepted by the first and last strings, and  $m_2'$  is the intersection of the first and last strings, thus locating the mean value of the observations in the row under consideration. For purposes to be explained,  $m_1$  is located directly under  $m_1'$ , and on the center of the row. This line,  $u_1 - v_1$ , when multiplied by  $H_{xy}$ , using proper scales, gives the moment of this unit about the Mean- $X$  line, or  $\Sigma n x$ , for this row.

It is now desired to obtain  $\Sigma n x y$  or  $\Sigma n x A_1$ .  $\Sigma n x$  may be represented by  $u_1 - v_1$ . In Fig. 10 (a) choose some point,  $a$ , any convenient distance, such as  $H_{xy-1}$ , from the Mean- $X$  line. Then,  $a - u_1 - v_1$  becomes a force polygon in

the ordinary meaning of the word. By modifying somewhat the theorem for simple moment, an intercept between strings drawn parallel to Rays  $a-u_1$  and  $a-v_1$ , on a vertical line a distance,  $\Delta_1$ , from  $a$ , will give the result sought. Extend  $a-u_1$  and  $a-v_1$  to get the points,  $x_1$  and  $y_1$ , these points being located so that  $x_1-y_1$  is parallel to the Y-axis and so that the perpendicular distance from  $a$  to  $x_1-y_1$  (Fig. 10 (a)), equals  $\Delta_1$ .

From the theorem for simple moment:

$$(u_1-v_1) H_{xy} = \sum n x$$

$$(x_1-y_1) H_{xy-1} = (u_1-v_1) \Delta_1$$

By construction,  $y = \Delta_1$ ; therefore,

$$\sum (n x y) \text{ for the first row} = (x_1-y_1) (H_{xy}) (H_{xy-1})$$

Although the procedure for all the rows is the same, one with a larger number of units will be used to demonstrate. Consider the fourth. In Fig. 9, the distance, 5-6, represents to scale the two units in the first square of this row; 6-7, the two units in the second square; 7-8, the two units in the third square; and 8-9, the single unit in the fourth square.

The point,  $c$ , is chosen so that its distance from the number line, 0-38, is the same as that of  $a$ , or  $H_{xy}$ . All these points,  $a, b, * * * m$ , must be so located. Now, draw Rays  $c-5, c-6, c-7, c-8$ , and  $c-9$ . In Fig. 10 (c) start preferably so that  $m_4'$  will fall in Row 4 and draw strings parallel to the corresponding rays in Fig. 9 as for any space polygon. The first and last strings produced will intersect at  $m_4'$ , locating the mean of the observations in this row. This point projected upward to the center of the row gives the point,  $m_4$ , which corresponds to  $m_1$  for Row 1. The first and last strings produced to meet the Mean- $X$  line gives the points,  $u_4$  and  $v_4$ . Through  $c$ , Fig. 10 (c), located as was  $a$  in Fig. 10 (a), draw  $c-u_4$  and  $c-v_4$ , and extend these lines to get the points,  $x_4$  and  $y_4$ , these points being so located that Line  $x_4-y_4$  is parallel to the Y-axis and a perpendicular distance from  $c$  equal to  $\Delta_4$ .

This construction is similar to that for the first row, hence the intercept,  $x_4-y_4$ , when measured to the proper scale and multiplied by  $H_{xy}$  and  $H_{xy-1}$  will give  $\sum n x y$  for this row. Since  $H_{xy}$  and  $H_{xy-1}$  are made constant for all the rows, the ordinates may be added and the multiplication made in one operation. This is shown in Fig. 11. It should be noted that  $\sum n x y$  for the seventh row is zero, since the first and last strings intersect on the Mean- $X$  line.

With  $\sum n x y$ ,  $S. D. x$ ,  $S. D. y$ , and  $N$  known,  $r$ , may be found. In this case, from Fig. 11,

$$\sum x y = (X_1-y_{12}) (H_{xy-1}) (H_{xy}) = 66.4 \times 20 \times 40 = 53120$$

Then,

$$r = \frac{\sum x y}{N \times S. D. x \times S. D. y} = \frac{53120}{147 \times 20.1 \times 20} = 0.900$$

This denotes a high relationship and shows that, in general, those sands having a high 7-day tensile ratio will have a high 28-day tensile ratio. This conclusion could have been reached by inspection, but the absolute value of the

relationship could not be found for further use or for comparison with other results.

The regression lines are readily drawn by graphical methods. Points  $m_1, m_2$ , etc., have been located on the mean value of the rows. A broken line joining these points is called the "raw regression line", and the straight line that best fits this broken line is called the "mean regression line" (see Fig. 12). This line shows how  $x$  regresses on  $y$ . A given set of observations having identical  $y$ -values would not have identical  $x$ -values, but there would be considerable range or spread. For example, referring to Fig. 2, it may be seen that those briquettes having 28-day tensile ratios between 70 and 80% had 7-day tensile ratios ranging from 60 to 100 per cent. It would be expected, however, that the mean of the 7-day tensile ratios for this row would be about 80%, as indicated by the mean regression line.

If the mean of the  $x$ -values in any row had been plotted instead of the actual values, these points would have fallen nearly on a straight line, and the facts sought for might have been found approximately without the aid of correlation. Unfortunately, this has been done by many investigators, but the procedure is wrong, for the cause of this spread may be the solution of the problem and as soon as averaging begins the cause is buried never to be uncovered. The raw regression line must be plotted to determine the linearity of the variation, but a study should be made of the entire data, not of a few average results. The mean regression line of  $x$  on  $y$  may be drawn as follows:

Designate the point of intersection of the mean lines as  $M$ . From  $M$  lay off a distance,  $M-N$ , on the Mean- $X$  line equal to  $\frac{S. D. y}{r}$ . At  $N$  erect a perpendicular,  $N-Q$ , equal to  $S. D. x$ .  $Q-M$  is the mean regression line sought. This is seen to be correct from the regression equation,

$$x = \text{Mean-}X - r \frac{S. D. x}{S. D. y} (\text{Mean-}Y - y)$$

This may be stated as,

$$x = \text{Mean-}X - S. D. x \frac{(\text{Mean-}Y - y)}{\frac{S. D. y}{r}}$$

$$\text{Now, when } (\text{Mean-}Y - y) = \frac{S. D. y}{r}, \text{ or } y = \text{Mean-}Y - \frac{S. D. y}{r},$$

$$x = \text{Mean-}X - S. D. x$$

This point  $(x, y)$  has thus been located. The other raw regression line, that of  $y$  on  $x$ , must be located by finding the centers of the columns in the same manner as the centers of the rows. To locate the corresponding mean regression line, lay off on the Mean- $Y$  line, a distance,  $M-R = \frac{S. D. x}{r}$ .

Then, lay off an ordinate,  $R-S$ , perpendicular to  $M-R$  and equal to  $S. D. y$ . This locates the desired regression line,  $M-S$ . Predictions may be made from these lines.

While this method of studying widely variable data will appeal to only a few people, it should be remembered that graphical methods have not gone through the process of evolution experienced by arithmetical methods. Furthermore, good draftsmanship is required to make the method a success. While the solution of  $r$  will increase in difficulty as the number of units in the table increases, principally because of the determination for  $\sum nxy$ , the solution for the standard deviations is affected but little, and the method of plotting the mean regression lines is not affected at all.

The accuracy of the results will depend to a large extent on the scales used. However, careful work and ordinary size drawings should give results accurate to the third decimal place. Where pictorial results are required, these methods should prove very satisfactory.

For purposes of comparison the arithmetical solution is shown on Fig. 12. To the right of the diagram, which is similar to that shown in Fig. 2, are various numerical values. In Column (1), for example, will be found the number of observations,  $N$ , falling in each row. In the graphical solution, the Mean- $X$  line was used for a  $Y$ -axis; hence,  $\sum nx$  for the table was zero. This is the ideal method, but for a mathematical solution it would necessitate replotting the table or at least a tedious process of getting variations from the mean with which to obtain the required summations. It is much easier to assume an origin and, after the mean values are found, change the results by the use of a transfer formula.

For convenience, the  $Y$ -axis should be chosen so that  $x$ -values will be as small as possible, but not negative. It will be assumed to pass through the center of the first column as indicated on Fig. 12. The same results are obtained with much less work if  $x$  and  $y$  are expressed in terms of class interval, or, in this case, units of ten, rather than in percentage; that is, the difference between the center of the first column and the center of the second would normally be ten, but is used as unity. For the present the numbers along the axes have lost their meaning. Consider the fourth row for illustration. Taking the observations in each column in order from left to right,  $\sum nx$  for the row becomes,  $(2 \times 0) + (2 \times 1) + (2 \times 2) + (1 \times 3) = 9$ , the result found in Column (2), Fig. 12. Values in Column (3) are the means of the observed values in the respective rows and correspond to the points,  $m$ , in Fig. 2.

At the bottom of the table are seven rows which correspond to the seven columns at the right, except that the  $x$ 's and  $y$ 's are interchanged. The results are the same, except in Row 2 where the mean values for the columns are found instead of the mean values of the rows. The summations are now complete.

The standard deviations of  $x$  and  $y$ , also the correlation coefficient, are found as indicated on Fig. 12. These standard deviations and the means are, however, in terms of class interval rather than percentage. The true  $S. D.$  is equal to the  $S. D.$  as found, multiplied by the class-interval. Therefore:

$$S. D. x = 2.008 \times 10 = 20.08\%$$

$$S. D. y = 2.002 \times 10 = 20.03\%$$

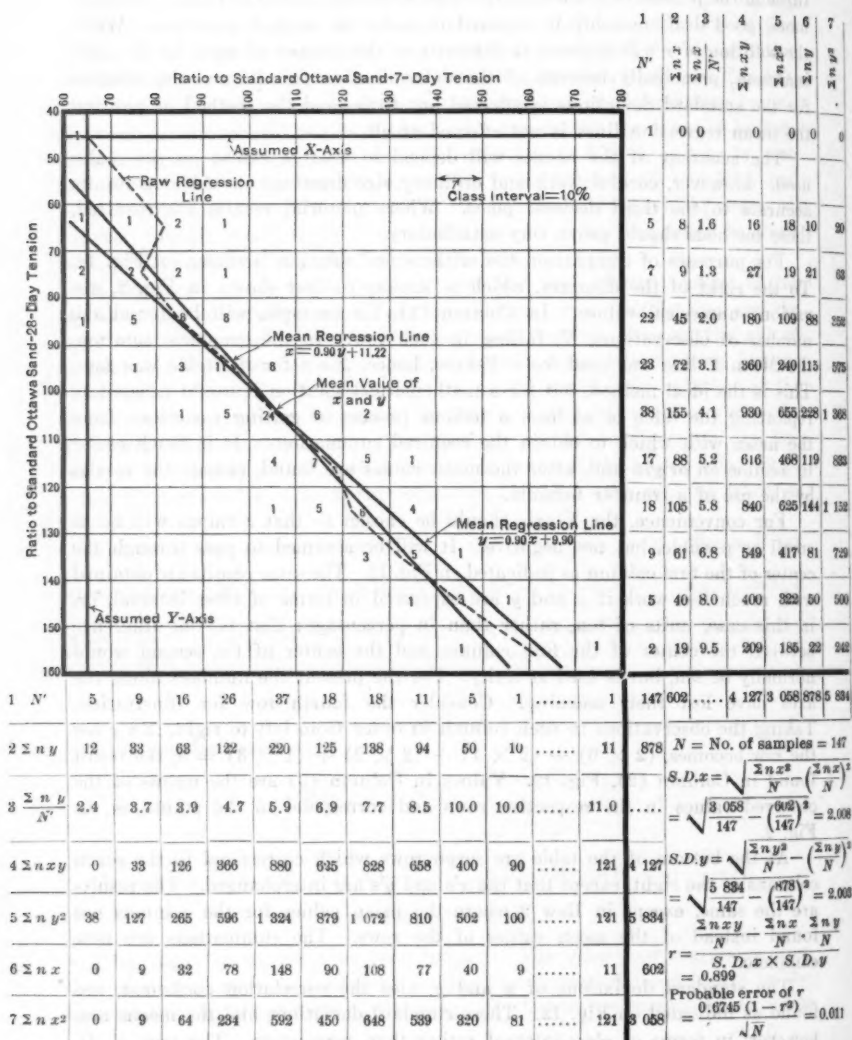

FIG. 12.—ARITHMETICAL SOLUTION OF A CORRELATION TABLE.

The true mean is equal to the mean as found, multiplied by the class-interval, plus the interval between the assumed axis and the true axis passing through 0, 0 (outside the limits of Fig. 12);

$$\text{Mean-}X = (4.095 \times 10) + 65 = 105.95\%$$

$$\text{Mean-}Y = (5.973 \times 10) + 45 = 104.75\%$$

These true values must be used to obtain the mean regression lines.

The raw regression line of  $x$  on  $y$  is drawn by plotting the values in Column (3), Fig. 12, in the respective rows and connecting the points. The raw regression line of  $y$  on  $x$  is drawn by plotting the values in Row 3 in the respective columns and connecting the points.

The mean regression line of  $x$  on  $y$  is given by:

$$x = \text{Mean-}X - r \frac{S. D. x}{S. D. y} (\text{Mean-}Y - y) \dots \dots \dots (5)$$

referred to the origin at 0, 0.

If this be referred to the intersection of the mean lines as an origin, it becomes  $x = r \frac{S. D. x}{S. D. y} y$ , and if the  $S. D. x = S. D. y$  as it does, practically, in this case,

$$x = r y \dots \dots \dots (6)$$

Here is seen a tangible meaning for the value of  $r$ .<sup>\*</sup> It is the slope of a line, for should the standard deviations be unequal this obstacle may be overcome by arranging scales so that, graphically, the two standard deviations will be represented by the same length of line.

The other mean regression line is, in the first form,

$$y = \text{Mean-}Y - r \frac{S. D. y}{S. D. x} (\text{Mean-}X - x) \dots \dots \dots (7)$$

or, in the simple form,

$$y = r x \dots \dots \dots (8)$$

For the table (Fig. 12) as made, the first form should be used, giving the following equations:

$$x = 0.90 y + 11.59 \dots \dots \dots (5a)$$

$$y = 0.90 x + 9.74 \dots \dots \dots (7a)$$

Apparently, it is common practice among engineers to average results and consider as their data what is actually only one raw regression line. It may be seen that the equation derived will depend somewhat on how the data are averaged. The means of the rows give different results from the means of the columns. If it is desired to predict 28-day ratios from 7-day ratios, then Equation (7a) must be used; but if it is desired to predict 7-day ratios from 28-day ratios, then Equation (5a) must be used. Present methods probably would place the line between these two, and the results would be in error accordingly. Under any circumstances it would seem that the usual practice—plotting the data, drawing the best looking line the equation of which may be easily obtained, and calling this good enough—should be abandoned.

<sup>\*</sup> This relationship was first stated by Francis Galton about 1880.

The mathematical solution is now complete. About four hours should be required to solve the table completely by either method.

#### CONCLUSION

The first purpose of this paper was to present the correlation table in a new light. It has been shown that the term called "standard deviation" may be obtained by those same methods by which for many years engineers have evaluated the radius of gyration of any shape. The  $\Sigma nxy$  is known to the Engineering Profession as the product of inertia, and means are located as is the center of gravity. With the regression lines plotted, the table may be used very readily to predict one quantity from a known value of a related quantity.

The second purpose of the paper was to present graphical methods which might be used for similar purposes, such as to find centers of gravity, moments of inertia, and products of inertia of irregular areas which are not handled easily by any other method.\*

The third purpose of the paper was to offer a short method to obtain means and standard deviations. Where the table must be drawn, and where frequency curves and regression lines are required, it is believed that this method will prove efficient, as the extra work for completing the solution will not be great.

---

\* These methods are treated in the text referred to in the foot-note on p. 937, with the exception of the product of inertia.

## DISCUSSION

WALTER H. DUNLAP,\* ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a well written exposition of the application of graphical methods to a statistical problem, but the writer thinks that while the graphical solution has certain advantages, they are not great enough to make up for the additional time required.

The writer believes that Professor Evans has over-estimated the time required for the arithmetical method. Dr. Frank McG. Phillips, of the U. S. Bureau of Education, has solved this problem by arithmetic in 20 min., using one and one-half sheets of letter-size paper. While it is not fair to assume that the time required for an expert is normally to be expected in every case, the writer believes that 4 hours is too long.

The advantage of the graphical solution is in the understanding and grasp derived of the problem of correlation while learning about this method of analysis; but after having acquired a fairly good understanding of the method, the regular run of such problems may best be solved by the arithmetical method with the aid of a computing machine. In college the graphical solution is used in the design of a plate girder or a Pratt truss, but the practicing bridge engineer uses the arithmetic method for such a standardized problem. The correlation problem presented by Professor Evans is in much the same category. It is a job to be turned over to an assistant or a computer the same as the computation of the closure and area of a survey of a boundary would be. In fact, some of the computing-machine manufacturers have perfected and are selling a correlation computing machine. However, it is designed for the computation of correlations between time series rather than frequency distributions.

In Professor Evans' problem, the lines of regression are straight and the coefficient of correlation is unusually high. In a problem in which the correlation table clearly indicates a curved line of regression, the writer wonders how the graphical solution would be modified and whether it would show an advantage over the arithmetic solution. For example, suppose the raw regression line (Fig. 12) in the problem had shown a much more pronounced tendency to curve up at the ends than it does, thus indicating the necessity of fitting a regression line of the form,  $y = a + bx + cx^2$ , to the data, would the solution of the problem by the graphical method be more advantageous than that by the arithmetic solution?

Three of four places of decimals are quite sufficient for the problem presented, but for partial correlation, additional places are necessary as additional factors are added. For example, if it were desired to analyze the recorded results of many tests of strength of concrete for the purpose of estimating the effect produced by various proportions of cement, sand, crushed stone, water, etc., the methods of partial correlation are indicated as applicable. Partial correlation provides a means of estimating the effect produced by

\*Engr., Public Utilities Comm., District of Columbia, Washington, D. C.

each individual component cause on the assumption that all other causes are held constant.

It is better to take the assumed origin as near as possible to the center of gravity of the table than to place it in one corner for the sake of avoiding negative values. The position of the center of gravity can usually be approximated by inspection; in the author's example it is in the block containing a "frequency" of 24 samples. The advantage is the same as that of assuming the meridian near the middle of a boundary in computing the area; it results in smaller figures with which to work. The correlation table (Fig. 12) in the problem is a comparatively small one. In a table having 18 or 20 or perhaps 25 classes each way, with the total number of cases,  $N$ , as much as 1 000, or more, the arithmetic is much simpler if the assumed origin is taken near the center of gravity of the table. One can multiply in his head by 12, but if the multiplier becomes 18 or 23, for example, it is easier to use paper and pencil. By assuming the origin near the center of gravity, virtually all the work down to the computation of the standard deviations can be done in the head, because the multipliers will seldom be greater than 12. For example, in Fig. 12, it will be noted that in the fourth row,  $N = 22$ ,  $\Sigma ny = 22 \times 4 = 88$ , and  $\Sigma ny^2 = \Sigma ny \times y = 88 \times 4 = 352$ .

In addition to the text by Yule, cited by Professor Evans (which may be regarded as standard), the writer recommends\* a text by Frederick C. Mills, Associate Professor of Business Statistics at Columbia University.

ROBERT C. STRACHAN,† M. Am. Soc. C. E. (by letter).—The author lays more stress on methods of obtaining "standard deviation", "coefficient of correlation", and "mean regression line", than on the question, "Why a correlation table?"

As the answer is by no means self-evident, it seems proper to state that—in connection with the theory of probabilities, with its voluminous literature concerning frequency curves, probability curves, frequency surfaces, normal law of error, and kindred subjects—the correlation table or diagram has been developed for the purpose of exhibiting two observed properties or qualities pertaining in different degree to a group of objects, in such a way that the probable influence of either property on the other, may be made apparent.

Thus, the regression lines, Equations (5a) and (7a), or their loci in Fig. 12, indicate that if a mortar similar to the tested group has a strength ratio of 80 at 7 days, it should have a ratio of 81.9 at 28 days. On the other hand, for a mortar showing a ratio of 90 at 28 days, the probable ratio is 92.2 at 7 days. These are, of course, expectations founded on the averages represented by the regression lines.

The data chosen by the author to illustrate his method are of a type occurring frequently in engineering work. For example, the effect of temperature on electrical resistance, the influence of percentage of constituent metals on the strength of an alloy, or that of wire-drawing on the elastic modulus of steel, might be studied effectively by similar means.

\* "Statistical Methods Applied to Economics and Business", by Frederick C. Mills, Henry Holt & Co., New York, N. Y.

† Cons. Engr., New York, N. Y.

The author's graphical derivation of the elements essential to the building of the diagram is ingenious, and gives evidence of much study. It also tends to prove that most problems, however complex, may be made to yield to graphics. The desideratum, however, is clearness combined with a simplicity commensurate with the conditions of the problem. Clearness and simplicity appear to the writer to characterize the arithmetical summarization of Fig. 12, rather than Figs. 4 to 10, inclusive.

The author estimates that 4 hours should be sufficient for the complete solution of this particular table by either procedure; so that no superiority is claimed for the graphical method on the score of speed. The writer's impression is that if a 4-hour record for this work exists, it must have been made by an exceedingly clever draftsman.

S. L. MOYER,\* Esq. (by letter).—In translating the probable error,  $r$ , into a spread between two bounds of a zone of uncertainty, Professor Evans attaches a graphic meaning to this elusive index that is most interesting. While the capacity of mathematics to express the degree of credibility may always be subject to question, yet the divergence between the mean regression lines of  $X$  on  $Y$  and of  $Y$  on  $X$  in Fig. 12 does furnish a portrait of the relative accuracy of the different parts of the graph of conclusions, reflecting the wealth or scarcity of the data supporting it.

The procedure involves the method of least squares as applied by Professor Karl Pearson, and his collaborators to the scatter of observations along the two axes of  $X$  and  $Y$ . As a practical test of the validity of these methods, Professor Pearson's favorite experiment was to examine the scatter of 1000 shots fired at a line on a target, and these examinations constitute the only positive proof of the departure characteristics presumed to exist. Under this method of interpretation, the trend or true value at which the shots are conceived to be aimed, is missing; and the problem is to discover this line without giving an unwarranted weight to a few scattering values.

The method of least squares was used by Karl Friedrich Gauss as early as 1795, and as later shown by him, it depends for its validity on the Gaussian Law of Error. This law results from a generalization of the binomial theorem known as the multi-nomial theorem. It is, in effect, an indefinite extension of the algebra of a game of dice, in which the numbers or quantities accidentally united, are conceived to add to produce the phenomena or score. This whole mathematical structure, therefore, rests on the premise that the haphazard values of the elemental causes unite by addition to produce the scatter effect.

It seems reasonable to believe that the human, mechanical, and other variations incident to gunfire are most likely to unite, by an addition of the haphazard contributions from these sources, in influencing the scatter of shots on the target. In fact, there seems to be very little question concerning the applicability of the Gaussian law to the reconciliation of the ordinary human and mechanical errors of observation, all of which may be considered as exerting an additive influence on the haphazard combination of causes. In the case of natural phenomena, however, a great number of the known results are

\* Civ. Engr., Montevideo, Minn.

multiples of the causes, rather than summations, and it seems worth while to bear this fact in mind as a check on any unwise assumption of accuracy which may be ascribed to a reconciliation of this kind.

The various increments of the chance in the haphazard throw of one die, may be symbolized by the successive terms in the following expression:  $x^1 + x^2 + x^3 + x^4 + x^5 + x^6$ . This may be called the one-die series, and each term or  $(x)$  represents one face of the die or one of the six different, equally likely ways in which one die may fall. The plus signs are merely convenient bounds setting off the divisions between the different kinds of chances or opportunities and have no significance in the chance interpretation, although these signs do serve a mathematical purpose in the determination of the chances for a number of dice in combination. The coefficient of each term of this expression (understood to be unity) indicates the count of ways, while the exponent of each  $(x)$  represents the numeral or score on the face of the die. This symbolism means that there is one way to get a score of (1), one way to get a score of (2), one way to get a score of (3), etc., throughout the whole series of numbers carried by the various faces. Assuming that the numerals, which are accidentally exposed by the throw of two dice, are added to arrive at a score; this sort of coincidence may be symbolized by expanding the one-die series to the second power; that is, by multiplying the same by another such series symbolizing a second die. In this process, the exponent representing the numeral on each face of the first die will be added to the exponent representing the numeral on each face of the second die, and the coefficient of each term of the result will total the count of ways in which each new exponent or additive score may be obtained. This result may be called the two-dice series and it reads as follows:

$$x^2 + 2x^3 + 3x^4 + 4x^5 + 5x^6 + 6x^7 + 5x^8 + 4x^9 + 3x^{10} + 2x^{11} + x^{12}$$

This symbolism means that there is but one way to get a score of (2), two ways to get a score of (3), three ways to get (4), etc., throughout the whole series, ending in two ways to get a score of (11) and but one way to get a score of (12). The actual process of carrying out the multiplication of two single-die series to arrive at this result, seems to afford the most illuminating approach to an adequate conception of chance that has ever been devised.

The power to which the single-die series is raised, in this process, symbolizes the number of dice in combination, and this holds true for any number of dice falling in fortuitous coincidence. For four dice in haphazard addition, the chance is symbolized by expanding the single-die series to the fourth power, or the two dice series to the second power. In this expansion, the total of the ways to fall in combination, must always equal the number of faces on one die raised to the power of the number of dice in combination, or in the case of four dice, six to the fourth power of 1296 ways. The resulting scores and counts of ways for four dice scored by addition are shown in Table 2.

It must be obvious that the dice may be scored by multiplication of the numerals accidentally exposed, without violating any of the dictates of logic or reason. In order to typify multiple scoring of the dice, it is necessary to violate the strict principles of algebra in the process of expanding to the

power of the number of dice. In strictly proper expansion, whenever any two terms are multiplied together, the exponents are added, and this addition symbolizes the addition of these two dice numerals to arrive at a score. It must be apparent then, that the purpose of scores by multiplication may be attained by simply multiplying the exponents in each of these operations, instead of adding. The number of products or ways of combination, in this process, will be exactly the same as the number of sums or ways of combination with exponents added, but the multiplication of exponents or dice numerals gives rise to entirely different scores and radically different coefficients or counts of ways for each sort of exponent or dice score.

TABLE 2.—FOUR DICE IN HAPHAZARD COMBINATION.

BY ADDITION:		BY MULTIPLICATION:	
Score.	Ways.	Ways.	Score.
4	1	520	1 to 62
5	4	255*	63 to 124
6	10	148	125 to 186
7	20	98	187 to 248
8	35	65	249 to 310
9	56	46	311 to 372
10	80	30	373 to 434
11	104	24	435 to 496
12	125	16	497 to 558
13	140	18	559 to 620
14	146*	5	621 to 682
15	140	12	683 to 744
16	125	4	745 to 806
17	104	4	807 to 868
18	80	6	869 to 930
19	56	....	931 to 991
20	35	....	992 to 1 053
21	20	4	1 053 to 1 113
22	10	....	1 114 to 1 174
23	4	....	1 175 to 1 235
24	1	1	1 236 to 1 296

\* Median or middle of count of ways.

In this multiplication of exponents or dice numerals, the least score for four dice is the product of four ones or unity while the maximum score is the product of four sixes or 1 296. This range, from 1 to 1 296 for four dice in multiplication, is comparable to the range from 4 to 24 for four dice in addition, and in order to show a fair comparison of these two styles of count distribution, the multiple dice scores have been divided into twenty-one classes of magnitudes corresponding to the twenty-one additive dice scores. The count of ways for each of these classes or arrays of multiple scores for four dice have been totaled and given in Table 2 so as to show the relative scatter of these two different styles of haphazard combination. The total of all the different arrays of count of ways will be seen to be exactly the same for either additive or multiple combination (or 1 296), while the count distribution has very different characteristics for these two styles of combination.

A comparison of the distribution of ways by haphazard addition, as shown in Table 2, with the count distribution,  $N'$ , of observations in Fig. 12 against the two axes of  $X$  and  $Y$ , suggests that the principles of the Gaussian law may

be said to be fairly applicable to the problem illustrated. There are, however, possible limitations to the capacity of the Pearsonian system of correlation that it seems well to weigh. Considering the distribution of the count of ways resulting from the haphazard multiplication of four dice, as shown in Table 2, it becomes apparent that it would be futile to attempt to reconcile this style of scatter by any such methods.

TABLE 3.—FOUR DICE IN A COMBINATION OF QUANTITIES OF COMMON PROBABILITY KIND, OR ALWAYS INVOLVING A COINCIDENCE OF FOUR OF A KIND.

	BY ADDITION (REGENERATIVE).		BY MULTIPLICATION (GEOMETRIC).	
	Score.	Ways.	Ways.	Score.
4 ones.....	4	1	1	1
4 twos.....	8	1	1	16
4 threes.....	12	1	1	81
4 fours.....	16	1	1	256
4 fives.....	20	1	1	625
4 sixes.....	24	1	1	1 296

The possibility of causes in multiplication is not the only prospective difficulty which may be encountered. A great number of the contributions to a given result in Nature, in turn, may originate in some common cause or circumstance, and the values combined are thus of the common probability kind instead of the haphazard probability kind; that is, they display a style of combination analogous to a dice score of 4 ones, 4 twos, 4 threes, etc. In the case of elements combining by addition, this results in a magnification of the trend of magnitudes for the original elements, whatever that may be; and in the case of elements combining by multiplication, the results must bear a geometric relation to the sources. These two phases of the possible ways of combination are illustrated in Table 3.

The importance of the distinctions drawn between these different styles of combination, has been previously suggested by the writer\* in studies of rainfall and run-off expectancy. These studies are still too fragmentary but, inasmuch as the literature of the subject extending back over a period of more than a century seems to be unaccountably silent concerning these aspects, it seems wise to call attention at this time to the possible revolutionary effect on correlation conceptions that these distinctions may involve.

THEODORE HATCH,† Esq. (by letter).—The engineer is frequently confronted with the problem of determining the relation between two variable measures. There are several methods of doing this, varying in their accuracy from the simple, direct method of fitting the curve by eye, to the more elaborate method of Least Squares. To obtain the equation of the curve, a straight-line relationship between the variables or functions of the variables is usually

\* Transactions, Am. Soc. C. E., Vol. 93 (1929), pp. 909 to 919.

† Instructor in San. Eng., Harvard Univ., Cambridge, Mass.

sought. Although a visual examination of the extent of scatter or deviation of the points from the straight line of best fit gives some idea of the closeness of fit, the degree of relationship is not fixed. This disadvantage is overcome when correlation is made the basis of analysis. This approach possesses several advantages not generally appreciated by engineers.

Two measures are said to be correlated\* when, a series of the first measure of definite sizes being selected, the means of the corresponding sizes of the second measure are found to be a function of the first. If they are independent of the first measure, the measures are said to be non-correlated. A fundamental requirement of this method of analysis is that the relationship be linear, or capable of being rectified to a linear function. Low correlation, therefore, does not necessarily mean absence of relationship; it may imply, simply, the absence of linear correlation. Thus, when  $y = kx^2$ , there may be low correlation between  $y$  and  $x$ , but high correlation between  $\log y$  and  $\log x$ , since in the latter form the function is linear. In order to meet this difficulty, a test for linearity has been developed.

By plotting the means of the second measure against the selected sizes of the first, and *vice versa*, two lines known as regression lines are obtained. When perfect correlation exists, these two lines are straight and they coincide. When the two measures are mathematically independent, the regression lines assume positions perpendicular to each other. As the degree of mathematical relationship varies from complete independence to perfect correlation, the angle between the regression lines decreases from 90 to 0 degrees. The coefficient of correlation, defined by the author, finds its basis in this fact. It can be shown that the slope of the regression line of  $Y$  on  $X$  has the value:

$$b_y = r \frac{\sigma_y}{\sigma_x} \dots \dots \dots (9)$$

and of  $X$  on  $Y$ ,

$$b_x = r \frac{\sigma_x}{\sigma_y} \dots \dots \dots (10)$$

when  $r = 1.0$ ,  $b_y$  becomes the reciprocal of  $b_x$ , and the two lines fall together. When  $r = 0$ ,  $b_y = 0$  and  $b_x = 0$ , and the regression lines are perpendicular to each other.

The coefficient of correlation may have any value between  $+1.0$  and  $-1.0$ , a positive value indicating a direct relation between the two measures and a negative value an inverse relation. It is easily shown that  $r$  can never have a value greater than  $+1.0$  nor less than  $-1.0$ . The following arbitrary scale of relationship in terms of the coefficient has been suggested:

Perfect correlation.....	$r = \pm 1.0$
High correlation.....	$r = 0.75$ to $1.0$
Considerable correlation.....	$r = 0.50$ to $0.75$
Moderate correlation.....	$r = 0.25$ to $0.50$
Low correlation.....	$r = 0.25$

\* See "Medical Biometry and Statistics," by Raymond Pearl, W. B. Saunders Co., Philadelphia, 1923.

An additional measure of the degree of relationship is given by the probable error of the coefficient of correlation. By definition, it is a measure of the reliability of the coefficient itself, this reliability increasing as the ratio of the coefficient to its probable error increases. In practice, the coefficient is not considered to be statistically significant unless it has a value greater than six times its probable error. Thus, a value of  $r = 0.3976 \pm 0.0103$  indicates moderate, but nevertheless significant, correlation; whereas a value of  $r = 0.7693 \pm 0.2610$  indicates high correlation, but has little statistical reliability, since the coefficient is only three times its probable error.

It should be understood that correlation does not necessarily imply casual relationship. The coefficient of correlation is simply a measure of the mathematical relation existing between two variables. If this fact is kept in mind, many erroneous conclusions may be avoided.

From a knowledge of the coefficient of correlation, it is possible to write the equations of the mean regression lines of  $Y$  on  $X$  and  $X$  on  $Y$ , and it can be shown that the curves and equations thus obtained are identical with those given by the Method of Least Squares.

The coefficient of correlation may also be used as a measure of the relative value of various "yardsticks" proposed as indices of a certain condition. An index that does not take into account all factors involved will show low correlation with the condition to be measured; conversely, an index made up of all factors will be highly correlated with that condition.

This point is well illustrated in a recent paper dealing with the comparative values of "cooling power" and "effective temperature" as measures of conditions of comfort in ventilation.\* Taking pulse rate as a measure of body comfort, the following coefficients were obtained for the two methods:

Pulse rate and effective temperature.....	$r = 0.7845 \pm 0.029$
Pulse rate and cooling power.....	$r = 0.5632 \pm 0.052$
Difference .....	$= 0.2213 \pm 0.0595$

These results indicate high correlation between pulse rate and effective temperature and lower correlation between cooling power and pulse rate. Moreover, the coefficient of correlation between effective temperature and pulse rate is twenty-seven times its probable error; whereas in the case of cooling power and pulse rate, the coefficient is only ten times its probable error. Hence, it may be concluded that effective temperature constitutes a better index of body comfort (as measured by pulse rate) than cooling power.

The preceding statements have to do with simple correlation between two related variables. Not infrequently, however, it is necessary to determine the laws of relationship between three or more variables. In laboratory investigations, this is done by controlling certain of the variable factors in each experiment. In dealing with natural phenomena, this procedure is not possible, but it can be done mathematically by methods of partial correlation. The coefficient of partial correlation gives the degree of relationship between two vari-

\* "Physiological Reactions of Resting Subjects to Cooling Power and Effective Temperature," by J. Argyll Campbell and T. C. Angus, *Journal of Industrial Hygiene*, December, 1928, 10, 331.

ables, when all others are held constant by the mathematical process, and can be expressed, as follows:

$$r_{12.34 \dots n} = \frac{r_{12.34 \dots (n-1)} - [r_{1 \cdot n.34 \dots (n-1)}] [r_{2 \cdot n.34 \dots (n-1)}]}{[1 - r_{1 \cdot n.34 \dots (n-1)}^2]^{\frac{1}{2}} [1 - r_{2 \cdot n.34 \dots (n-1)}^2]^{\frac{1}{2}}} \dots (11)$$

The subscripts indicate that the correlation is between Measures 1 and 2, with Measures, 3, 4, ...  $n$  held constant. For three variables, the expression becomes:

$$r_{12.3} = \frac{r_{12} - r_{13} \cdot r_{23}}{(1 - r_{13}^2)^{\frac{1}{2}} (1 - r_{23}^2)^{\frac{1}{2}}} \dots (12)$$

The following example will illustrate the application of Equation (12). The effect of altitude and distance from the ocean upon the annual rainfall in San Diego County, California, are to be determined from the data given in the records of the various rainfall stations.\* By simple correlation, the following coefficients are obtained:

Rainfall and altitude,  $r = +0.8779 \pm 0.2346$

Altitude and distance,  $r = +0.8747 \pm 0.354$

Rainfall and distance,  $r = +0.6172 \pm 0.0934$

From these coefficients of simple correlation, it seems that (a) rainfall increases with altitude; (b) altitude increases with distance; and (c) rainfall increases with distance. The increase of rainfall with distance, however, is actually due, not to the effect of distance from the ocean, but to the fact that, with increasing distance, the altitude is greater. To take this into account, the coefficients of partial correlation may be used. These are found to be as follows:

Partial coefficient between rainfall and altitude,  $r = +0.887$

Partial coefficient between rainfall and distance,  $r = -0.206$

These coefficients show high positive correlation between rainfall and altitude when distance is held constant and rather low negative correlation between rainfall and distance when altitude is held constant. This inverse relationship between rainfall and distance which is obtained by partial correlation is in accordance with the laws of rainfall.

From a knowledge of the coefficients of partial correlation, it is possible to write the equation of the relationship between the variables. For three measures, the equation has the form:

$$X_1 = \left[ \beta_{12.3} \frac{\sigma_1}{\sigma_2} \right] X_2 + \left[ \beta_{13.2} \frac{\sigma_1}{\sigma_3} \right] X_3 + M_1 - a M_2 - b M_3 \dots (13)$$

in which,  $X_1$ ,  $X_2$ , and  $X_3$  are the measures;  $M_1$ ,  $M_2$ , and  $M_3$  are their means;  $\sigma_1$ ,  $\sigma_2$ , and  $\sigma_3$  are their standard deviations; and

$$\beta_{12.3} = \frac{r_{12} - r_{13} \cdot r_{23}}{(1 - r_{23}^2)} \dots (14)$$

$$\beta_{13.2} = \frac{r_{13} - r_{12} \cdot r_{23}}{(1 - r_{23}^2)} \dots (15)$$

\* Data taken from Mead's "Hydrology," p. 294, McGraw-Hill Book Co., N. Y., 1919.

$$a = \beta_{12.3} \frac{\sigma_1}{\sigma_2} \dots\dots\dots (16)$$

$$b = \beta_{13.2} \frac{\sigma_1}{\sigma_3} \dots\dots\dots (17)$$

For this example, when  $X_1$  is the annual rainfall, in inches,  $X_2$  is the altitude, in feet, and  $X_3$  is the distance from the ocean, in miles:

$$X_1 = 0.00796 X_2 - 0.628 X_3 + 15.1 \dots\dots\dots (18)$$

These single examples are cited in order to illustrate the use of correlation in experimental work and investigation and, in particular, to suggest to engineers the possible advantages of applying this method to the analysis of their problems.

B. F. JAKOBSEN,\* M. AM. SOC. C. E. (by letter).—The author is to be complimented for submitting his graphical method for determining the coefficient of correlation,  $r$ , and its probable error. The method presented is certain to appear at a disadvantage, due to the small scale made necessary in reproducing it in a paper. The small scale gives the impression of a complexity that probably would not occur if the scale was large, as it would be, in actual use. Fig. 12 gives a clear illustration of the entire problem, including the analytical or arithmetical solution for those who may prefer that. Mr. Arne Fisher has pointed out† that, when the probable error cannot be determined, no great importance can attach to the result, since the probable error may be as large, or even larger, than the result itself.

The writer believes engineering will benefit, if engineers will acquire the habit of analyzing their "facts" by appropriate mathematical methods, such as those outlined in this paper. The truth is that the writer leans somewhat to the opinion that "facts" may not become "facts" until they are so analyzed by proper methods, or, at least, that they are not useful facts in a scientific sense, until analyzed and properly qualified.‡

The main problem is to determine the probable error, for it gives information as to the reliability of the observations and the theory. If the probable error is larger than the actual errors likely to have been made in measuring, it signifies that the equation assumed does not represent the phenomenon under investigation with sufficient accuracy. For simple problems the method of least squares suffices, but for more complicated phenomena, correlation must be used.

When Kepler was studying the observations made by Tycho Brahe, in order to determine the orbits of the planets, he assumed at first a circular path. He found "errors" of 7' and 8', but his confidence in Tycho's measurements was so implicit that he refused to believe that the actual errors of observations were that great. He then tried an elliptic orbit, assuming the sun to be located in one focus, and found "errors" of only 1'; this led to the discovery of the

now famous Kepler's laws of planetary motion, from which Newton derived his law of gravitation.

The writer has analyzed the results of tests on the Stevenson Creek Dam and has found for the arch at Elevation 30, that  $p$ , the water load carried by the arch, was 9.80, and its probable error,  $\pm 0.50$ ; for a factor,  $k$ , determined by the shrinkage, he found  $k$  equal to  $-681 \pm 480$ .\* The probable errors show that the value found for  $p$  is quite reliable, while the value for  $k$  is much less so.

Professor Karl Pearson has shown† that experience does not and cannot prove causation, which is an assumption supplied by Man and then projected into the world of phenomena; but experience does show correlation. The coefficient of correlation with its probable error makes it possible to determine the degree of correlation and to compare one experience with another. A great many important problems, now generally drowned in a mass of words, can be attacked intelligently and effectively only by means of the coefficient of correlation. Such problems as the effect of strikes on wages, the effect of concentration of industry in large establishments on wages and working conditions, etc., can be unraveled only by appropriate mathematical treatment.‡

Every engineer must often have been vexed or amused when reading the voluminous opinions offered by successful business men, politicians, or chiefs of police departments, on the causes of automobile accidents. This problem might be profitably studied by a few men properly trained and equipped, and such a study would hinge largely on the determination of the various coefficients of correlation.

Leonardo da Vinci wrote:§ "He who scorns the certainty of mathematics will not be able to silence sophistical theories which only end in a war of words." Although written more than four centuries ago, and in spite of considerable progress made in the meantime, this statement applies as if it were written only yesterday.

WESTON S. EVANS,|| Esq. (by letter).—The trend of the discussion seems to indicate that the writer considered the graphical solution to be superior to the arithmetical solution for solving correlation tables. This is not the case. Mr. Dunlap was correct in stating that "the advantage of the graphical solution is in the understanding and grasp derived of the problem of correlation while learning about this method of analysis."

If a numerical answer only is sought, plain arithmetic is the best method by which to obtain it. Means and standard deviations are very easily determined graphically, and, if it becomes necessary or desirable to produce a finished drawing to scale, the extra time required to complete the solution is not great. The four hours required to solve the table in Fig. 2 was the time necessary to draw Fig. 12. If the finished drawing is not required, the graphical solution is entirely out of place and 20 min. is sufficient. The writer has solved

many similar tables in that length of time, after making the table which is a part of the graphical solution. If speed is the controlling factor, then punching, sorting, tabulating, and calculating machines are the implements which should be used. The average engineer, however, has many lessons to learn before he is able to use such devices in solving his statistical problems.

Mr. Dunlap states that it is better to assume the origin as near as possible to the center of gravity of the table than near one corner in order to avoid negative numbers. For pencil and paper solution this is probably correct. The writer has been accustomed to adding machines on which the negative sign becomes a source of trouble and the magnitude of the numbers is of little consequence. Furthermore, when the data are tabulated on cards for use in sorting and tabulating machines, the code for any variable must start with the lowest values, and hence the origin will be in the lower left-hand corner. Although the choice of origin is optional, the writer believes that the best practice is to avoid negative signs.

The explanation of the regression equations as given by Mr. Strachan is worthy of some elaboration. In the two regression formulas,  $x = 0.90y + 11.59$ , and  $y = 0.90x + 9.74$  (Equations (5a) and (7a)), it becomes evident that, although both apply to the same data, a given value of  $y$  gives evident values of  $x$ . For example, if  $y = 100$  in Equation (5a),  $x$  will equal 102.22; but it cannot be said that if  $x = 102.22$ ,  $y$  will equal 100, since, from Equation (7a),  $y$  would equal 101.00. As  $r$  decreases, the difference between the two equations will increase. In Equation (5a),  $x$  is the mean of all 7-day ratios that will occur for any given 28-day ratio; while in Equation (7a)  $y$  is the mean of all 28-day ratios that will occur for a given 7-day ratio. This principle, so seldom applied to engineering data, is one of the best answers to the question, "Why a correlation table?"

The discussions by Messrs. Moyer and Hatch are somewhat aside from the problem of solving a correlation table, but are nevertheless very interesting. Mr. Hatch has presented very well the possibilities of partial and multiple correlation.

Mr. Jakobsen has well expressed the value of determining the probable error of observations, estimates, and mathematical conclusions. The writer fully agrees that such statistical methods as have been discussed, if applied to many problems relative to engineering work, would produce definite conclusions rather than long drawn-out discussions which frequently lead to nothing.

In closing, the writer wishes to emphasize that means, standard deviations, and correlation coefficients are constants which are necessary to establish facts in regard to the relationship existing between pairs of variables. For simple relationship between two variables the simple correlation coefficient is satisfactory; but as relationships become intricate and many, the partial and multiple coefficients, as outlined by Mr. Hatch, will relate facts that can be obtained in no other way. Whether the correlation table is solved graphically or arithmetically, its use in the engineering field should become more common and thereby give a better understanding of the relationship between cause and effect.

### EXPERIMENTS TO DETERMINE RATE OF EVAPORATION FROM SATURATED SOILS AND RIVER-BED SANDS\*

BY RALPH L. PARSHALL,† Assoc. M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. SAMUEL FORTIER, A. L. SONDEREGGER, HARRY F. BLANEY, N. W. CUMMINGS, CARL ROHWER, IVAN E. HOUK, AND RALPH L. PARSHALL.

#### SYNOPSIS

Much study has already been given by various investigators to the loss of moisture from soils by evaporation, as well as the effect of mulches in retarding or preventing this loss.‡ The moisture content of the soil, which is held in capillary form, is least at the surface where the evaporation occurs, and leaves there a deposit of such salts as were dissolved in the soil moisture. Heavy Western soils, which usually carry alkaline salts, have the greatest capillary attraction; that is, such soils will bring moisture to the surface from greater depths but at a slower rate than the sandy or the lighter soils.

This paper is based on a study of the evaporation loss from soils contained in tanks under like exposure, the materials ranging from coarse river sand to heavy dark alkaline soil, with the water-table maintained at 1, 6, and 12 in. beneath the surface. It is not the writer's intention to present conclusive data as to the loss by evaporation from moist soil surfaces, but rather to describe the methods and procedure followed in this study and to submit such information

NOTE.—The Special Committee on Irrigation Hydraulics has selected the subject of "Evaporation from Soils" as one of ten for study and research. This paper was submitted to the Committee by its author, and the Committee recommended its publication (see Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1928, Society Affairs, p. 173).

\* Published in April, 1929, *Proceedings*.

as is now available as an indication of the general trend of the relations existing between the various soils and conditions as well as supporting the general conclusions drawn.

### DESCRIPTION OF APPARATUS

Heretofore, the evaporation loss from soils has been determined by weighing the soil mass contained in tanks at stated intervals, the difference in weights equalling the loss by evaporation for the period. The problem of maintaining a constant and fixed position of the water-table in the soil, as well as that of determining the rate of loss due to evaporation, was solved, in the experiments herein reported, by the use of the principle of the Mariotte flask. In this regulating apparatus (Fig. 1) a calibrated air-tight drum, *D*, serves as the supply reservoir and is connected to a buried soil tank by a  $\frac{1}{2}$ -in. supply pipe. A glass tube is mounted beside the supply reservoir and is connected to the system at both top and bottom so that the water level in the drum may be observed. The quantity withdrawn is indicated by differences read on the meter stick.

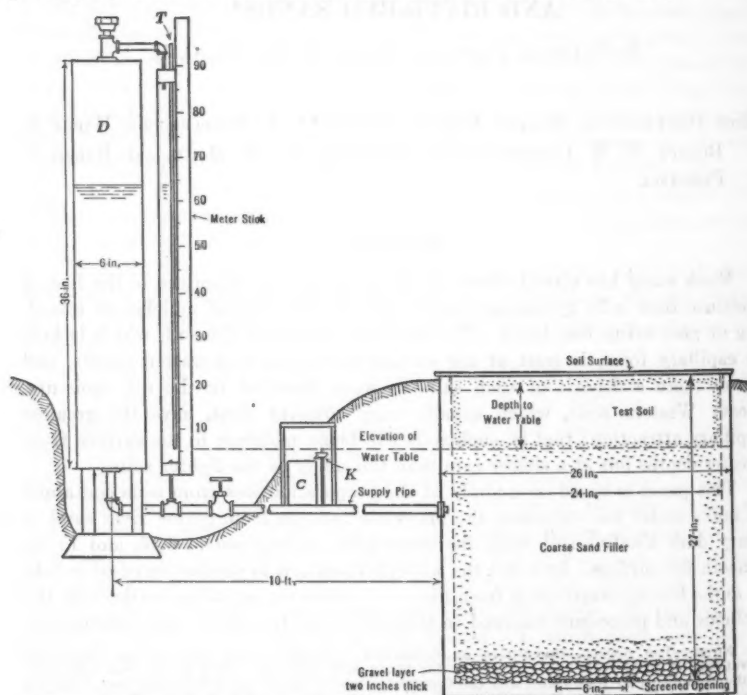

FIG. 1.—MARIOTTE REGULATION FEED TO SUPPLY EVAPORATION LOSS FROM SOIL TANKS.

Previous experience with the apparatus indicated that variations of temperature of the partial vacuum in the supply reservoir changed the vapor

pressure to such an extent that dependable readings were not possible for short periods. In order to reduce the effects of outside temperature changes to a minimum all supply reservoirs are well covered with corrugated asbestos board next to the drum,  $D$ , and this is covered with one layer of building paper. Each individual set of apparatus is mounted in a wooden housing, and the space between the insulated drum and the sides of the housing is filled with clean dry wood shavings. A hinged lid at the top of the housing is provided for convenience in refilling the supply reservoir.

The valve in the supply pipe is necessary to prevent over-charge of the soil tank when the supply reservoir is being refilled. To insure against the water-table in the soil tank being overcharged, either accidentally or by excess water entering from the supply reservoir as an effect of temperature, a vertical tube, *K* (Fig. 1), is attached to the supply pipe. The top end agrees in elevation with the plane of the water-table in the soil tank. Excess water in this tank is wasted through this small tube into the container, *C*, where it is measured, and the indicated evaporation loss corrected accordingly.

The outside of the housing is whitewashed. A bulb of a thermograph has been sealed inside the supply reservoir of Tank No. 17 (Fig. 2) to indicate the variation of temperature. Covers are provided for all tanks to shield them against rain.

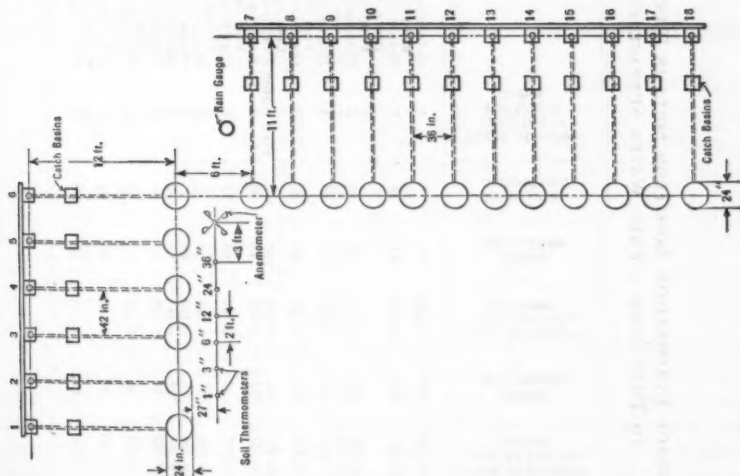

FIG. 2.—LAYOUT PLAN OF APPARATUS FOR MEASURING EVAPORATION FROM MOIST SOILS.

The soil tank consists of two shells, the outer constituting a water-tight container, while the inner, containing the soil, is supported at the top by an angle-iron rim so that a 1-in. space separates the inner tank from the outer at the sides and bottom. A hole, 6 in. in diameter, through the bottom of the inner tank, is covered by a coarse screen, and immediately above this is a 2-in. layer of gravel. Except in two tanks, coarse sand is placed on the gravel layer

up to the plane of the water-table, and on this porous material the test soil is laid. The water contained between the inner and outer shells of the tank is fed upward through the large hole in the bottom of the inner tank and thence through the soil to supply the moisture lost by evaporation at the surface. Loss of water by evaporation from the water surface between the two shells is prevented by sealing the top of the outer tank with heavy canvas and coal-tar. Tanks Nos. 1 to 6, inclusive, contain different types of soil, with the water-table at 1 in. below the soil surface. Tanks Nos. 7 and 8 contain water only. In Tanks Nos. 9 to 13, inclusive, the water-table is 6 in. beneath the surface, while in Tanks Nos. 14 to 18, inclusive, it is 12 in. beneath the surface. Six soil thermometers are placed parallel to the axis of Tanks Nos. 1 to 6 at depths ranging from 1 to 36 in. A Robinson anemometer and a standard rain-gauge are mounted near Tank No. 7. Tanks Nos. 7 and 8 are equipped with hook-gauges, reading to 0.01 in. A maximum thermometer is supported in the former and a minimum thermometer in the latter.

The Arkansas River sand in Tanks Nos. 1 and 2 was removed at the beginning of the 1927 season and coarse and medium river sand substituted. The materials in all other tanks used in 1927 were the same as those used in 1926 (see Table 1). A mechanical analysis of the materials in six of the tanks is shown in Table 2.

TABLE 2.—MECHANICAL ANALYSIS OF SOILS IN TERMS OF PERCENTAGE OF THE COMPLETE SAMPLE.

The alkaline soil from Tank No. 5 and the loam soil from Tank No. 6, which is identical to that contained in Tank No. 15, were analyzed to determine the percentage of water-soluble materials. This was found to be 0.261% and 0.153%, respectively. As usual, the analysis of these water-soluble portions present some difficulties; however, the salts present were the ordinary ones, such as sulfate of lime, magnesia, and soda. The chlorine content was low, a feature common to the alkalis in Northern Colorado. While the quantity of carbonate in Tank No. 5 was about the average, that in Tank No. 6 appeared to be greater. It seems to be a question as to how much manganese, phosphoric acid, alumina, and ferric oxide may be expected in the water-soluble portion.

All tanks are not filled in the same manner. In Tanks Nos. 1 to 6, the water-table is carried at a nominal depth of 1 in. Tanks Nos. 1 to 4, inclusive, are filled with coarse river sand to within about 4 in. of the top. The sample material, 2½ in. deep, is then added, which leaves about 1½ in. between the top

of the soil and the rim of the tank. Tank No. 5, which contains the heavy alkali soil, was filled from the gravel layer in the bottom to a point within about  $1\frac{1}{2}$  in. of the rim. Tank No. 6 was also completely filled in a manner similar to Tank No. 5, with soil taken from the excavation made in installing the equipment. Tanks Nos. 9 to 13 were filled with coarse sand to 6 in. below the top or rim, above which was placed the test soil. Tanks Nos. 14 to 18 were likewise filled to a level 12 in. below the rim and topped with the test soil.

In the case of Tanks Nos. 5 and 6, which were completely filled with heavy soil, the intention was to ascertain what relative effect would be apparent when the water that was lost in evaporation was drawn through a greater depth of soil than that represented in the other tanks.

Tanks Nos. 1 to 6 were the first set installed. The angle-iron rim at the top of the inner tank was placed so that the inner tank was exposed above the ground surface about  $1\frac{1}{2}$  in. This arrangement was improved in Tanks Nos. 7 to 18, by banking soil around the tank as shown in Fig. 1.

The surface of the soil in all tanks was kept free of plant growth and in an undisturbed condition. The high water-table in Tanks Nos. 1 to 6 developed a slight surface scum of algae or bacterial formation. This yellowish-brown coating is thin and more or less elastic. What effect it may have on the rate of evaporation is not known, but it is believed to be small. No doubt, copper sulfate added in small quantities to the surface of the soil would retard or prevent the growth, but because a natural condition was sought, the surface was left untouched.

The appearance and texture of the soil surfaces were observed on September 17, 1926. Tanks Nos. 1 to 6 were all yellowish-brown with a scum of growth about  $\frac{1}{2}$  in. in thickness. This covering or membrane was somewhat elastic, but did not cover the entire surface; that is, it was in patches of various areas. The edges of these patches were in some cases rolled back. The layer of scum on the soil surface of Tank No. 6 was thin. A deposit of alkali showed on the surface of Tank No. 5. The soil surface in Tank No. 9 was a light gray color, showing some alkali. Small cracks appeared here and there, with the soil becoming dry and mealy.

The soil in Tank No. 10 was dark brown, with damp surface and patches of scum. A very thin scum showed on the soil surface of Tank No. 11, the soil being damp, with concentrated isolated alkali crystals, compact and dark colored. No alkali showed on Tanks Nos. 12 and 13. The surface was damp with a thin scum, generally greenish-brown in color.

The surface of Tank No. 14 was almost white with an alkali deposit, very irregular or uneven, dry and mealy, with a few small surface cracks. This surface, when touched, would crumble to a fluffy mass. No alkali appeared on the soil surface of Tank No. 15 which was damp, with a very slight, brownish scum, and of mealy texture. Concentrated alkali crystals were spread over one-half the surface area of Tank No. 16 which was damp, with slight scum; the soil was more compact. The surface of Tank No. 17 was clean, smooth, and dry. Tank No. 18 showed a damp surface, inclined to be slightly incrustated.

## EFFECT OF DEPTH TO WATER-TABLE ON RATE OF EVAPORATION

Soil Tanks Nos. 1 to 6 were set up and filled in May, 1925, and Tanks Nos. 7 to 18 were installed in July, 1925. Because the filling of soil was uncompacted and the apparatus untried, only preliminary observations were made during this first season to ascertain the characteristics of the equipment. Fragmentary results of the comparison of the evaporation loss from the several moist soils and the free water surface are given in Table 1. This record covers only a part of September, 1925. The insulation for the Mariotte tanks was not sufficient at first to give reliable readings because of the variation of pressure of the water vapor in the space,  $D$  (Fig. 1). Considerable trouble was also caused by leakage of air into the Mariotte system. The instability of this equipment and the fact that the tanks were newly filled do not justify the placing of much dependence on these first results, although they show, in a general way, the trend of the evaporation loss as determined for the season of 1926. The period from September 14 to 23, 1925, was excluded because of the interference of rainy weather.

At the beginning of the season of 1926, the Mariotte tanks were completely overhauled and re-set. Thermograph records of the temperature of the partial vacuum within the supply reservoir (Tank No. 17) show a maximum daily range of  $7^{\circ}$  Fahr. and a minimum range of  $1^{\circ}$  Fahr. This range of temperature change is sufficient to affect materially the night and morning readings of the water level in the Mariotte supply reservoir. Theoretically, there can be no return of water to the supply reservoir from the soil tank as a result of reduction of the pressure of the water vapor in the space,  $D$  (Fig. 1). In order to investigate the apparent inconsistency of the action of the Mariotte regulation, special apparatus was set up by which the pressure of the water vapor in the space,  $D$ , could be greatly increased and decreased by changing the temperature. It was demonstrated that when a very slight decrease in temperature occurred, with no evaporation from the exposed sustaining or balancing water surface, an accumulation of water in the supply reservoir was possible. During a period of falling temperature, the pressure of the water vapor decreases slowly, and for a condition of balanced pressures a small bubble of air is held at the lower end of the small brass vent tube,  $T$  (Fig. 1). The surface tension holding this bubble in place operates as a seal at the lower end of the vent tube. Manifestly, if this tube is sealed, a decrease of pressure in the space,  $D$ , will cause water to flow from the soil tank into the reservoir of the Mariotte apparatus.

At first, it was thought possible to differentiate between the night and day losses of evaporation from the several types of soil, but when the data were studied thoroughly, no correlation of these losses appeared. The observations during the season of 1926 were taken at approximately 8:00 A. M., an hour when the air temperature was reasonably uniform for the weekly periods. For the season of 1927, the observations were taken at about 11:00 P. M.

Table 3 gives the average evaporation loss, in inches per day, for 1926 and 1927 and a comparison of losses from the soils with that from a water surface. During 1926, a complete evaporation record from a free-water surface was

also observed in an area distant about 500 ft. northwest of the experimental apparatus. This is designated Tank A in Table 3.

Covers were provided to protect the tanks against rain, but nearly each week more or less rain fell on the exposed soil surfaces. It was found practically impossible to guard against this condition because all soil surfaces were being exposed to natural conditions. Experience with these tanks shows that a marked reduction in the evaporation loss occurs when the covers are in place.

The cooling effect of the rain on the soil increases the surface tension of the capillary moisture drawn up from the water-table. Rain water falling on the soil also dilutes the soil solution and if the solution is alkaline it increases the rate of evaporation. It is evident that, although adding moisture to the soil at the time, light showers may later cause a more rapid depletion of the moisture already within the soil. Messrs. F. H. King and J. B. Stewart,\* have also noted this phenomenon.

\* This is based on fifteen weekly averages. The averages from some of the soil tanks are for shorter periods, hence are not directly comparable with that for Tank No. 8.

† Tank, 3 by 3 by 3 ft., located 500 ft. northwest of evaporation plots.

To study more in detail the effect on evaporation, of sprinkling the soil surface in quantities that approximate a shower of rain, two soil tanks, Nos. 17 and 18, were so treated. Fig. 3 shows the relation of loss from a free water surface and the losses from Tanks Nos. 17 and 18 during the sprinkled and unsprinkled periods. The quantities of water applied during the sprinkled period are shown in Table 4. For the unsprinkled period, the ratio of loss from the tanks when compared with that from the free water was 11% for Tank No. 17 and 32% for Tank No. 18. The corresponding ratios for the

sprinkled period were 33% and 76%, respectively. To what extent the sprinkled water was held in the voids of the sands is not known, but because of the similarity of the rate-of-loss curves representing the soils to that representing the free water, the writer considers it fair to assume that the rate of evaporation loss for the sprinkled period was materially increased. The data given in Table 5 for Tank No. 17 indicate that the percentage of moisture held within the soil mass above the water-table was at or near the maximum capillary capacity, because the quantity used from the storage reservoir of the Mariotte regulation was very small, or showed an increase or an accumulation from the soil tank. Tank No. 18 drew liberally from the supply reservoir to make up for the increased loss due to evaporation.

Other experimenters studying evaporation losses from various types of soils have found results varying between rather wide limits. The problem involves too many factors to make possible any correlation which would show other than very general relations.

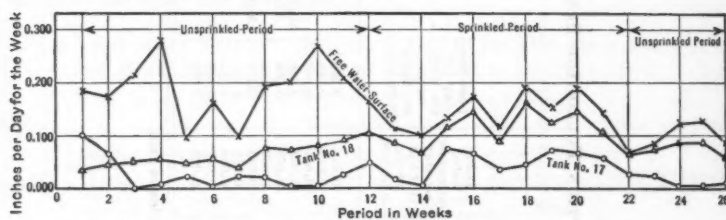

FIG. 3.—RELATION OF LOSS FROM FREE WATER SURFACE TO THE SPRINKLED AND UNSPRINKLED LOSSES FROM TANKS NOS. 17 AND 18.

In studying the evaporation losses from Yolo fine sandy loam, in tanks having diameters of 2 ft. 1 in., with the water-table at the surface and also at 1 in. below the soil surface, Samuel Fortier, M. Am. Soc. C. E., and Mr. S. Beckett, at Davis, Calif., found the following ratio of losses over a period of nine weeks, from August 2 to October 3:\*

	Percentage.
Free water surface .....	100
Saturated surface.....	84
Water-table at 1 in.....	82

The late R. B. Sleight, Assoc. M. Am. Soc. C. E., working at Denver, Colo., with a river-bed sand, in tanks having a nominal diameter of 2 ft., found the evaporation losses from August 4 to October 16 to vary with depth of water-table, as follows:\*

	Percentage.
Free water surface .....	100
Water-table at sand surface.....	77
Water-table at 3 in.....	69
Water-table at 6 in.....	64.5
Water-table at 10½ in.....	57.7
Water-table at 24 in.....	11.3

\* These data were taken from "Use of Water in Irrigation," by Samuel Fortier, M. Am. Soc. C. E., New York, 1926.

Mr. Sleight also found, for similar conditions and for a fine sandy loam soil, the following variation of evaporation losses according to depth to water-tables:\*

	Percentage.
Free water surface.....	100
Water-table at 4 in.....	88.2
Water-table at 16 in.....	79.8
Water-table at 28 in.....	62.4
Water-table at 38 in.....	33.0
Water-table at 43 in.....	7.63
Water-table at 50½ in.....	7.24

M. R. Lewis, M. Am. Soc. C. E., working at Twin Falls, Idaho, with a medium clay loam, in tanks having a diameter of 3 ft., found the following relation from May 27 to October 14:\*

	Percentage.
Free water surface.....	100
Saturated surface.....	134

The writer has studied the evaporation from different types of soils at Rocky Ford, Colo., where the water-table was held at about 4 in. in soil tanks having a diameter of 2 ft. The findings for the period of August to November, 1924, inclusive, are arranged in Table 5.

TABLE 5.—EVAPORATION FROM DIFFERENT TYPES OF SOILS AT  
ROCKY FORD, COLORADO.

Location.	Material.	Depth of water-table below surface, in inches.	Ratio, percentage.
	Free water surface.....	.....	100

Arkansas River.....	Fine sand mixed with clay and silt, Las Animas, Colo.....	4.1	58
Arkansas River.....	Fine sand mixed with silt, Lamar, Colo.....	3.8	68

The river sands in this group were substantially of the same general type. The sands in the Rocky Ford experiment were used as test soils in Tanks Nos. 1 to 4, as previously described (Table 1). The results obtained from June to October, 1926, for these same materials are as listed in Table 6.

Fig. (4) (a) and Fig. 4 (b) show graphically the trend of the evaporation loss from different soils with increasing depth of water-table. These losses are expressed as a ratio of that from a free water surface. In Fig. 4 (a) the four river samples of fine sand with the water-table at 1 in., show a loss equal to that from a free water surface. The loam and heavy adobe soils show a loss

\* These data were taken from "Use of Water in Irrigation", by Samuel Fortier, M. Am. Soc. C. E., New York, 1926.

of 83% and 75%, respectively, for a depth of 1 in. to the water-table, as compared with that from free water. When the water-table is 6 in. below the soil surface, the Rocky Ford sand and the adobe soil show a reduction of loss, while the loam soil and both the medium and coarse river sands show a loss equalling that from the free water surface. These three soils throughout the period, June to October, showed a consistently high rate of evaporation. The reason for this persistent high rate of loss is not apparent.

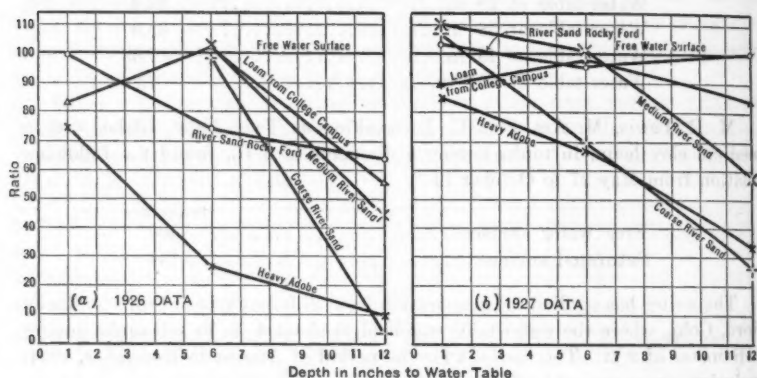

FIG. 4.—TREND OF EVAPORATION LOSS FROM DIFFERENT SOILS WITH INCREASING DEPTH OF WATER-TABLE.

### CONCLUSIONS

It is believed that the method of using the Mariotte principle in obtaining the evaporation loss from moist soils, even though there are some apparent

inconsistencies in its operation, gives more dependable results than the method of weighing. The results in Table 6 show very marked consistency for fine river sands, which are essentially identical, with the exception of the silt content. Those cited are as evidence of the dependability of the apparatus. The feature of automatic control is highly desirable.

## DISCUSSION

SAMUEL FORTIER,\* M. AM. SOC. C. E. (by letter).—The United States is mainly indebted to two Federal agencies for its knowledge of water supplies. The U. S. Weather Bureau measures and records the precipitation as it falls from the clouds in the form of rain and snow, and the U. S. Geological Survey measures and records the quantity of water that flows to the sea. The incoming waters derived from precipitation, particularly throughout the western half of the United States, greatly exceed the outgoing waters conveyed in stream channels. There are large areas in the West in which no water derived from precipitation ever reaches the ocean in the form of run-off. This is true of the Great Basin comprising an area, exclusive of the Imperial Valley, of 138 000 000 acres. A near approach to this condition is also found in the basin of the Colorado River containing 155 000 000 acres, in which the normal run-off is less than 0.8 in. over the surface drained.

These references and others which might be given, show that in that vast region comprised in the seventeen Western States, only a small part of the total precipitation is carried off by streams, the greater part being converted into vapor which is soon wafted to distant localities by the prevailing winds. No Federal agency has been specifically charged with the collection of data having for its objective the determination of the quantities of water transpired from native vegetation and evaporated from uncultivated soil surfaces, for the apparent reason that until recently those who live in the humid part of the country have not been generally interested in the subject. On the other hand, to those whose occupation and abodes are in the arid and semi-arid regions—and they comprise one-fifth of the total—the subject is of vital concern. While they do not claim to be able to control, to any great extent, transpiration from plants or evaporation from soils, yet they do require a general knowledge of this enormous loss of water in order to plan aright for the utilization to the fullest extent possible of what remains of the water supplies.

Until recently the main water problems of the Nation have been confined to the territory west of the Missouri River because water was scarce, and because much more was needed for agricultural purposes. Westerners discuss water, investigate it, litigate over it, and end by criticizing the water decisions of the Courts. Now, however, many Western water controversies are having their counterparts in the Eastern States. The rapid increase in the use of water for hydro-electric plants and municipalities has enhanced its value and has led corporations and municipal and State Governments to transfer supplies from one drainage basin to another and from one State to another. This is quite enough to start trouble, and no one is wise enough to predict when or how it will end. In view of this situation, which is certain to become worse, and in the interests of public welfare generally, increased Federal and State funds might profitably be expended in acquiring more complete and reliable data concerning water supplies. Western experience has demonstrated

\* Senior Irrig. Engr., Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, Berkeley, Calif.

that it is much cheaper and preferable in many ways to employ engineers to investigate water problems than lawyers to litigate over them.

A field that is practically unexplored and one that should be investigated at an early date is to be found in the wide gap between the accumulated knowledge available concerning precipitation on the one hand and run-off on the other. To call attention to but two vacant spaces in this unexplored field of knowledge, there still remain in this country about 470 000 000 acres of virgin forests and cut-over and burned-over forested areas. Does this vast area transpire annually, on an average, 1 acre-ft., 2 acre-ft., or some other quantity of water per acre? Nobody knows and nobody has ever tried to find out. Furthermore, there are about 658 000 000 acres of unimproved pasture and range land. What is the loss of water by transpiration and evaporation from this area? Nobody knows.

In many respects, transpiration of water from plants differs from evaporation of water from soils, each having distinct and separate functions to perform, but in studying water supplies and their utilization it is seldom practical to consider them apart. Four drops of water are lodged in soil side by side. Three drops are absorbed by the rootlet of a plant, drawn up through its stem, and transpired by its foliage. The other drop is evaporated directly from the soil. All four reach the clouds, but by different routes. If one part of the land surface of the United States were bare soil and the other covered with vegetation, the rate and extent of evaporation from the bare part might be determined, but the almost inseparable twin problems of transpiration and evaporation would be found in the other. As a matter of fact there is very little soil in which plants of one kind or another do not grow at least a part of each year, and the quantity of water which is transpired by plants from a unit of such surfaces cannot well be segregated from that evaporated from bare soil in their immediate vicinity.

Since 1898 the Congress of the United States has appropriated relatively small sums of money to the Division of Agricultural Engineering for irrigation investigations. By co-operation with Western agricultural experiment stations and other State agencies, it has been possible, through the increased funds thereby made available, to carry on such studies in all the Western States. Several thousand experiments have been conducted in widely separated localities to determine the water requirements of all the most common field crops and the quantities of supplemental irrigation water needed for their proper growth. As a result of these investigations it is now possible to define with reasonable accuracy the irrigation requirement of a farm in any one of the Western States, provided knowledge is available of its location, climate, extent of irrigable area, character of soil, and the crops to be grown. Since, however, the irrigated land in the seventeen Western States constitutes less than 2% of the total, a knowledge of the quantity of water transpired and evaporated from irrigated farms does not help much in the solution of what takes place in respect to these natural functions on the remaining 98%, particularly as little or no data are available on which to base an estimate. This is true of native grass lands and lands covered with brush, shrubs, and virgin forests. It is likewise true to nearly the same extent of arable lands which are

dry farmed. An erroneous impression prevails in attributing to soil evaporation the greater part of the vaporized waters escaping from uncultivated lands on which native plants, including forests, grow, whereas actually it is the native vegetation that transpires by far the greater part.

In passing from a consideration of the water yield of a Western drainage basin to the water problems of the irrigator, there are many ways in which evaporation from soils affects the irrigator's profits. In growing cultivated crops, such as orchard trees, cotton, sugar beets, or potatoes, the greater part of the ground surface is not only bare but is periodically watered and a large percentage of the water applied escapes as vapor into the atmosphere. To cite a single case, the average annual cost of irrigation water applied to the lands of 111 mutual water companies in California is \$15.50 per acre. The yearly cost of applying this water is about \$2.50 per acre, or \$18.00 per acre in all. If 30% of this water is evaporated from bare soil, it represents a considerable loss to the grower. In an effort to find ways and means to lessen this and similar losses, the writer, aided by his associates and collaborators, sought to determine some of the underlying principles of soil evaporation. Dr. John A. Widtsoe, when President of the Agricultural College of Utah, and W. W. McLaughlin, now Associate Chief of the Federal Division of Agricultural Engineering, were the first to ascertain quantitatively by controlled experiments in tanks that the more moisture the soil contained the greater was the evaporation.

A series of experiments conducted by the writer confirmed this fact and led to the use of deeper furrows in applying water to cultivated crops. In the case of the orchard groves of California, the top layer of soil from 6 to 9 in. in depth, although it is the most fertile and best aerated part of the soil column of the root zone, serves mainly as a blanket to protect the moist soil beneath. Orchard roots which are lured into this zone by winter rains perish from drought during the long rainless summer. The writer also determined by experiments that the factors of temperature, wind movement, and humidity which influence the rate of evaporation from water surfaces were applicable to soil surfaces. It is well, however, to keep in mind that the governing factor in evaporation from soils consists in the percentage of moisture in the top layer. Under like conditions saturated soils may be said to evaporate about 90% of that from a water surface, but with the soil moisture at the wilting point of plants the evaporation may be reduced to little or nothing.

Another phase of evaporation which concerns rural communities of the Western States, is to be found in the condition of Western streams and their flood-plains during low-water periods. Some Western stream channels carry water so seldom that their natural function is not always apparent to the casual observer. Other streams, like the Platte, Rio Grande, and Arkansas, in the late summer months carry a small volume of water spread out in a thin sheet, while the greater part of the flood-plain is either dry or partly moistened. It occurred to the writer that if the loss of evaporated water from the shallow water surface as well as from the bare river bed material could be determined with a fair degree of accuracy, a basis could be laid to determine the economic

feasibility of conveying the flow of the late summer months, either in an artificial canal or within a relatively small part of the flood-plain channel.

With this objective in mind, advantage was taken of a rather far-flung organization to collect twenty-seven typical 40-lb. samples of river-bed materials from each of sixteen stream beds. A mechanical analysis was made of each sample, and the percentage of pore space was also determined. The equipment was inadequate to make a separate evaporation test of each sample and, for this reason, the samples were combined into four groups ranging from the coarsest to the finest material. This grouped material was placed in double water-jacketed tanks of which the inner, with a few exceptions, was 23.5 in. in diameter and 48 in. deep. In an effort to duplicate Western stream-bed conditions in low-water periods, the water-table in each series of tank experiments was maintained at distances from the surface of 3 in., 12 in., and 24 in., and occasionally at other distances. Where the water-table was 3 in. below the surface, the results were fairly uniform for the different materials, varying from 66 to 77% compared with 100% from a water surface; but at depths of 12 and 24 in., the variations were greater. The experiments were carried on at the Denver, Colo., Field Laboratory and were in direct charge of the writer's assistant, the late R. B. Sleight, Assoc. M. Am. Soc. C. E.\*

In this brief discussion of Mr. Parshall's paper, the writer has endeavored to show the relationship between evaporation from soils and transpiration from plants, and to give a few reasons for the acquisition of more knowledge of both branches of this twin problem.

A. L. SONDEREGGER,† M. Am. Soc. C. E. (by letter).—This paper describes a method of determining evaporation which apparently is vastly superior to the cumbersome method of finding losses by weighing the soil mass in tanks, and also to the method of maintaining a fixed water-table by daily closing. The experiments themselves present a valuable addition to the study of evaporation losses from moist areas.

In many regions of the semi-arid West, the elimination of evaporation from moist areas will form the last link in the chain of efforts to salvage the losses that pertain to the natural disposal of water supply. The factors which affect the problem are the total volume of evaporation losses available for recovery and the depth to which the water-tables must be lowered, with different soils, in order to stop capillary action.

As far as the experiments described by the author are concerned, it is apparent that the adjustment of the Mariotte flask to the special conditions presented by each test tank offers the most difficult problem with which the experimenter has to contend.

The results graphically shown on Fig. 4 permit of practical application. The sharp descent of the curve for the two extremes in soils—adobe and coarse sand—would indicate that, with a water-table 2 ft. below the surface, evaporation losses are eliminated. In clay soils, capillary action is effective, but very slow, while in the coarse sand, capillary tubes are short and interrupted. On the other hand, the high rate maintained by Rocky Ford sand, which occurs

\* *Journal of Agricultural Research*, Vol. 10, No. 5, 1917.

† Cons. Engr., Los Angeles, Calif.

pies a position about half way between the two extremes, leads to the conclusion that the mixture of materials was such as to produce what might be called "optimum" capillary action, both as to time and rate. It must be remembered, however, that these soils were disturbed, having been removed from their original location.

In order to complete the evaporation curve, deeper tanks are required. Experiments to determine evapo-transpiration losses from undisturbed cores are being made (1929) by A. A. Young, Assoc. M. Am. Soc. C. E., under the supervision of H. F. Blaney, Assoc. M. Am. Soc. C. E., of the Division of Agricultural Engineering of the U. S. Department of Agriculture, in connection with the Santa Ana River investigation in Southern California, at San Bernardino, with tanks 23 in. in diameter and 40 in. in depth; and at Santa Ana with tanks 23 in. in diameter and 72 in. in depth, all of which are operated by the use of the Mariotte principle.

The effect of applying the water by sprinkling the soil surface has been to increase the evaporation losses two to three times as compared with a stationary water plane fed from below. While these results may not be directly applicable to a comparison between irrigation by sprinkling and by furrows, nevertheless they indicate that, of necessity, the evaporation losses must be much larger for overhead application.

Overhead sprinkling systems for citrus and avocado orchards are installed in Southern California on increasing areas and at costs of as much as \$300 per acre, yet sometimes apparently with little regard for the increased evaporation losses. In some cases this form of irrigation has not been successful. Some of the failures must be attributed to the fact that, despite comparatively heavy soils, no additional water supply was provided. With an abundant supply, overhead irrigation can be carried on successfully, provided soils are not too heavy. In such localities the trees appear to be healthy and are bearing abundantly. For steep slopes, this system presents a practical method of overcoming the washing of soils and excessive waste. Tests to establish evaporation losses from sprinkling systems, for different soils, in comparison with furrow irrigation, would be of general interest.

The author has given the mechanical analysis of soils in terms of the percentage of the complete sample. This method may be the most accurate, and, for very coarse materials, the only one, but it does not lend itself to a quick interpretation, except possibly by an experimenter.

Soil designation by the moisture equivalent is becoming a matter of common practice and permits of a ready comparison of different samples. In experiments of the character described, the results of which lend themselves more or less directly to the solution of concrete problems, the writer would suggest that the moisture equivalent and, with undisturbed cores, also the volume weight and porosity of the samples, be given.

The author refers to an experiment\* of Professor F. H. King by which it was proved that for dry surface soils the effect of an application of water, which does not produce percolation, is to strengthen capillary flow so that,

\* "The Soil," by F. H. King, 1898, p. 196.

"The surface foot draws upon the deeper soil moisture at a more rapid rate than before, causing a translocation of the lower soil moisture, the deeper soil becoming measurably dryer soon after such a rain than it was before it, while the surface foot is found to contain more water than has fallen on it."

This phenomenon is believed to be responsible for the drying out of bare soils to great depths during periods when rain storms are generally light and even when the maximum storm of the season does not exceed 3 in.

HARRY F. BLANEY,\* Assoc. M. Am. Soc. C. E. (by letter).—In Southern California evaporation losses from soils and river-bed sands are an important factor in water supply studies and could be estimated fairly accurately, provided basic data, such as the author describes, were available. Data of this nature may also prove valuable in estimating surface evaporation from soils immediately after an irrigation. The Division of Agricultural Engineering, Bureau of Public Roads, U. S. Department of Agriculture, in co-operation with the California Department of Public Works, is now making (1929) a study of evaporation losses from moist lands in the Santa Ana River area of Southern California. In this work Mr. Parshall's method of using the Mariotte principle has been extended to tanks 6 ft. in depth, with a water-table maintained at 2 ft. and 4 ft. below the ground surface. The tanks are filled with undisturbed soil and are operated in triplicate.

During 1919 the writer continued the evaporation studies† begun by the late R. B. Sleight, Assoc. M. Am. Soc. C. E., at Denver, Colo., under the direction of Samuel Fortier, M. Am. Soc. C. E., and was very much impressed with the effect of the size of tanks on the depth of evaporation from a water surface. In extending evaporation data obtained from small soil tanks to larger land areas the engineer is confronted with the problem of selecting a proper reduction factor. Very few data are available for accomplishing this. However, factors have been established for extending evaporation data from various sizes of tanks to larger water surfaces. Mr. Sleight‡ concluded that evaporation data from circular tanks at least 2 ft. in depth "may be quite safely extended to large open water surfaces under exactly the same conditions of wind, air temperatures, and relative humidity, by multiplying the evaporation depth from a 2-ft. tank by 0.77, a 4-ft. tank by 0.84, a 6-ft. tank by 0.90, a 9-ft. tank by 0.98 and a 12-ft. tank by 0.99." The writer believes that a somewhat similar relation exists between evaporation from various sizes of tanks containing saturated soils, and that if no better data are available the factors mentioned may be used in estimating the evaporation losses from larger land areas where the water-table is near enough to the surface to saturate the soil.

The data presented by Mr. Parshall in Table 4, for Tank No. 17, August 21 to September 25, are of value in showing the surface evaporation loss after rain storms. Tank No. 17 generally lost a very small amount before the sprinkling started. During this period no water was supplied from the Mariotte tank. About 0.3 to 0.5 in. was applied per week and most of this was evaporated. It is probable that the water applied by sprinkling would not imme-

\* Irrig. Engr., U. S. Dept. of Agriculture, Los Angeles, Calif.

† *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 303.

‡ "Evaporation from the Surfaces of Water and River-Bed Materials," *Journal of Agricultural Research*, Vol. X, 1917, No. 5, p. 237.

diately drain down to the water-table, but that at least five days would elapse before equilibrium was again established and, during this time, surface evaporation of the sprinkled water would be taking place. If the quantities applied were small enough, none would move down to the water-table.

N. W. CUMMINGS,\* Esq. (by letter).—The author states that covers were provided to protect the tanks from rain. Presumably, they also prevented solar and sky radiation from reaching the moist surfaces under study because Mr. Parshall states further that a marked reduction in evaporation loss occurs when the covers are in place.

The use of the covers causes the experiments to represent a very important set of conditions, because a vast proportion of moist soil and other earthy material in which engineers are interested is shaded. This fact, however, does not destroy the interest which attaches to a comparison of the shaded and unshaded condition.

When the surface is shaded, nearly all the energy required for supplying the heat of vaporization necessary for converting the water from the liquid to the vapor state, is derived from the air that passes over the evaporating surface. On the other hand, when the surface is unshaded, this atmospheric component of the energy is usually small; it averages about 20% and is in the direction from water to air. This means that air temperature and humidity at the ground level are proportionately vastly more important when the surface is shaded than when it is unshaded.

This is evident from the fact that, in the case of the unshaded surface, atmospheric conditions at the ground level can affect only the smaller components of the energy; they can have no appreciable effect on radiation which is by far the largest component.

It is undoubtedly due, in large measure, to this fact that the depth of evaporation from a standard pan agrees as closely as it does with the loss from a lake subjected to the same sky conditions. The average humidity and air temperature over the lake surface are frequently not the same as over the surface of the water in the pan, yet the depths of evaporation seldom differ by more than 30 per cent.

When the surface is shaded, however, making the atmospheric component of the energy the important factor, there is no reason to expect that results from a small tank will bear anything approaching a definite relation to the loss from a large surface. The atmospheric component of energy depends on both temperature and humidity and as the air passes over an extended surface which is cooler than the air, as a shaded surface is almost sure to be, both temperature and humidity must change in such a direction as to decrease evaporation. Consequently, the loss per unit area might reasonably be expected to decrease very materially, as the area itself increases.

Engineers are confronted, therefore, with the necessity of finding the relation between the loss from a small surface and that from a very large surface under various conditions of wind, air temperature, and humidity when both

\* Research Associate, The Scripps Institution of Oceanography, Univ. of California, La Jolla, Calif.

surfaces are shaded. It is probable that some studies by Jeffreys\* may be valuable in connection with this problem.

The fact that air temperature at the ground level does not have any marked influence on the largest energy component reaching an unshaded surface may seem inconsistent with the well established relation between air temperature and evaporation from lakes. The apparent contradiction may be easily explained, however, by noting that radiation cannot be controlled by atmospheric conditions at the ground level, even if the temperature may roughly indicate its magnitude.

CARL ROHWER,† ASSOC. M. AM. SOC. C. E. (by letter).—The evaporation from moist soils is an important factor in the application of irrigation water to crops and in the determination of the quantity of water stored in the soil, due to rainfall. The measurement of the evaporation presents some difficulty, but the method described by Mr. Parshall permits more accurate control of the ground-water level than is possible by other methods, and materially reduces the work of making observations. As explained by the author, the Mariotte control apparatus is affected by temperature, and care should be used in insulating the equipment as completely as possible.

The principal effect of temperature on the apparatus is in the expansion and contraction of the air in the chamber above the water surface, and in the change in the vapor pressure in the air with the change of temperature. Both effects increase as the temperature increases. The pressure of the air in a closed vessel is directly proportional to the absolute temperature, but the change in vapor pressure with the temperature does not follow so simple a law. The variation, however, has been determined experimentally and shows that there is an appreciable effect on the pressure, due to the change of vapor pressure. The relative magnitude of the two effects of temperature is not important. The only concern is the total effect of the two forces.

When the temperature increases in the Mariotte control apparatus, the pressure in the chamber, *D*, Fig 1, increases and destroys the balance. As a result, water is driven from the water tank. This water usually raises the level of the water in the soil tank slightly, and if the increase in temperature is great enough some of the water will drain out at *K* into *C*. In case the evaporation from the soil surface exceeds the rate at which the water is driven from the water tank, due to the increase in temperature, no error in the record will result. The only effect will be in decreasing the amount of air drawn through the tube, *T*, to maintain the balance. If the temperature drops, the pressure in *D* will decrease and, as pointed out by the author, air should be drawn in through the tube, *T*, to re-establish the balance in the apparatus. Actually, however, the change in temperature is so gradual that the force is not sufficient to break the bubble from the lower end of the tube, *T*, and, as a result, water is drawn from the soil back into the tank. The result of this condition is that the indicated evaporation is too small.

\* Summarized by Humphreys in "Physics of the Air."

† Associate Irrig. Engr., Colorado Experiment Station, Fort Collins, Colo.

The original 1928\* records of the observations on the evaporation from saturated soils and river-bed sands show that there was a definite rise and fall of the water in the Mariotte tubes, due to the change in temperature. It was found that Tank No. 17 (Fig. 2), which contained coarse sand and in which the water level was maintained at a depth of 1 ft. below the surface, lost no water during the season. There was, however, a pronounced rise and fall of the water in the Mariotte apparatus which, apparently, bears some relation to the rise and fall of the air temperature. This is shown graphically in Fig. 5, which is a plot of the air temperature at 7:00 A. M. and 7:00 P. M., taken from

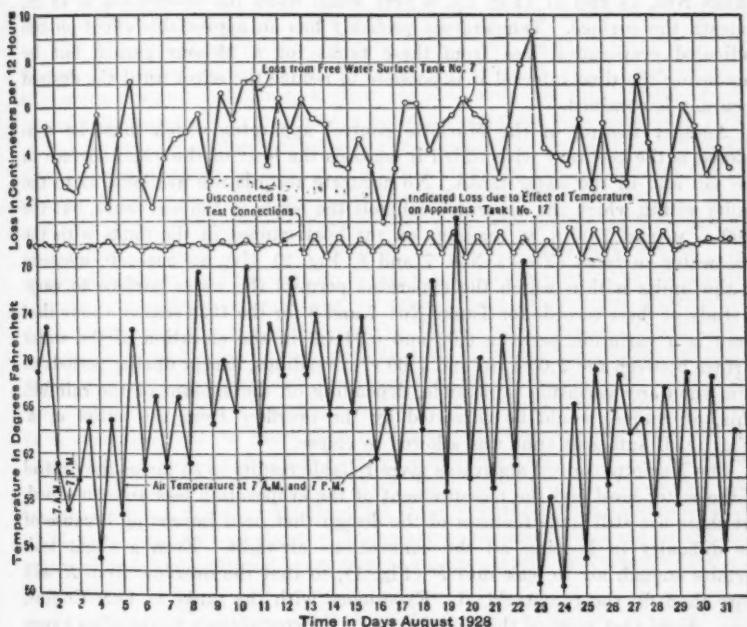

FIG. 5.—EFFECT OF TEMPERATURE ON MARIOTTE CONTROL APPARATUS.

the meteorological records of the Colorado Experiment Station, and the gain and loss of the water levels in Tank No. 17, in centimeters, for the 12-hour intervals between the 7:00 P. M., 7:00 A. M., and 7:00 P. M. readings for each 24-hour period during the month of August, 1928. The plot indicates, in general, that the water rose in the Mariotte tank when the temperature decreased, and fell when the temperature increased; but the amount of the rise and fall was not proportional to the change in temperature. This is probably due to the fact that since the tanks were carefully insulated, the temperature in the tank did not follow the temperature of the air very closely.

\* Unpublished records of the Irrigation Investigations of the Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, co-operating with the Colorado Agricultural Experiment Station.

For comparison, the record of the evaporation loss from a free water surface under similar conditions, as shown by Tank No. 7 (Fig. 2), is also given. The plot shows that the loss due to evaporation from the free water surface is many times the fluctuation in Tank No. 17 due to the change in temperature. If the comparison had been made on the basis of 24-hour intervals, the difference would have been several times greater because the loss from the free water surface would be nearly doubled and the net change in Tank No. 17 would have been considerably less. The author has shown (Fig. 4) that the evaporation loss from coarse river sand and heavy adobe, Tanks Nos. 14 and 17 (Fig. 2), is very small when the water-table is 12 in. beneath the surface. Temperature probably has an appreciable effect on the indicated evaporation loss from these tanks for a 24-hour period, but by increasing the time interval it is possible to reduce the effect until the desired accuracy is obtained.

Another feature of the Mariotte control apparatus which must be considered is the accuracy with which it controls the level of the water surface in the soil and in the water tanks. No accurate records are available as to the limits within which the apparatus controls the levels in the soil tanks, but the 7:00 A. M. and 7:00 P. M. readings on the hook-gauges in the tanks with the free water surfaces (Tanks Nos. 7 and 8, Fig. 2) give an accurate measure of the limits within which the apparatus permits the water surface to vary. A study of these records for Tanks Nos. 7 and 8 for the 1928 season, shows that there is a variation between 0.02 and 0.04 in. in the elevation of the water surface between the 7:00 A. M. and 7:00 P. M. readings, except during periods of rain when any variation is possible, depending on the amount of the rainfall. This, of course, would be corrected by the overflow from the outlet at *K* (Fig. 1), if sufficient time was allowed to elapse.

The Mariotte control apparatus gives reliable results in so far as the control of the water level and the measurement of the evaporation loss are concerned, but there are still some features of the design that need improving because of the difficulty in keeping all the connections air-tight. Even a slight leak permits enough air to leak into *D* (Fig. 1), so that the overflow from *K* will more than fill the receptacle, *B*. Experience with the tanks at Fort Collins, Colo., shows that most of the leaks occur in the connections to the glass gauge tubes. The writer believes that this condition could be corrected by introducing the tube, *T*, into the chamber, *D*, through a packed gland. This would permit using a smaller gauge glass which would be much easier to keep air-tight.

IVAN E. HOUK,\* M. AM. SOC. C. E. (by letter).—This paper is valuable to hydrologic engineers for two reasons: First, it presents carefully observed data on the quantities of water evaporated from different soils, with different depths to ground-water; and, second, it describes an automatic method of delivering easily measured quantities of water to soil tanks, as needed to supply evaporation losses, without materially changing the level of the ground-water surface.

\* Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

It is to be regretted that the experiments did not include soil tanks with ground-water surfaces maintained at greater depths than 12 in., especially in the case of the fine sand and loam soils where the 1927 ratios of soil evaporation to free water-surface evaporation for the 12-in. depths varied from 50 to 100 per cent. Depths to ground-water along sandy river channels may vary from zero to several feet. Consequently, engineers engaged in hydrologic studies of such areas need to know the relations between rates of soil evaporation and depths to ground-water for the entire range of depth in which any appreciable quantities of soil moisture are raised to the ground surface by capillary action. Investigations of soil evaporation made thus far seem to indicate that the limiting depth is about 4 ft. in the case of bare sandy or sandy loam soils.

The advisability of using covers to protect the tanks from rain in conducting soil evaporation measurements is questionable. The installation of the covers when the rain begins, their removal when the rain ceases, and the proper adjustment of the evaporation records when some rain unavoidably falls on the soil tanks is probably much more troublesome, as well as more uncertain, than the measurement of total rainfall in a standard rain gauge and the correction of total measured evaporation by total measured precipitation. Moreover, the latter method would furnish data more comparable with actual field evaporation. Nature does not provide covers when the rain begins. The engineer has more need for data on actual rates of soil evaporation immediately following rainfall occurrence than on rates of soil evaporation under watertight covers. For this reason the data in Table 4 are valuable. Conditions of air movement and radiation comparable with those existing under the covers would occur only in the densest jungles of the tropical regions. In most forests the conditions of air movement and radiation at the surface of the ground would be intermediate between those existing under covers and in the open. In this connection the writer would like to know how the average rates of evaporation given in Table 3 were derived. Were they computed for the total times between limiting dates, or for the total times reduced by the intervals during which the covers were in place? The writer would also like to see some photographs showing the general arrangement of the station and typical details of installation.

During the fall of 1926, the U. S. Bureau of Reclamation, in co-operation with the Middle Rio Grande Conservancy District and the U. S. Weather Bureau established a soil evaporation station near Los Griegos, N. Mex., about four miles northwest of Albuquerque. The station was designed for use in studying evaporation from the low undrained bottom-lands and river sandbars along the Middle Rio Grande Valley. It was first equipped with a rain gauge, anemometer, sling psychrometer, maximum and minimum thermometers, two water-surface evaporation pans, two sand pans, and three salt-grass sod pans. Two additional soil pans were added after the station had been operated one year. Fig. 6 shows the arrangement of the equipment and the topography in the vicinity of the station, and Table 7 gives some brief notes regarding the depth and nature of the pans.

Fig. 7 shows the two water-surface evaporation pans; Fig. 8 shows one of the sand pans; and Figs. 8 and 9 also show the three small tubes placed in the soil pans for use in measuring depths to ground-water.

The water-surface evaporation pans were designated Nos. 1 and 2. Pan No. 1, 4 ft. in diameter by 2 ft. deep, was set in the ground to a depth of 21 in., and was kept filled to within 3 in. of the rim. It was more nearly like a floating pan than an ordinary ground pan, since the ground-water table was relatively close to the surface, the depth usually varying from about 8 to 20 in. Pan No. 2 was a standard U. S. Weather Bureau Class A evaporation pan, 4 ft. in diameter by 10 in. deep, mounted on a timber platform, having a surface about 7 in. above the ground.

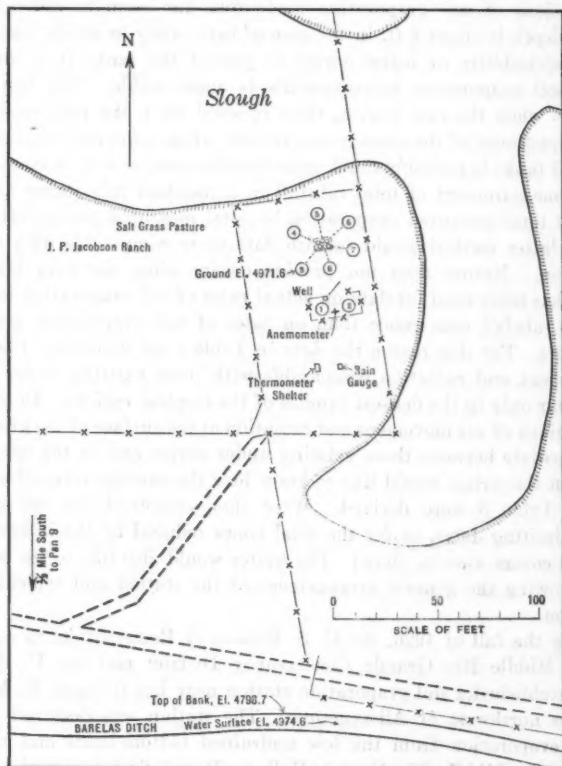

FIG. 6.—PLAN OF INSTALLATION AND TOPOGRAPHY AT LOS GRUEGOS EVAPORATION STATION.

The plans for the installation of the soil tanks were based on the author's Fort Collins Station, but were modified somewhat so as to secure larger pans and tanks and more substantial pipe connections. Standard 18-gal. hot-water tanks, nominally 12 in. in diameter by 36 in. high, with the usual plumbing connections, were used as supply tanks; and standard farm stock tanks, approximately 4 ft. in diameter, were used as pans. All equipment was

carefully tested for water-tightness before installation. The stock tanks were set in the ground, without the use of outside tank containers. The double-tank arrangement is necessary when the soil evaporation is determined by weighing, since then the tanks must be lifted out to be weighed. However, when the Mariotte system is used, about the only advantage of the double tank is that the water-tightness of the outside container can be easily checked at any time by simply removing the inner tank and filling the outer one with water.

TABLE 7.—DESCRIPTION OF PANS SHOWN IN FIG. 6.

Pan No.	Depth, in inches.	Date of installation.	Contents.
1	24	September, 1926	Water.
2	10	September, 1926	Class A, U. S. Weather Bureau.
3	48	September, 1926	Sand, no vegetation.
4	48	September, 1926	Soil, salt-grass sod.
5	36	September, 1926	Soil, salt-grass sod.
6	24	September, 1926	Soil, salt-grass sod.
7	24	September, 1926	Sand, no vegetation.
8	48	September, 1927	Soil, salt-grass sod.
9	36	September, 1927	Soil, tules.

At the Los Griegos Station the water supply pipes were connected directly to the bottoms of the tanks, which were covered with from 6 to 8 in. of coarse gravel, so as to supply water uniformly to the entire bottom of the test soil filling. Pans Nos. 3 and 7 (see Fig. 8) were filled with river wash material composed of a rather fine sand with traces of silt. The material was hauled from a sand-bar on the bank of the Rio Grande and was placed in the pans in water so as to simulate the original manner of deposition. Depths to ground-water were maintained at from 3 to 5 in. in Pan No. 7, and from about 20 to 28 in. in Pan No. 3. Pans Nos. 4, 5, and 6 were filled with the soil excavated to provide holes for the pans. The soil was placed in the pans in thin layers, tamped, and in the same order as excavated. Depths to ground-water were maintained at from 20 to 28 in. in Pan No. 4, from 12 to 19 in. in Pan No. 5, and from 3 to 6 in. in Pan No. 6. Samples of the various soils placed in these three pans were sent for analysis to the Agricultural Experiment Station at State College, N. Mex., and were classified as Gila clay loam. The various strata encountered were described as follows:

Depth below ground surface, in inches.	Material.
0 to 15.....	Clay loam
15 to 31.5.....	Fine, sandy loam
31.5 to 42.....	Clay
42 to 48.....	Sand

The average results of mechanical analyses of the Gila clay loam soils of the Middle Rio Grande Valley\* are given in Table 8.

\* As given in the Soil Survey Bulletin, 1912.

A sample of the ground-water used in supplying both soil and water pans was taken August 28, 1926. It was analyzed at the Agricultural Experiment Station at State College, N. Mex., with the following results:

Chemical analysis.	Mineral matter, in parts per 100 000.
Sodium carbonate .....	23.0
Sodium chloride .....	8.6
Sodium sulfate .....	13.2
Total .....	44.8

The water in Pans Nos. 1 and 2 was renewed frequently, in order to avoid a concentration of alkaline salts which might influence the observed evaporation rate. Some difficulty with the soil tanks was anticipated because of the high content of sodium salts in the water used. However, the salt-grass grew vigorously, especially in Pan No. 6 which received a full supply of water.

During dry periods the evaporation rate at Pan No. 5 was decreased in comparison with that at the other pans, due to the formation of a fine alkaline dust on the surface of the soil. The evaporation rate at Pan No. 3 was also relatively low during such periods, due to the presence of a somewhat similar mulch made up of several inches of loose dry sand. These mulches greatly reduced capillary action.

TABLE 8.—MECHANICAL ANALYSIS OF GILA CLAY LOAM SOILS.

Gradation.	Soil.	Subsoil.	Lower subsoil.
Fine gravel .....	0.0	0.3	0.3
Coarse sand .....	1.3	1.3	4.7
Medium sand .....	2.3	4.0	14.6
Fine sand .....	15.5	29.8	55.1
Very fine sand .....	14.7	26.5	17.6
Silt .....	35.3	17.2	3.7
Clay .....	30.9	16.2	4.1

For measuring depths to ground-water, three pipes were provided in each soil pan. The pipes terminated a short distance above the saturated layer of gravel at the bottom of the pan. However, the holes at the lower ends gradually opened until finally the elevations of the water-table in the pipes corresponded to the storage-tank pressures. In the case of Pans Nos. 4 and 5 the depths to ground-water measured in the pipes were somewhat less than the actual depths to the water-table in the soil, as determined by additional holes, bored as needed, using care not to penetrate the gravel.

Violent fluctuations in elevation of ground-water surface at Pan No. 7 sometimes occurred due to sudden changes in meteorological conditions. A change of as much as 4 in. sometimes took place within a few hours for no apparent reason, probably due to unnoticeable changes in temperature and barometric pressure. The sudden occurrence of a strong, warm, dry wind would increase the rate of soil evaporation so much that the ground-water would be depleted more rapidly than it could be supplied by the Mariotte flask. Variations in ground-water level also occurred, due to variations in temperature and vacuum at the supply tanks. However, these fluctuations in ground-water level were relatively unimportant as regards the total monthly or annual evaporation losses.

¶ Pans covered with ice during most of December and up to January 9, 1927.

In the fall of 1927 a study of the first year's records showed the need for a salt-grass sod pan in which the ground-water table could be kept at a somewhat greater depth than was possible with the pans already in use. Consequently, Pan No. 8 was installed, with provisions for maintaining the ground-water surface at a depth of approximately 3 ft. In filling Pan No. 8 the clay layer encountered between depths of 2 ft. 7½ in. and 3 ft. 6 in. was omitted so as to secure data more nearly comparable with those obtained at Pans Nos. 5 and 6. Another new pan (No. 9) was installed at that time. This was planted with tules and the ground-water kept at, or slightly above, the surface of the ground so as to determine the total depths evaporated and transpired

in tule swamps. This pan was located in a small tule swamp in an old river channel about  $\frac{1}{2}$  mile south of the station. The swamp was usually dry in the fall of the year, for a period of from one to two months, due to the lowering of the ground-water level.

Tables 9 and 10\* are summaries of the data secured during the first two years of operation. Table 9 gives the monthly meteorological data includ-

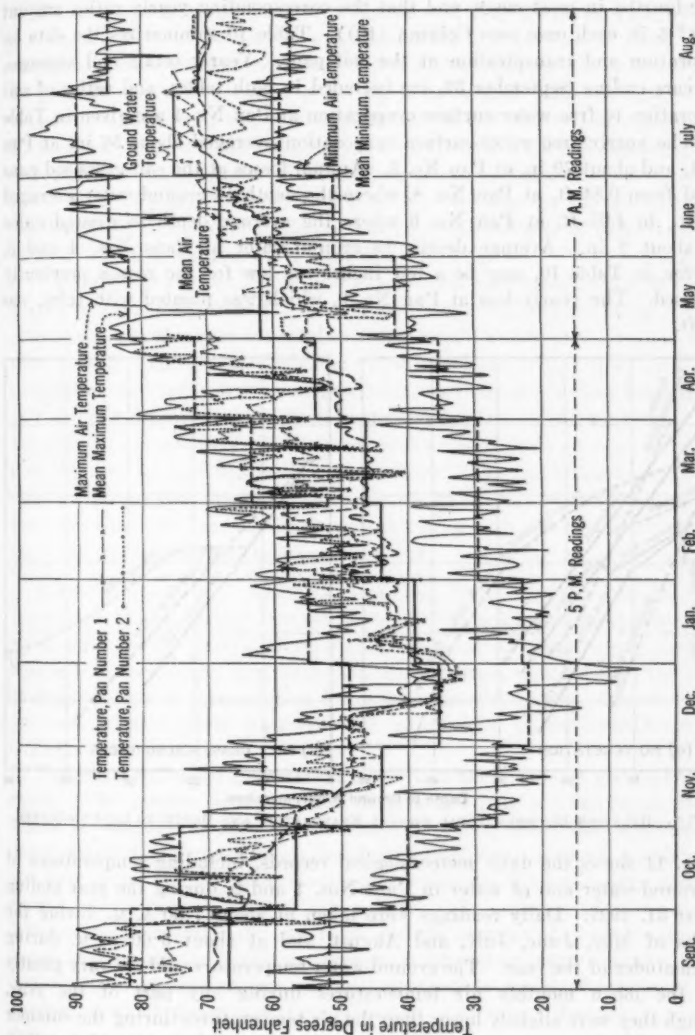

FIG. 11.—AIR AND WATER TEMPERATURES, LOS GRIEGOS EXPERIMENT STATION.

ing the measurements of free water-surface evaporation. It will be noticed that the ratios of monthly ground-pan evaporation (Column (8)) to monthly Class A pan evaporation (Column (9)) vary from about two-thirds to about three-fourths in most cases, and that the corresponding yearly ratios amount to 70.7% in each case (see Column (10)). Table 10 summarizes the data on evaporation and transpiration at the soil pans. Yearly totals and averages, for years ending September 30, are included in both tables, and ratios of soil evaporation to free water-surface evaporation at Pan No. 1 are given in Table 10. The yearly free water-surface evaporation averaged about 56 in. at Pan No. 1, and about 79 in. at Pan No. 2. Annual losses at the salt-grass sod pans varied from 0.84 ft. at Pan No. 8, where the depth to ground-water averaged 3.07 ft., to 4.03 ft. at Pan No. 6 where the average depth to ground-water was about 3 in. Average depths to ground-water at Pans Nos. 4 and 5, as given in Table 10, may be a few inches too low for the reason previously discussed. The yearly loss at Pan No. 9, which was planted with tules, was 5.39 ft.

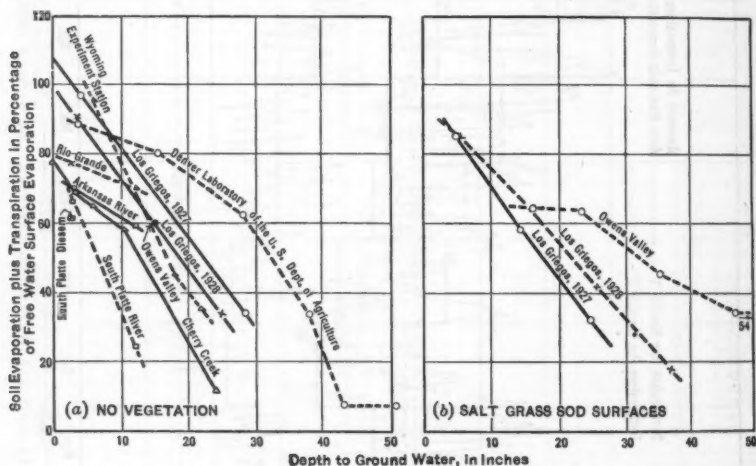

FIG. 12.—RELATION BETWEEN TOTAL ANNUAL EVAPORATION AND DEPTH TO GROUND-WATER.

Fig. 11 shows the daily meteorological records, including temperatures of the ground-water and of water in Pans Nos. 1 and 2, during the year ending August 31, 1927. Daily readings were taken at about 7:00 A. M. during the months of May, June, July, and August, and at about 5:00 P. M. during the remainder of the year. The ground-water temperatures did not vary greatly from the mean monthly air temperatures during any part of the year, although they were slightly lower than the air temperatures during the summer when the measurements were made in the morning, and slightly higher than the air temperatures during the remainder of the year when the observations were made late in the afternoon. Water temperatures in the evaporation pans were nearly as great as the maximum air temperatures when the observa-

tions were made at 5:00 P. M. and slightly lower than the mean air temperatures when the readings were made at 7:00 A. M. Water temperatures in Pan No. 1 were a few degrees lower than those in Pan No. 2, as would be expected.

Fig. 12(a) shows the annual soil evaporation at Pans Nos. 3 and 7, in percentage of free water-surface evaporation, plotted against the average depths to ground-water. For comparative purposes similar data obtained at the Wyoming Agricultural Experiment Station,\* at the Denver Laboratory of the U. S. Department of Agriculture,† and in Owen's Valley, California,‡ have been added on the diagram. The data presented by the author have not been added since they are similarly shown in Fig. 4. Fig. 12 (a) would indicate that but little, if any, evaporation occurs from the surfaces of bare, sandy soils when the depth to ground-water exceeds about 4 ft.

Fig. 12 (b) shows the annual soil evaporation and transpiration at the salt-grass sod tanks, Pans Nos. 4, 5, and 6, the Owen's Valley data being added for comparison. In this case the results of the Owen's Valley investigations constitute the only similar data available. It will be noticed that the ratios of soil evaporation and transpiration to free water-surface evaporation were appreciably lower at the Los Griegos Station than at the Owen's Valley Station. The Los Griegos records were also more consistent as regards relation of evaporation losses to average depths to ground-water. The Los Griegos experiments seem to indicate that the loss of soil moisture by evaporation and transpiration, from the Gila clay loam covered with salt-grass sod, practically ceases when the depth to ground-water reaches about 4 ft.

RALPH L. PARSHALL,§ ASSOC. M. AM. SOC. C. E. (by letter).—The writer is gratified in the general interest shown in the subject of evaporation from moist soils, by the several discussions. Because of water supply problems, especially in the West, now being studied in considerable detail, the matter of evaporation and transpiration losses from extended areas of both irrigated and non-irrigated lands requires basic information in the solution of these important problems.

Numerous studies of evaporation losses have been made by previous investigators. The present apparent lack of data covering a wide range of soils, depths to water-table, and various kinds of plants, offers the opportunity of more extended and detailed study of this important research problem, and Mr. Fortier, in his very able discussion, points out the immediate need of a more complete investigation of this nature. The question of water supplies is becoming more and more important and the element of evapo-transpiration losses, bearing on the problem, likewise is becoming more urgent. Present investigations of this subject are still confined to tanks of relatively small dimensions which necessitate the application of correction factors for extended areas.

§ Irrig. Engr., U. S. Dept. of Agriculture, Fort Collins, Colo.

The want of such factors as mentioned by Mr. Blaney is fully appreciated. The application of such correction factors for evapo-transpiration losses, based on the evaporation from a free water surface, or from a saturated soil surface, can not be reasonably approximated. The vegetative draft on the soil moisture is much more than is commonly supposed and, therefore, until more extensive studies are made on a large scale, covering a rather wide range of conditions, the engineer will be obliged to apply very uncertain corrections in summing up the losses due to evaporation and plant use. The investigation by Messrs. Blaney and Young in California is without doubt the most extensive and detailed study yet attempted, and from this work will come a substantial advancement in the knowledge of this important question.

Mr. Sonderegger's statement that the losses from the fine river-bed sands were from disturbed material is true. However, as these sands were originally laid down by the deposition from the flood flows of the river, it may be fairly concluded that, in the case of the experimental set-up of these materials, the density or compaction was essentially the same as in the original bed. The practical engineering use of the data resulting from experimental studies must of necessity be applied to a very wide range of soil conditions. To assume that the results of an investigation of a single soil condition are applicable to the wide variation found over an extended area, would therefore seem to be rather doubtful. The writer is somewhat inclined to question whether any marked difference in the rate of evaporation from a cored sample or otherwise would be evident in an experimental set-up.

The use of sprinkling in the application of water to the soil, is believed to be uneconomical from two standpoints: First, if the application is moderate, the cooling of the ground surface and the temporary linking up of the capillary movement have been shown to deplete the soil moisture; and, second, the fact that the spray vastly increases the evaporating area of the water surface results in a much greater loss than if the water was applied as a stream in contact with the ground. As pointed out by Mr. Sonderegger, the classification of soil by the moisture equivalent percentage, from the standpoint of evaporating medium, is no doubt much more satisfactory than the simple classification of a mechanical analysis. It seems reasonable to suppose that possibly the rate of capillary movement in a soil column might be a better index than either the mechanical or the moisture equivalent. The apparent evaporation loss from soil surfaces where the water-table is at some depth, is, in effect, a function of the capillary movement of the moisture to the surface where it is dissipated as evaporation. The loss can only be as rapid as the capillary movement of the soil moisture from the water-table to the surface.

The proposal to place covers over the experimental soil tanks, as a means of protection against rain, may be considered questionable. Experience indicates that where rain falls on the exposed area, an element of uncertainty in the resulting records becomes apparent, because of the inability to determine the amount of the correction to be applied due to the precipitation. Splash from a dashing shower, wide rims on the tanks, and the inherent inaccuracy of measuring the rainfall in a standard rain gauge, all result in a doubtful cor-

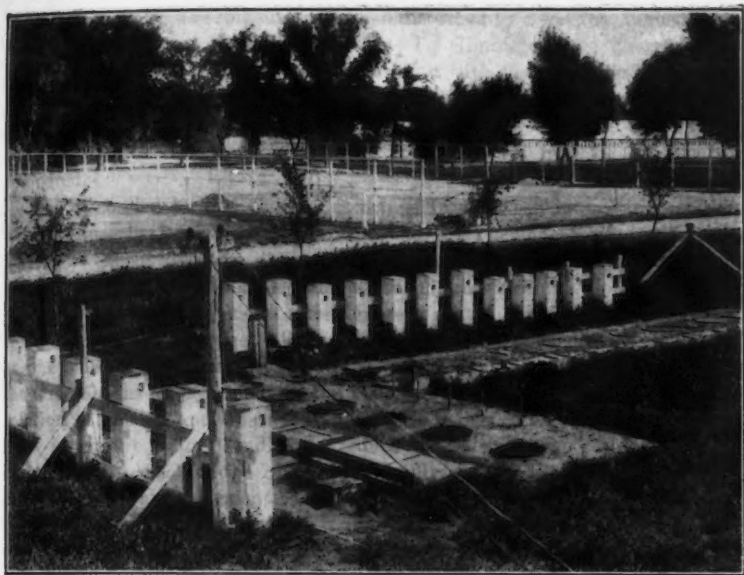

FIG. 13.—GENERAL VIEW OF ARRANGEMENT OF SOIL TANKS AND METEOROLOGICAL EQUIPMENT.

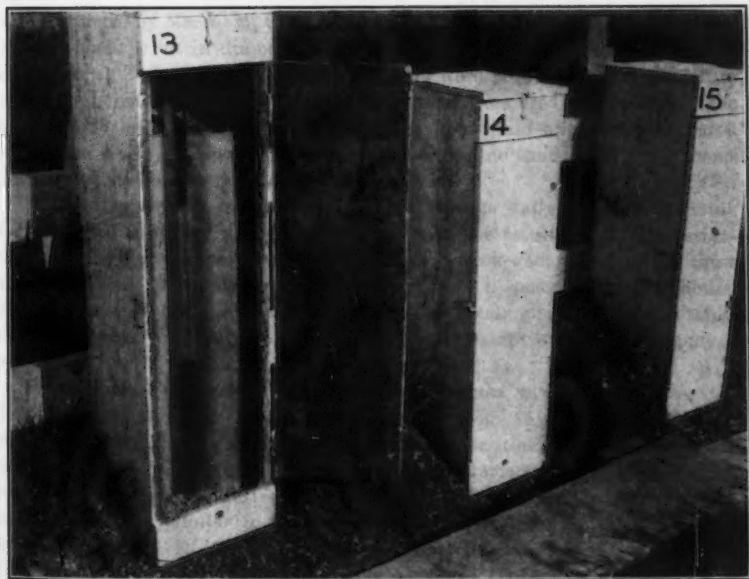

FIG. 14.—HOUSING FOR MARIOTTE TUBE REGULATION.

rection factor; also, the soil surfaces, when disturbed by a wetting, immediately assume a different evaporating medium. To eliminate these uncertainties, covers were provided. The rate of evaporation with the covers on resulted in a marked decrease in the rate of loss. Ordinarily, these covers were on only for a short period to protect against a passing shower. Inasmuch as all tanks were covered for the same period, the relative losses may be consistently compared.

The discussion by Mr. Cummings brings forward the interesting relation of the atmospheric component of energy to the phenomena of evaporation. Energy is expended in the dissipation of water by evaporation and when the surface of the evaporating medium is shaded, the incoming solar energy is reduced. The experiments in question were not in sufficient detail to draw conclusions as to this effect. The covers were partly opened at the ends and at one side, thus permitting some circulation of air currents. However, as the sun was shaded by clouds at the time the covers were in place, no direct relation of shaded and unshaded effects is possible. It is assumed that the most important factors tending to reduce the rate of evaporation when the covers are in place, are the increased humidity due to the rain and the protection against air movement.

Mr. Houk's discussion presents valuable data, especially for depths of soils exceeding those reported by the writer. At the time of the set-up of the apparatus to study the evaporation loss from moist soil surfaces, it was the intention to determine the relative losses for shallow depths of water-table for various types of fine sands and other soils. In 1913 a series of experiments were conducted by Mr. V. M. Cone to determine the rate of capillary rise in soil columns about 1 in. in diameter. It was found that, for a fine sandy loam soil, taken at Eads, Colo., more than 100 days were required for the moisture to reach a height of 58 in. For the river-bed sand, as used by Mr. Houk, the writer would be inclined to assume that the loss would approach zero for a water-table much less than 4 ft. For the medium fine sand (Fig. 4), it seems evident that no loss would occur at about 20 in.

The data presented in Table 3 give the average daily loss per 24 hours for the period indicated. The first tabulation of the results of this investigation gave the average loss per 24 hours for each week and, in compiling these data, corrections were made where the covers were in place for several hours. For the most part the covers were put on just long enough to protect the tanks during a shower and for these short periods no attempt was made to apply a correction.

Fig. 13 is the general arrangement of soil tanks with housing over the Mariotte tube regulators. (See, also, Fig. 2.) Fig. 14 shows Tank No. 13 with the exposed glass tube and adjacent fixed meter stick used in determining the evaporation loss. Previous to the use of the Mariotte principle as applied to maintaining and regulating the water supply for an evaporation tank, an arrangement very similar to the apparatus described by the writer was used by O. V. P. Stout, M. Am. Soc. C. E., and Carl Rohwer, Assoc. M. Am. Soc. C. E., in the study of seepage losses from canals in California.

### PROBLEMS CONCERNING ELASTIC STABILITY IN STRUCTURES\*

By S. TIMOSHENKO,† Esq.

---

WITH DISCUSSION BY MESSRS. H. M. WESTERGAARD, WILLIAM HOVGAARD,  
A. NADAI, AND S. TIMOSHENKO.

---

#### SYNOPSIS

Sometimes the strength of a structure does not depend on the ultimate strength of the material used, but on the elastic stability of the members. Such problems become of great practical importance in steel structures where materials of high strength are used. Problems of this kind, involving buckling of built-up columns, buckling of a compressed top chord of a half-through span, and stability of webs in compressed members and girders, are considered.

---

#### I.—INTRODUCTION

The simplest case in which the strength of a structure does not depend on the ultimate strength of the material, but on the elastic stability of the members of the structure, is a strut or a column under the action of a compressive force. If the length of the strut is large in comparison with its cross-sectional dimensions, failure will occur as a result not of a high compressive stress but of elastic instability. The strut may buckle sidewise at a stress less than the yield point of the material.

In steel structures, materials of high strength are used and, as a consequence, the transverse dimensions of members are likely to become small in comparison with the length. With the modern tendency to increase the yield

† Prof. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

point of structural steels the field of application of theoretical solutions, based on the assumption of a perfectly elastic material, increases and these solutions are, therefore, of practical interest. Several solutions of this kind will be given and their application to such problems as stability of built-up columns, stability of  $\Gamma$ -beams, and stability of webs of girders, will be considered.

## II.—STABILITY OF BUILT-UP COLUMNS

A solid column with hinged ends will be taken as a fundamental case and the critical loads,  $P_{cr}$ , for different built-up columns will be compared with the known critical load for this case, which is:

$$P_{cr} = \frac{EI \pi^2}{l^2} \dots \dots \dots (1)$$

in which,  $EI$  is the flexural rigidity of the column in the plane of buckling, and  $l$  is the length of the column.

FIG. 1.

FIG. 2.

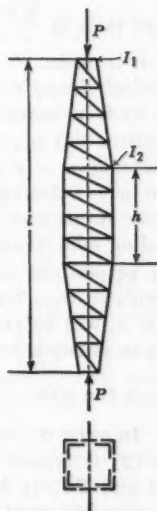

FIG. 3.

Critical loads for built-up columns are always less than those for solid columns having the same value of  $\frac{EI}{l^2}$  and depend on such details as lattice-bars and spacing plates, or battens. The value of critical loads for such columns can always be represented by the equation:

$$P_{cr} = \alpha \frac{EI \pi^2}{l^2} \dots \dots \dots (2)$$

in which,  $\alpha$  is a factor less than unity.

Take, for instance, the case shown in Fig. 1. The factor,  $\alpha$ , in Equation (2) for this case can be represented in the following form.\*

$$\alpha = \frac{1}{1 + \frac{E I \pi^2}{l^2} \left( \frac{a c}{12 E I_2} + \frac{a^2}{24 E I_1} \right)} \dots \dots \dots (3)$$

in which,

$a$  = distance between the axes of battens.

$c$  = distance between centers of gravity of channels.

$I$  = moment of inertia of the cross-section about the  $y$ -axis.

$I_1$  = moment of inertia of the cross-section of a channel about the axis through its center of gravity and parallel to the  $y$ -axis.

$I_2$  = moment of inertia of the cross-section of a batten about the axis through its center of gravity and perpendicular to the axis of the column.

It is seen that the strength of the column against buckling depends not only on the value of  $\frac{E I}{l^2}$ , but also on the rigidity of the channels and battens of which it is made.

*Numerical Example.*—For a cross-section consisting of the 15-lb., 10-in. channels, let it be assumed that  $l = 30$  ft.,  $a = 36$  in.,  $c = 7.3$  in., the thickness of battens =  $\frac{3}{8}$  in., and the width of battens = 9 in. Then, for the cross-section, calculated as a solid column,  $I = 123$  in.<sup>4</sup>, while  $I_1 = 2.3$  in.<sup>4</sup>, and  $I_2 = 45.6$  in.<sup>4</sup>. Substituting in Equation (3),  $\alpha = 0.82$ . Hence, in this case, the ultimate strength of the built-up column is 0.82 of the critical load of the corresponding solid column.†

If the proportions of a built-up column are such that the compressive stress calculated from Equation (2) is beyond the yield point of the material, the factor,  $\alpha$ , will be greater than that given by Equation (3). Hence, the difference in strength between the two types of columns will diminish with a decrease of the ratio,  $\frac{l}{r}$ . This conclusion can also be deduced from Equa-

tion (3). In order to obtain  $P_{cr}$  analytically when the stress as calculated by Equation (2) is beyond the yield point of the material, the constant quantities,  $E I$  and  $E I_1$ , in Equation (3), because of the decrease in modulus of elasticity above the yield point, must be replaced by variable quantities diminishing with the increase in compressive stress. At the same time, the rigidity,  $E I_2$ , of the battens, which are not subjected to compression, remains equal to unity. This means that the value of  $P_{cr}$ , calculated from Equation (3), for the cases of short columns, will always be on the safe side.

In the case of a latticed column (Fig. 2), the values of the factor,  $\alpha$ , in Equation (2) can be calculated from the equation:

$$\alpha = \frac{1}{\frac{E I \pi^2}{l^2} \frac{1}{E \sin \theta \cos^2 \theta A}} \dots \dots \dots (4)$$

in which,  $A$  is the cross-sectional area of a lattice-bar.

\* For the derivation of this equation see "Applied Elasticity," by S. Timoshenko and J. M. Lessells, pp. 180-182.

† A central application of the compressive force,  $P$ , is always assumed.

The latticing is usually so proportioned that the factor,  $\alpha$ , differs little from unity. Then, the formula for solid columns can be used.

Consider now a square column shown in Fig. 3. The middle part (of the length,  $h$ ) has a constant moment of inertia,  $I$ , decreasing toward the ends, where it is  $I_1$ . Assuming that the latticing is proportioned in such a manner that the column can be considered as solid and of variable cross-section, the critical value of compressive force will be found from the equation:

$$P_{cr} = \beta \frac{EI}{l^2} \dots \dots \dots (5)$$

in which,  $\beta$  is a numerical factor, the value of which depends on the ratios,  $\frac{h}{l}$  and  $\frac{I_1}{I}$ . Evidently, the value of  $\beta$  must approach  $\pi^2$  when the ratios,  $\frac{h}{l}$  or  $\frac{I_1}{I}$ , approach unity because then the column becomes almost uniform in cross-section. Some values of the factor,  $\beta$ , are given in Table 1.\*

TABLE 1.—VALUES OF THE FACTOR,  $\beta$ , IN EQUATION (5).

Values of $\frac{I_1}{I}$	VALUES OF $\frac{h}{l}$

### III.—BUCKLING OF STRUTS HAVING LATERAL ELASTIC SUPPORTS

This type of problem is encountered, for instance, in considering sidewise buckling of the compressed top chord of a half-through truss span. As a simple case, assume that a strut of uniform cross-section, when buckled under the action of compressive forces,  $P$  (Fig. 4), encounters a resistance produced by an elastic medium such that the lateral reactions continuously distributed along the strut are proportional to the corresponding deflections. Because of these lateral reactions the critical load will be greater than that given by Equation (1). The magnitude of this load can be found from a consideration of the potential energy of the system.† The critical value of the compressive force,  $P$ , is that at which the work done during sidewise buckling by the compressive forces is equal to the potential energy of bending of the strut, together with the energy of deformation of the elastic medium. For the potential energy of bending of the strut the following equation applies:

$$V_1 = \frac{EI}{2} \int_0^l \left( \frac{d^2 y}{dx^2} \right)^2 dx \dots \dots \dots (6)$$

\* This table was calculated by Prof. A. Dinnik, Polytechnical Inst., Ekaterinoslaw (Russia).

† For discussion of this energy method, see "Applied Elasticity," p. 169.

In considering the potential energy of the elastic medium, a factor,  $K$ , called the modulus of the medium, is taken such that the product,  $K y$ , represents the reaction of the medium per unit length of the strut when the deflection is equal to  $y$ . Then the work done by this reaction during deflection will be  $-\frac{1}{2} K y^2$  and, consequently, the potential energy of the deformed elastic medium will be:

$$V_2 = \frac{K}{2} \int_0^l y^2 dx \dots \dots \dots (7)$$

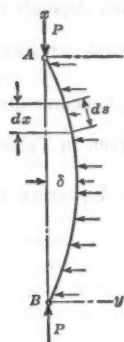

FIG. 4.

FIG. 5.

The work done by the compressive forces during buckling will be obtained by multiplying  $P$  by the displacement of the end,  $A$ , with respect to  $B$ , which occurs during sidewise buckling of the strut. Taking into consideration the fact that the difference between the element,  $ds$ , of the deflection curve and its vertical projection,  $dx$  (since  $\frac{dy}{dx}$  is small), is equal to:

$$ds - dx = dx \sqrt{1 + \left(\frac{dy}{dx}\right)^2} - dx = \frac{1}{2} \left(\frac{dy}{dx}\right)^2 dx$$

the work,  $T$ , produced by the compressive forces during buckling will be:

$$T = \frac{P}{2} \int_0^l \left(\frac{dy}{dx}\right)^2 dx \dots \dots \dots (8)$$

Now, from Equations (6), (7), and (8), the condition for the critical load will be:

$$\frac{1}{2} P \int_0^l \left(\frac{dy}{dx}\right)^2 dx = \frac{1}{2} EI \int_0^l \left(\frac{d^2y}{dx^2}\right)^2 dx + \frac{1}{2} K \int_0^l y^2 dx \dots \dots (9)$$

If the elastic medium has a small rigidity so that the factor,  $K$ , is small, the deflection curve will be the same as in the case of a strut without lateral support. Therefore, it can be represented by:

$$y = c \sin \frac{\pi x}{l} \dots \dots \dots (10)$$

Substituting this in Equation (9),

$$P_{\sigma} = \frac{E I \pi^2}{l^2} \left( 1 + \frac{K l^4}{E I \pi^4} \right) \dots \dots \dots (11)$$

The second term in the brackets represents the effect of the elastic medium on the critical load.

In the case of a medium of greater rigidity, the deflection curve of the buckled strut has a more complicated shape consisting of several waves (Fig. 5). With an increase in rigidity of the medium, the number of waves of the deflection curve increases, but each wave is a simple sine wave and for calculation of critical loads Equation (11) can be used. To do this it is only

necessary to substitute in this equation, instead of the length,  $l$ ,  $\frac{l}{m}$ , in which,  $m$  denotes the number of waves. Then:

$$P_{\sigma} = \frac{E I \pi^2}{l^2} \left( m^2 + \frac{K l^4}{E I \pi^4 m^2} \right) \dots \dots \dots (12)$$

In each case,  $m$  must be chosen in such a manner as to make the sum in the bracket a minimum. This number, which depends on the rigidity of the medium, increases with the increase of the quantity,  $K$ , and can be determined in the following manner: Let  $K$  be the rigidity at which the number of waves in the deflection curve of the strut changes from  $m$  to  $m + 1$ . Then, the sum in the brackets of Equation (12) will remain unchanged by replacing  $m$  by  $(m + 1)$ , and, consequently,

$$m^2 + \frac{K l^4}{E I \pi^4 m^2} = (m + 1)^2 + \frac{K l^4}{E I \pi^4 (m + 1)^2} \dots \dots \dots (13)$$

from which,

$$m^2 (m + 1)^2 = \frac{K l^4}{E I \pi^4} \dots \dots \dots (14)$$

In this manner for each value of  $m$  the limiting value for the rigidity,  $K$ , can be calculated. For a value of  $K$  slightly less than this calculated value, the deflection curve will have  $m$  waves, while for a value of  $K$  slightly greater the deflection curve will have  $m + 1$  waves.

If the rigidity,  $K$ , or the length,  $l$ , are very large, the number,  $m$ , will also be large and, neglecting unity in comparison with  $m$  in Equation (14),

$$m^4 = \frac{K l^4}{E I \pi^4}$$

Substituting this in Equation (12),

$$P_{\sigma} = \frac{2 E I \pi^2 m^2}{l^2} \dots \dots \dots (15)$$

The critical load in this case is thus twice as great as in the case of a strut without lateral support and having a length equal to,

$$\frac{l}{m} = \sqrt[4]{\frac{E I \pi^4}{K}} \dots \dots \dots (16)$$

#### IV.—BUCKLING OF COMPRESSED TOP CHORD OF A HALF-THROUGH TRUSS SPAN

To determine the critical compressive force for the top chord of a half-through truss span is much more complicated because the compressive forces are distributed along the chord, the section of the chord is not constant, and instead of a continuous elastic medium there are lateral elastic supports represented by vertical truss members. Consider the simplest case of a through-truss span of a constant height,  $h$  (Fig. 6), and assume that the top chord has a uniform cross-section and that all the vertical truss members are of the same section except the end verticals which are so rigid that the ends of the top chord do not move laterally during buckling of the chord.

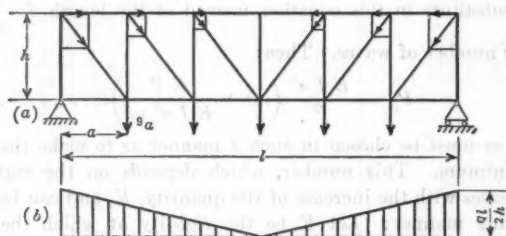

FIG. 6.

Assuming that the truss is subjected to the action of a uniformly distributed load of intensity,  $q$ , the tensile forces in the diagonals and their horizontal components, producing compression in the top chord, will be proportional to the distances from the middle of the span. Replacing the concentrated compressive forces acting on the top chord by equivalent continuously distributed forces, the distribution of the compressive forces will be as shown by the shaded area in Fig. 6 (b). The maximum compression will be at the middle of the chord and will be equal to  $\frac{q l^2}{8 h}$ . The critical value of

this compressive force corresponding to the beginning of sidewise buckling of the top chord can be found in the same manner as in the simple case of a strut in an elastic medium, already discussed. It is only necessary to replace the concentrated elastic reactions of the verticals, opposing the lateral deflection of the compressed chord, by continuously distributed reactions of an equivalent elastic medium. The modulus,  $K$ , of the equivalent medium will be:

$$K = \frac{Q}{a} \dots \dots \dots (17)$$

in which,  $Q$  is the lateral force which, if applied to the vertical member at the top chord panel point (neglecting for the moment the lateral resistance of the chord) will produce a lateral deflection of the vertical member equal to unity; and  $a$  is the distance between the verticals.

Assuming, for instance, that the lower ends of the verticals are absolutely fixed and putting  $E I_1$  equal to the flexural rigidity of the verticals in a lateral

direction, the force,  $Q$ , will be obtained from the expression,\*

$$\frac{Q h^3}{3 E I_1} = 1$$

from which,

$$Q = \frac{3 E I_1}{h^3} \dots \dots \dots (18)$$

Calculating  $K$  from Equations (17) and (18), and using an energy equation similar to Equation (9), it will be found (see Appendix) that the critical value of the maximum compressive force in the top chord can be represented by:

$$\left(\frac{q l^2}{8 h}\right)_{cr} = \gamma \frac{E I \pi^2}{l^2} \dots \dots \dots (19)$$

in which,  $\gamma$  is a numerical factor, greater than unity, and depending on the modulus,  $K$ , the lateral flexural rigidity,  $E I$ , of the top chord, and the span,  $l$ .

TABLE 2.—NUMERICAL VALUES OF THE FACTOR,  $\gamma$ , IN EQUATION (19),  
ENDS OF TOP CHORD FIXED Laterally.

$\frac{K l^4}{16 E I} =$	0	5	10	15	22.8	56.5	100	163	200	300	500	1 000
$\gamma =$	2.06	3.63	5.10	6.37	7.58	9.51	11.9	14.9	16.5	19.8	24.0	33.0

By using Table 2 the factor,  $\gamma$ , can be found for a given value of  $\frac{K l^4}{16 E I}$ . Then, the critical compressive force in the chord will be the same as for a simple strut, the length of which is equal to  $\frac{l}{\sqrt{\gamma}}$ . For  $K = 0$  the case is that of a strut without lateral supports and loaded as shown in Fig. 6 (b). The critical compressive force is then about twice as great ( $\gamma = 2.07$ ) as for a strut compressed by forces applied at the ends.

This method can be applied also in the case when end verticals are of the same rigidity as the intermediate verticals and the ends of the top chord are free to move laterally during buckling. Equation (19) can be used also in this case, but the numerical values of the factor,  $\gamma$ , are, however, somewhat different (Table 3).

TABLE 3.—NUMERICAL VALUES OF THE FACTOR,  $\gamma$ , IN EQUATION (19),  
ENDS OF TOP CHORD FREE TO MOVE Laterally.

$\frac{K l^4}{16 E I} =$	0	1	3	5	10	15	20	50	100	150	200	300	500	1 000
$\gamma =$	0	0.203	0.610	1.015	2.02	3.03	3.40	5.38	8.64	13.05	14.70	17.98	23.6	32.3

\* The bending of the cross-beam of the floor structure and the effect of the compressive force in the verticals on the deflection are neglected in this equation.

With an increase in the quantity,  $\frac{K l^4}{16 E I}$ , the values of  $\gamma$  approach those given in Table 2 for rigid end verticals. This result is easily understood since for the compressed top chord the deflection curve during lateral buckling may have several waves as in the case of a strut in an elastic medium (Fig. 5). The number of waves increases with the rigidity,  $K$ ; hence when this number is large, the critical load is no longer affected substantially by a variation in the end conditions.

#### V.—LATERAL BUCKLING OF I-BEAMS

It is known that, in the absence of lateral supports, an I-beam bent in the plane of the web may prove to be insufficiently stable. If the loads are increased beyond a certain critical limit, it buckles sidewise and collapses. The critical load can be found by the energy method; for a beam on two supports it always can be represented in the form:

$$P_{cr} = \frac{n \sqrt{B_2 C}}{l^2} \dots \dots \dots (20)$$

in which,

$B_2 = E I_2$  = the flexural rigidity of the beam in the direction perpendicular to the web.

$C$  = the torsional rigidity of the I-beam in twisting.

$l$  = the span.

$n$  = a numerical factor depending on the distribution of load, on the manner of fastening the ends of the beam, and on

the magnitude of the ratio,  $\frac{C l^2}{B_2 h^3}$ ,  $h$  being the depth of the beam.

Tables of the factor,  $n$ , for various cases, and the application of Equation (20) have been discussed previously.\* In Fig. 7,† beams of very narrow

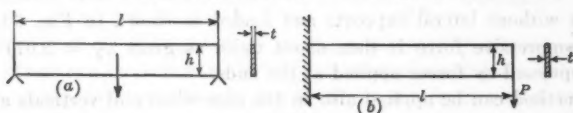

FIG. 7.

rectangular cross-section, instead of I-section, are taken. For such a beam supported at the ends, Fig. 7 (a), the critical load,  $P_{cr}$ , at which sidewise buckling begins, is:

$$P_{cr} = \frac{16.9 \sqrt{B_2 C}}{l^2} \dots \dots \dots (21)$$

In the case of a cantilever beam (Fig. 7 (b)):

$$P_{cr} = \frac{4.01 \sqrt{B_2 C}}{l^2} \dots \dots \dots (22)$$

\* Transactions, Am. Soc. C. E., Vol. 87 (1924), p. 1247.

† These cases have been discussed by L. Prandtl, in his dissertation, "Klipperscheinungen," München, 1899.

If  $h$  is the depth,  $t$ , the thickness of the web, and  $G$ , the modulus of shear,

$$B_2 = \frac{E h t^3}{12} \text{ and } C = \frac{1}{8} G h t^3$$

Substituting these in Equations (21) and (22), the critical load for each particular case easily can be calculated.

#### VI.—BUCKLING OF COMPRESSED PLATES

A.—In compression members of large cross-section, buckling of compressed plates may be of practical importance. Consider, for instance, the cross-sections given in Fig. 10. By diminishing the thickness of the column wall the member will fail under compression by the sidewise buckling of the plates themselves and not by the deflection of the column as a whole. The sides of columns may be considered as long rectangular plates under compression and with various conditions of fixity along the edges. In the simplest case a rectangular plate simply supported is compressed by forces uniformly distributed along the edges,  $x = 0$  and  $x = a$  (Fig. 8). When the compressive stress exceeds certain limits (critical compressive stress), the flat form of the plate becomes unstable and lateral buckling will occur. By application of the energy method, the equation for the critical stress will be:

$$p_{cr} = \alpha_1 p_e \dots \dots \dots (23)$$

in which,

$$p_e = \frac{E \pi^2 t^2}{12 h^2 (1 - \sigma^2)} \dots \dots \dots (24)$$

$h$  = the width of the plate.

$\sigma$  = Poisson's ratio for the material.

$\alpha_1$  = a numerical factor depending on the ratio,  $\frac{a}{b}$ .

It is easy to see that  $p_e$  represents the critical compressive stress as obtained by an equation analogous to Equation (1) for a strip having the length,  $h$ , and the thickness,  $t$ , equal to the thickness of the plate. In Table 4 several

values of  $\alpha_1$  for various ratios,  $\frac{a}{h}$ , are given.

TABLE 4.—VALUES OF  $\alpha_1$  IN EQUATION (23) FOR RECTANGULAR PLATE  
SIMPLY SUPPORTED ON ALL SIDES.

$\frac{a}{h} =$	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8	2.0
$\alpha_1 =$	8.41	5.14	4.20	4.00	4.13	4.47	4.20	4.04	4.00
$p_{cr}$ , in pounds per square inch =	22 800	14 000	11 400	10 900	11 200	12 100	11 400	11 000	10 900

It is seen that  $\alpha_1$  is a minimum for a square plate. If a long plate buckles under compression it subdivides in squares or in rectangles, almost square. For each of these rectangles Equation (23) can be applied, the length,  $a$ , being the distance between the two consecutive nodal lines parallel to the  $y$ -axis.

For a longer plate, say, when  $\frac{a}{b} > 3$ , a value,  $\alpha_1 = 4$ , always represents a good approximation.

In Table 4 the values,  $p_{cr}$ , are calculated on the assumption that  $E = 30 \times 10^6$  lb. per sq. in.,  $\sigma = 0.3$ , and  $\frac{h}{t} = 100$ . Taking into consideration that the critical stress is proportional to  $\frac{t^2}{h^2}$  (Equation (24)), the critical stress for any value of  $\frac{h}{t}$ , different from 100, is obtained by multiplying the tabular values by  $10^4 \frac{t^2}{h^2}$ . Take, for instance, a long steel plate having a yield point of 40 000 lb. per sq. in. To determine the value of the ratio,  $\frac{h}{t}$ , at which the critical stress becomes equal to the yield point, assuming  $\alpha_1 = 4$ : From Table 4,

$$10\,900 \times 10^4 \times \frac{t^2}{h^2} = 40\,000$$

that is,

$$\frac{h}{t} = \sqrt{\frac{10\,900}{4}} = 51 \pm$$

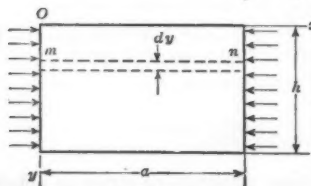

FIG. 8.

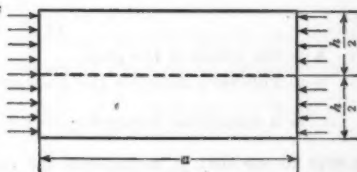

FIG. 9.

For larger values of the ratio,  $\frac{h}{t}$ , failure will occur as a result of instability and at a compressive stress less than the yield point. This means that in consequence of lateral buckling the complete strength of the material of the plate will not be utilized.

*B.*—By properly increasing the thickness of the plate, the buckling will not occur below the yield point; but such a uniform increase in thickness is not always the most economical solution. Sometimes, for compressed plates of considerable width, it appears more advantageous to keep the thickness as small as possible and to increase the stability against buckling by introducing longitudinal stiffeners. Such methods of reinforcement are used sometimes in shipbuilding, where the economy in the proper weight of the hull is of great practical importance. In proportioning such reinforcement, it is important to know how the stability of the reinforced plate depends on the flexural rigidity and cross-sectional area of the stiffeners. This problem can be solved by using the energy method.\*

\* For detailed investigation of this question, see the writer's paper in *Der Eisenbau*, Vol. 12 (1921), p. 147.

If the plate is reinforced by one longitudinal stiffener at the middle of the width (Fig. 9), the maximum reinforcement occurs when the flexural rigidity of the stiffener is sufficient to prevent it from bending during buckling of the plate. Then each half of the plate will be in the condition of a plate of the width,  $\frac{h}{2}$ . At smaller values of the flexural rigidity the stiffener bends with the plate during buckling and the value of the critical compressive stress will depend on the ratios:

$$\frac{a}{h}; \frac{B}{h D}; \frac{A}{h t} \dots \dots \dots (25)$$

in which,

$B = EI$  = flexural rigidity of the stiffener in bending at right angles to the plane of the plate.

$h D = h \frac{E t^3}{12 (1 - \sigma^2)}$  = the flexural rigidity of the plate.

$A$  = cross-sectional area of the stiffener.

$h t$  = cross-sectional area of the plate.

For calculating the critical compressive stress, Equation (23) can be used. The values of the numerical factor,  $\alpha_1$ , for various values of the ratios in Equations (25) are given in Table 5.

*Numerical Example.*—Let a compressed steel plate with simply supported edges have the following dimensions:  $a = 48$  in.;  $h = 80$  in.;  $t = \frac{1}{8}$  in.;  $E = 30 \times 10^6$  lb. per sq. in.; and  $\sigma = 0.3$ . Then,  $\frac{a}{h} = 0.6$  and from Table 4,

$$p_{cr} = 14\,000 \times 10^4 \times \frac{9^2}{16^2 80^2} = 6\,900 \pm \text{lb. per sq. in.}$$

By using a stiffener of such a flexural rigidity that it does not bend while the plate is buckling, the critical stress becomes:

$$p_{cr} = 11\,200 \times \frac{9^2}{16^2 40^2} = 22\,100 \pm \text{lb. per sq. in.}$$

From Table 5 it is seen that (for  $\frac{a}{h} = 0.6$ ) such a condition can be obtained

by using a stiffener, for which  $\frac{B}{h D} = 5$  and  $\frac{A}{h t} < 0.2$ . In calculating the quantity,  $B$ , note that the stiffener is riveted to a plate of great width and this results in a considerable increase of rigidity. By taking, for instance, the stiffener in the form of a channel, or a **Z**, riveted to the plate by its flange, the center of gravity of the section consisting of the stiffener and the plate will be very near to the surface of the plate, and the moment of inertia of the cross-section of the stiffener with respect to the axis coinciding with the outer surface of the flange must be taken in calculating  $B$ . Using two longitudinal stiffeners, sub-dividing the plate into three equal parts, Equation (23) still applies for calculating the critical compressive stress. The corresponding values of the factor,  $\alpha_1$ , are given in Table 6.

C.—When the edges of the plate parallel to the direction of compression, instead of being simply supported, are built in, the stability of the plate is increased. For calculating the critical values of compressive stress, Equation (23) can be used, but the values of the factor,  $\alpha_1$ , must be taken from Table 7.

It is seen that the minimum value of the factor,  $\alpha_1$ , corresponds to the ratio,  $\frac{a}{h} = 0.7 \pm$ , so that a long compressed plate, when it buckles, subdivides into rectangles approaching these proportions. For a plate of considerable length, say,  $\frac{a}{h} > 2$ ,  $\alpha_1 = 7.00$  is always a good approximation.

TABLE 6.—VALUES OF THE FACTOR,  $\alpha_1$ , IN EQUATION (23) FOR A RECTANGULAR PLATE REINFORCED BY TWO LONGITUDINAL STIFFENERS.

$\frac{a}{h}$	$\frac{B}{hD} = \frac{10}{3}$		5		$\frac{20}{3}$		10	
	$\frac{A}{ht} = 0.05$	0.1	0.05	0.1	0.05	0.1	0.05	0.1
0.6	26.8	24.1	36.4	33.2	36.4	36.4	36.4	36.4
0.8	16.9	15.0	23.3	20.7	29.4	26.3	37.2	37.1
1.0	12.1	10.7	16.3	14.5	20.5	18.2	28.7	25.6
1.2	9.61	8.51	12.6	11.2	15.5	13.8	21.4	19.0
1.4	8.32	7.36	10.5	9.32	12.7	11.3	17.2	15.2
1.6	7.70	6.81	9.40	8.31	11.1	9.82	14.5	12.8
1.8	7.51	6.64	8.85	7.83	10.2	9.02	12.9	11.4
2.0	7.61	6.73	8.70	7.69	9.78	8.65	11.9	10.6

D.—When one longitudinal side ( $y = 0$ ) of the plate shown in Fig. 8 is built in and another ( $y = h$ ) is free, the critical value of the uniform compressive stress can be calculated again from Equation (23). The values of the numerical factor,  $\alpha_1$ , for this case are given in Table 8.

TABLE 7.—VALUES OF THE FACTOR,  $\alpha_1$ , IN EQUATION (23) FOR A RECTANGULAR PLATE, THE TWO SIDES OF WHICH, PARALLEL TO COMPRESSION, ARE BUILT IN AND TWO OTHERS ARE SIMPLY SUPPORTED.

$\frac{a}{h} =$	0.4	0.5	0.6	0.7	0.8	0.9	1.0
$\alpha_1 =$	9.44	7.69	7.05	7.00	7.29	7.83	7.69
$p_{cr}$ , in pounds per square inch, for $\frac{h}{t} = 100 =$	25 000	20 800	19 100	19 000	19 800	21 200	20 800

It is seen that the minimum value of the factor,  $\alpha_1$ , corresponds to a value of the ratio,  $\frac{a}{h}$ , about 1.7. A long plate, while buckling, will subdivide in rectangles approaching these proportions. Taking  $\alpha_1 = 1.33$  and the yield point as 40 000 lb. per sq. in., for a long steel plate ( $E = 30 \times 10^6$  lb. per

sq in.;  $\sigma = 0.3$ ), the limiting value of the ratio,  $\frac{h}{t}$ , at which the critical stress and yield point coincide, will be:

$$p_{cr} = 1.33 \frac{E \pi^2}{12 (1 - \sigma^2)} \frac{t^2}{h^2} = 40\,000$$

from which,  $\frac{h}{t} = 30 \pm$ .

TABLE 8.—VALUES OF THE FACTOR,  $\alpha_1$ , FOR A COMPRESSED RECTANGULAR PLATE, ONE OF THE LONGITUDINAL EDGES OF WHICH IS BUILT IN AND ANOTHER FREE.

$\frac{a}{h} =$	1.0	1.1	1.2	1.3	1.4	1.5	1.6	1.7	1.8	1.9	2.0	2.2	2.4
$\alpha_1 =$	1.70	1.56	1.47	1.41	1.36	1.34	1.33	1.33	1.34	1.36	1.38	1.45	1.47

For a larger value of the ratio,  $\frac{h}{t}$ , the buckling of the plate will occur at a stress less than the yield point of the material and for improving the conditions the reinforcement of the free edge of the plate by riveting a stiffener becomes necessary. By using Tables 4, 5, and 8, the necessary thickness of steel sheets for built-up sections of compressed members, such as those shown in Fig. 10, can easily be calculated.

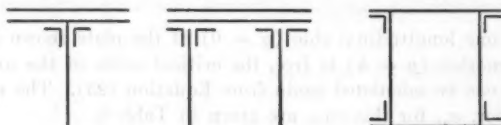

Fig. 10.

## VII.—STABILITY OF THE WEB OF A PLATE GIRDER

In the design of plate girders, the thickness of the web is usually calculated for safety in shearing. The calculation does not give sufficient thickness and in order to prevent buckling usually it is necessary to increase the thickness and to use stiffeners, without considering the stability of the stressed web. This results in types of construction having widely varying factors of safety with respect to buckling. For example, plate girders of one large American railroad system, with a span,  $l = 100$  ft., and with a depth,  $h = 10$  ft., have a web thickness,  $t$ , equal to  $\frac{5}{8}$  in., while similar girders of another railroad have a web thickness of  $\frac{1}{4}$  in. near the supports and only  $\frac{3}{8}$  in. at the middle. These girders, both satisfying American specifications, have very different factors of safety with regard to the buckling of the web.

A more satisfactory design can be obtained from a consideration of the stability of the stressed web. Near the supports the shearing force is the most important factor, and stresses due to bending can be neglected. Considering the part of the web between two stiffeners as a rectangular plate with sup-

ported edges, subjected only to the action of shear (Fig. 11), the critical value of shearing stress can be found from consideration of the energy, and the equation for calculating this value has the same form as Equation (23). The corresponding values of the numerical factor,  $\alpha_1$ , are given in Table 9.

TABLE 9.—VALUES OF THE FACTOR,  $\alpha_1$ , IN EQUATION (23) FOR A RECTANGULAR PLATE SUPPORTED AT THE EDGES AND SUBMITTED TO SHEAR.

$\frac{h}{a} =$	1	1.2	1.4	1.5	1.6	1.8	2.0	2.5	3.0
$\alpha_1 =$	9.42	8.0	7.3	7.1	7.0	6.8	6.6	6.3	6.1

Applying these results to steel plates ( $E = 30 \times 10^6$  lb. per sq. in.,  $\sigma = 0.3$ ), and assuming the distance between the stiffeners equal to 5 ft., the critical values of shearing stress for different depths,  $h$ , and different thicknesses,  $t$ , are as given in Table 10.

TABLE 10.—CRITICAL SHEARING STRESSES, IN POUNDS PER SQUARE INCH.

Values of $h$ , in feet.	VALUES OF $t$ , IN INCHES.			
	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$
5	9 980	13 600	17 700	22 400
7	7 730	10 500	13 700	17 400
10	6 990	9 510	10 400	15 700

Assuming the factor of safety as 2 and the average shearing stress at the support as 5 000 lb. per sq. in., Table 10 shows that for both the plate girders mentioned, a thickness of  $\frac{1}{2}$  in. will insure the stability of the web near the supports.\*

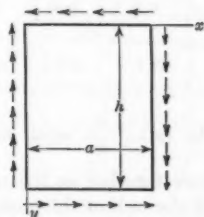

FIG. 11.

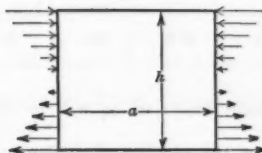

FIG. 12.

It was assumed that the buckling of the web was not accompanied by bending of the stiffeners. This assumption will be true only when the stiffeners have a sufficient flexural rigidity. The necessary magnitude of the moment

\* Under actual conditions the factor of safety will be greater than 2, because the edges of the plate are assumed as simply supported and the stiffening effect of fixed edges is neglected.

of inertia of the cross-section of the stiffeners can be found from the potential energy of bending of these stiffeners, giving the data of Table 11.\*

The quantity,  $\delta$ , of Table 11 denotes the ratio,  $E I: \frac{E a t^3}{12 (1 - \sigma^2)}$ , in which,  $E I$  is the necessary flexural rigidity of the stiffeners, and  $\frac{E a t^3}{12 (1 - \sigma^2)}$  is the flexural rigidity of the part of the web between two consecutive stiffeners.

TABLE 11.

$\frac{a}{h} =$	1.0	0.750	0.625	0.500
$\delta =$	3.3	11.6	25.2	60

Taking, for instance,  $a = 5$  ft.,  $h = 10$  ft., and  $t = \frac{1}{2}$  in.:

$$I = 60 \frac{60 \left(\frac{1}{2}\right)^3}{12 (0.91)} = 41 \pm \text{in.}^4$$

This is the necessary value for the moment of inertia of the cross-section of the stiffeners.

At the middle of the span the shearing stresses can be neglected in comparison with normal stresses. Then, the part of the web between two stiffeners will be in the condition represented in Fig. 12. Applying the same general energy method, Equation (23) will be found for calculating critical values of bending stresses. The corresponding values of the factor,  $\alpha_1$ , are given in Table 12.

TABLE 12.—VALUES OF THE FACTOR,  $\alpha_1$ , FOR A SIMPLY SUPPORTED RECTANGULAR PLATE STRESSED AS SHOWN IN FIG. 12.

$\frac{a}{h} =$	0.40	0.50	0.60	0.667	0.75	0.80	1.0	1.5
$\alpha_1 =$	29.1	25.6	24.1	23.9	24.1	24.4	25.6	24.1

The minimum value of  $\alpha_1$  will be for the ratio,  $\frac{a}{h}$ , equal to 0.67. Evidently, however, the placing of stiffeners closer together at the middle of the span will not affect materially the stability of the web at this point.

Applying Table 12 in the case of the plate girder having  $a = 5$  ft.,  $h = 10$  ft., and  $t = \frac{3}{8}$  in. at the middle,

$$p_{cr} = 25.6 \frac{E \left(\frac{3}{8}\right)^2}{(12) (120)^2 (0.91)} = 6\,800 \pm \text{lb. per sq. in.}$$

\* See the writer's paper in *Der Eisenbau*, Vol. 12 (1921), p. 147.

This stress is smaller than that generally considered safe for plate girders. It was assumed that the edges were simply supported; in practice they are always rigidly connected with the flanges. Therefore, the actual critical stresses will be somewhat greater than the theoretical. Nevertheless, probably some buckling of the web occurs under ordinary loading conditions. This buckling does not represent an immediate danger to the girder, but it causes an over-stressing of the girder flanges and of the rivets, which is undesirable.

## APPENDIX

### STABILITY OF THE COMPRESSED TOP CHORD OF A HALF-THROUGH TRUSS SPAN

Considering the compressed top chord of a half-through bridge as a strut of uniform cross-section having hinged ends, and assuming that the compressive forces are continuously distributed, as shown by the shaded area in Fig. 6(b), the critical value of the compressive force at the middle can be calculated by using the energy method. In this manner an equation analogous to Equation (9) can be established. Equations (6) and (7) for the potential energy of bending and the potential energy of deformation of the elastic medium can be used also in this case. In calculating the work done by the compressive forces during lateral buckling (Fig. 13) assume that Support *B* is on rollers so that during buckling it moves toward Support *A*. Due to displacement of one element,  $dx$ , of the strut (Fig. 13) the loads acting on the right-hand portion of the strut are displaced toward Support *A* by an amount equal to  $ds - dx = \frac{1}{2} \left( \frac{dy}{dx} \right)^2 dx$ , and the work produced during this displacement will be,

$$-\frac{1}{2} \left( \frac{dy}{dx} \right)^2 dx \int_x^l \frac{q}{2h} \left( 1 - \frac{2x}{l} \right) dx = \frac{q}{4h} \left( \frac{dy}{dx} \right)^2 (l-x) x dx$$

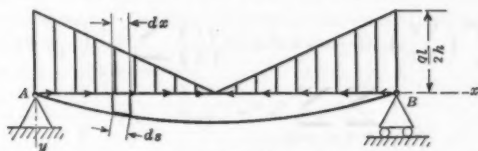

FIG. 13.

The complete work given by the compressive forces during bending will be:

$$T = \frac{q}{4h} \int_0^l \left( \frac{dy}{dx} \right)^2 (l-x) x dx \dots \dots \dots (A)$$

so that the equation for determining the critical value of the compressive force,  $\frac{q l^2}{8h}$ , will have the form:

$$\frac{q}{4h} \int_0^l \left( \frac{dy}{dx} \right)^2 (l-x) x dx = \frac{1}{2} E I \int_0^l \left( \frac{d^2 y}{dx^2} \right)^2 dx + \frac{1}{2} K \int_0^l y^2 dx \dots \dots \dots (B)$$

The deflection curve in this case is not a simple sine curve, but it can always be assumed to be represented in the form of the series:

$$y = a_1 \sin \frac{\pi x}{l} + a_2 \sin \frac{2\pi x}{l} + a_3 \sin \frac{3\pi x}{l} + \dots \quad (C)$$

each term of which satisfies the conditions at the ends of the strut. Substituting this series in Equation (B) the right-hand member becomes:

$$\begin{aligned} & \frac{1}{2} E I \int_0^l \left( \frac{d^2 y}{dx^2} \right)^2 dx + \frac{1}{2} K \int_0^l y^2 dx \\ &= \frac{E I \pi^4}{4 l^3} \sum_{n=1, 2, 3, \dots} n^4 a_n^2 + \frac{K l}{4} \sum_{n=1, 2, 3, \dots} a_n^2 \dots \dots \dots (D) \end{aligned}$$

In calculating the left-hand member of Equation (B), the following formulas will be used:

$$\begin{aligned} \int_0^l x \cos^2 \frac{m\pi x}{l} dx &= \frac{l^2}{4} \\ \int_0^l x^2 \cos^2 \frac{m\pi x}{l} dx &= \frac{l^3}{6} + \frac{l^3}{4\pi^2 m^2} \end{aligned}$$

in which,  $m$  is an integer.

$$\int_0^l x^2 \cos \frac{n\pi x}{l} \cos \frac{m\pi x}{l} dx = \frac{2l^3}{\pi^2} \frac{(m^2 + n^2)}{(m^2 - n^2)^2} 2(-1)^{m+n}$$

in which,  $m$  and  $n$  are both integers.

$$\int_0^l x \cos \frac{n\pi x}{l} \cos \frac{m\pi x}{l} dx = 0$$

when  $m + n$  is an even number; and,

$$\int_0^l x \cos \frac{n\pi x}{l} \cos \frac{m\pi x}{l} dx = -\frac{2l^2}{\pi^2} \frac{m^2 + n^2}{(m^2 - n^2)^2}$$

when  $m + n$  is an odd number.

Then,

$$\begin{aligned} \frac{q}{4h} \int_0^l \left( \frac{d^2 y}{dx^2} \right)^2 (l-x) dx &= \frac{q l}{4h} \left\{ \sum_{n=1, 2, 3, \dots} a_n^2 \left( \frac{n^2 \pi^2}{12} - \frac{1}{4} \right) \right. \\ &\quad \left. - 4 \sum_{(m+n) \text{ even } \dots} \sum a_n a_m \frac{n m (m^2 + n^2)}{(m^2 - n^2)^2} \right\} \dots \dots \dots (E) \end{aligned}$$

Substituting values from Equations (D) and (E) in Equation (B),

$$\begin{aligned} \frac{E I \pi^4}{8 l^2} \sum_{n=1, 2, 3, \dots} n^4 a_n^2 + \frac{K l^2}{8} \sum_{n=1, 2, 3, \dots} a_n^2 \\ \frac{q l^2}{8 h} = \frac{\sum_{n=1, 2, 3, \dots} a_n^2 \left( \frac{n^2 \pi^2}{12} - \frac{1}{n} \right) - 4 \sum_{(m+n) \text{ even } \dots} \sum a_n a_m \frac{n m (m^2 + n^2)}{(m^2 - n^2)^2}}{\dots \dots \dots} \dots \dots (F) \end{aligned}$$

In order to get the critical value of the compressive force, there only remains the coefficients,  $a_1, a_2, a_3 \dots$ , to be determined in such a manner that Equation (F) will be a minimum. By making the derivatives of this expression with respect to  $a_1, a_2, a_3 \dots$ , equal to zero, a system of equations will be found having the following form:

$$a_n \left[ \pi^2 n^4 + \alpha \pi^2 - \gamma \left( \frac{2}{3} \pi^2 n^2 - 2 \right) \right] + 16 \gamma \sum_{(m+n) \text{ even}} \sum_m a_m \frac{n m (m^2 + n^2)}{(m^2 - n^2)^2} = 0 \quad \text{.....(G)}$$

in which, for simplification, the following notations are used:

$$\alpha = \frac{K l^4}{E I \pi^4}; \gamma = \text{ratio of } \frac{q l^2}{8 h} : \frac{E I \pi^2}{l^2} \quad \text{.....(H)}$$

By taking for  $n$  the values, 1, 3, 5, . . . , the following equations result:

$$\left. \begin{aligned} & a_1 \left[ \pi^2 + \alpha \pi^2 - \gamma \left( \frac{3}{2} \pi^2 - 2 \right) \right] \\ & + \gamma \left( \frac{15}{2} a_3 + \frac{65}{18} a_5 + \frac{175}{72} a_7 + \dots \right) = 0 \\ & a_1 \frac{15}{2} \gamma + a_3 \left[ \pi^2 3^4 + \alpha \pi^2 - \gamma \left( \frac{2}{3} 9 \pi^2 - 2 \right) \right] \\ & + \gamma \left( \frac{255}{8} a_5 + \frac{609}{50} a_7 + \dots \right) = 0 \\ & a_1 \frac{65}{18} \gamma + a_3 \frac{255}{8} \gamma + a_5 \left[ \pi^2 5^4 + \alpha \pi^2 - \gamma \left( \frac{2}{3} 5^2 \pi^2 - 2 \right) \right] \\ & + \gamma \left( \frac{1295}{18} a_7 + \dots \right) = U \\ & a_1 \frac{175}{72} \gamma + a_3 \frac{609}{50} \gamma + a_5 \frac{1295}{18} \gamma \\ & + a_7 \left[ \pi^2 7^4 + \alpha \pi^2 - \gamma \left( \frac{2}{3} 7^2 \pi^2 - 2 \right) \right] + \dots = 0 \end{aligned} \right\} \quad \text{.....(I)}$$

Only the coefficients,  $a_n$ , with odd subscripts enter into Equations (I) and, as seen from Equation (G), only deflection curves symmetrical with respect to the middle of the span correspond to these equations.

By taking for  $n$  the consecutive even values, 2, 4, 6, . . . , the following equations are found:

$$\left. \begin{aligned} & a_2 \left[ \pi^2 2^4 + \alpha \pi^2 - \gamma \left( \frac{2}{3} \pi^2 2^2 - 2 \right) \right] \\ & + \gamma \left( \frac{160}{9} a_4 + \frac{15}{2} a_6 + \dots \right) = 0 \\ & a_2 \frac{160}{9} \gamma + a_4 \left[ \pi^2 4^4 + \alpha \pi^2 - \gamma \left( \frac{2}{3} \pi^2 4^2 - 2 \right) \right] \\ & + \gamma \left( \frac{1248}{25} a_6 + \dots \right) = 0 \\ & a_2 \frac{15}{2} \gamma + a_4 \frac{1248}{25} \gamma + a_6 \left[ \pi^2 6^4 + \alpha \pi^2 \right. \\ & \left. - \gamma \left( \frac{2}{3} \pi^2 6^2 - 2 \right) \right] + \dots = 0 \end{aligned} \right\} \quad \text{.....(J)}$$

Equations (J) contain only the coefficients,  $a_n$ , with even subscripts; hence, the corresponding deflection curves have an inflection point at the middle.

It is clear that in order for buckling to occur, at least one or more of the values of  $a_n$  given by Equations (I) or (J) must be different from zero. This condition will require that the determinant of Equations (I) or (J) become equal to zero. The critical values of the compressive force may now be calculated by the following method of successive approximations.

Begin with the case of a very small  $K$ ; then, as found from the discussion of the simple case in Part III, the deflection curve consists of one wave only and the system of Equations (I) must be used for the calculation of the critical compressive forces. Take, for instance,  $K = 0$ . Making all the coefficients,  $a_n$ , except  $a_1$ , equal to zero and retaining only the first equation of the system, (I),

$$\pi^2 - \gamma \left( \frac{2}{3} \pi^2 - 2 \right) = 0, \text{ or } \gamma = \frac{\pi^2}{\frac{2}{3} \pi^2 - 2} = 2.15$$

This first approximation, equivalent to the assumption that the deflection curve is a sine wave, is somewhat greater than the more accurate value,  $\gamma = 2.06$  given in Table 2. The error of the first approximation is about 4½ per cent.

In order to get a better approximation take two consecutive coefficients,  $a_1$  and  $a_3$ , and put the remaining coefficients equal to zero, in the system of Equations (I). Then, the first two equations of this system become:

$$a_1 \left[ \pi^2 - \gamma \left( \frac{2}{3} \pi^2 - 2 \right) \right] + a_3 \frac{15}{2} \gamma = 0$$

$$a_1 \frac{15}{2} \gamma + a_3 \left[ \pi^2 3^4 - \gamma \left( \frac{2}{3} \pi^2 9 - 2 \right) \right] = 0$$

These equations will yield for  $a_1$  and  $a_3$  a solution different from zero, and buckling will occur only when the following condition is fulfilled:

$$\left[ \pi^2 - \gamma \left( \frac{2}{3} \pi^2 - 2 \right) \right] \left[ \pi^2 3^4 - \gamma \left( \frac{2}{3} \pi^2 9 - 2 \right) \right] - \left( \frac{15}{2} \gamma \right)^2 = 0$$

Solving this quadratic equation,  $\gamma = 2.06$ . This second approximation is the value given in Table 2. Calculation of the third approximation shows that in this case the second approximation gives three correct figures for the factor,  $\gamma$ .

In the same manner, calculations were made for,

$$\frac{K l^4}{16 E I} = 5; \quad \frac{K l^4}{16 E I} = 10; \quad \frac{K l^4}{16 E I} = 15$$

and the corresponding values of  $\gamma$  are given in Table 2. For larger values of

$\frac{K l^4}{16 E I}$ , Equations (J) must be used, because in such cases the deflection curve will have two waves with an inflection point at the middle. With further increase of  $K$  curves will be obtained with three, four, and more waves. It is clear that for an odd number of waves, Equations (I), and for an even number, Equations (J), must be used in calculating the critical loads.

## DISCUSSION

H. M. WESTERGAARD,\* M. A. M. Soc. C. E.—The author has written a number of scientific papers on the subject of elastic stability, and has given a notable development to the technique of solving problems in this field. He has used extensively a general principle of equilibrium which is based on the variations of the potential energy of the deformed structure and the loads. The systematic use of this principle has been fruitful.† The particular problems treated in this paper are unquestionably important.

The principle of variation of the potential energy lends itself to mathematically exact solutions of the simpler problems and to approximate solutions of the more complex ones. Generally speaking, when approximations are admitted, the problems shift from mathematics to physics. In this connection a remark by the late C. Christiansen, Professor of Physics in Copenhagen, deserves to be quoted: "There is the difference", he said, "between mathematics and physics, that in mathematics everything is right and in physics everything is wrong." A method which belongs partly in mathematics and partly where "everything is wrong" requires mathematical technique of course, but it also requires sound judgment, as well as common sense on the part of the engineer or the physicist. These requirements are not easy to meet, but in the speaker's opinion, this paper meets both of them. It may be added that a sound judgment is expected also of those who are to interpret the results for the purpose of structural design.

The paper contains definite answers to definite questions which may be asked by the structural engineer. Answers are stated in terms of tabulated numerical values which are to be substituted in simple algebraic expressions.

After receiving these definite answers, it is reasonable to ask where one stands. This issue may be discussed by referring to the most familiar problem of elastic stability. Fig. 14 (a) shows diagrams of load and deflections for a slender column. The combination,  $OAB$ , represents what would happen if the column were perfectly straight, homogeneous, and centrally loaded. In a test, in which these conditions of the ideal column cannot be entirely satisfied, one would find, perhaps, the curve,  $OCD$ . These diagrams are characteristic of the buckling of slender structures in general. The ordinate,  $OA$ , represents the computed critical load. Under practical conditions one must expect a curve like  $OCD$ . It may be stated, however, that knowledge of the position of the horizontal line,  $AB$ , helps in forming a judgment as to the position of the curve,  $CD$ .

If the column is not particularly slender, but of medium length, one may obtain the curves shown in Fig. 14 (b):  $OAB$  for the ideal column, the part,  $AB$ , being curved because some of the stresses exceed the proportional limit; and  $OCD$  in a test, or in practice. Grant that the critical load,  $OA$ , has been computed, in spite of the difficulties which accompany a reduced modulus of

† For extensive bibliographical information, see the chapter by Professor Timoshenko under the heading, "Stabilitätsprobleme der Elastizität," in *Handbuch der physikalischen und technischen Mechanik*, v. 4, Lieferung 1, 1929, pp. 81-145.

elasticity. It is the ordinate of the apex,  $C$ , which is of practical interest. This true maximum load may be considerably less than the load,  $OA$ , obtained under idealized conditions. Th. von Kármán studied these relations for steel columns in an investigation published in 1910.\*

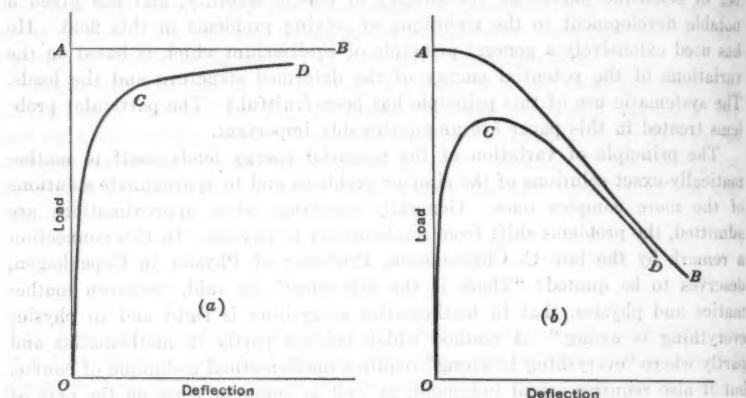

FIG. 14.

The diagrams in Fig. 14 (b) are characteristic of the buckling of the less slender structures in general. Professor Timoshenko refers occasionally to these less slender structures. It is true that an estimate of the position of Point A in Fig. 14(b) may help in forming a judgment as to the position of Point C. The problem involved here still represents a field for future research, both experimental and analytical.

The problems of elastic stability of slender structures, in which stresses exceeding the proportional limit need not be considered, are, of course, important for their own sake. It is a peculiar circumstance, however, that a study of the critical loads may lead to the solution of problems which are apparently of a totally different nature. A case, chosen on account of its simplicity, will serve as an illustration.

Fig. 15 (a) shows a straight stiff vertical member, with a hinged support at the bottom, supported by a horizontal spring with a modulus,  $S$ , at the top. When the load,  $P$ , reaches a critical value,  $Q$ , the structure may "buckle", as shown in Fig. 15 (b). The critical load may be determined either by direct consideration of the forces involved or by the principle of the potential energy. By the latter method one finds that the deflection in the direction of

$Q$  is equal to  $\frac{u^2}{2l}$ ; then, the potential energy may be expressed as  $\frac{1}{2} S u^2 - Q \frac{u^2}{2l}$ .

This potential energy remains zero, for any value of  $u$ , when  $Q = Sl$ , which therefore, is the critical load. The same deflection,  $u$ , may be produced by the

Ros, *Proceedings, Second International Cong. for Applied Mechanics*, Zürich, 1926 (pub. 1927), p. 368; and a paper by William R. Osgood, *Assoc. M. Am. Soc. C. E.*, and the speaker, *Transactions, Am. Soc. Mech. Engrs.*, v. 50, 1928, No. 17, p. 65.

horizontal load,  $W$ , in Fig. 15 (c). If, as in Fig. 15(d), the load,  $P$  (less than  $Q$ ), is introduced in addition to  $W$ , the deflection (as one finds from the condition that the potential energy is a minimum), becomes  $u' = u \frac{Q}{Q-P}$ , instead of  $u$ .

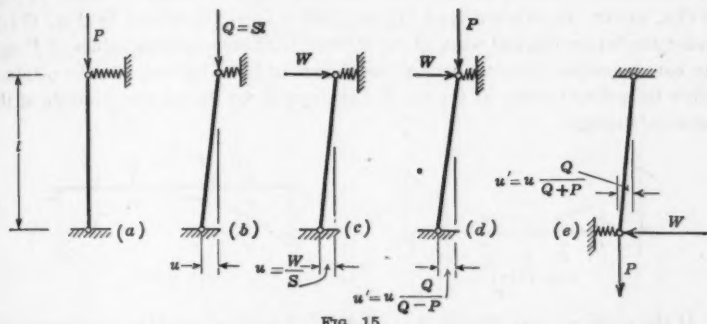

FIG. 15.

Now, turn this structure upside down, and load it as shown in Fig. 15(e). The same formula may be used, only with the sign of  $P$  reversed. The weight,  $P$ , in this case, steadies the structure, and this steadying effect is evaluated in terms of the load which produces buckling.

A steadying effect of this kind plays an important part in the mechanics of suspension bridges. This effect expresses itself in terms of the difference between what have been called the "elastic theory" and the "deflection theory". Melan\* originated the deflection theory as contrasted with the ordinary theory; the latter becomes incorrect and wasteful of material when applied to large suspension bridges. Leon S. Moisseiff,† M. Am. Soc. C. E., in discussing the suspension bridge between Philadelphia, Pa., and Camden, N. J., gave emphasis to the deflection theory, and showed its economic importance. As a matter of fact, the problem involved here may be treated from the point of view of elastic stability or buckling.

Consider the case in Fig. 16 (a). Turn the bridge upside down, as indicated in Fig. 16 (b). At a critical value of the load,  $P$ , the structure buckles by the bending of the stiffening beam. One must imagine that the sides of the polygon, which did represent the cable, remain straight, but that the polygon changes shape. By introducing this critical value in a formula similar to that applying to Fig. 15 (e), one may express an essential feature relating to the steadying effect which, in the case of the suspension bridge, is due to the dead load.

\* The problem referring to the suspension bridge is not quite as simple as that in Fig. 15 (e). The complication expresses itself through the fact that the structure in Fig. 16 (b) may be imagined to buckle in more than one way.

\* "Eiserne Bogenbrücken und Hängebrücken," 1888.

† "The Towers, Cables, and Stiffening Trusses of the Bridge Over the Delaware River between Philadelphia and Camden," *Journal, Franklin Inst.*, October, 1925.

The principle involved may be studied by examining a structure which is almost as simple as that in Fig. 15. Fig. 16 (a) shows this structure. The two stiff vertical members are connected by a hinge, and are supported by two horizontal springs of the same modulus,  $S$ . The lower member has a hinged support at the bottom. The structure supports a load,  $P$ , at the top. It may be imagined to buckle in the following two ways: Either as shown in Fig. 17 (b), under the critical load  $Q_1 = 0.382 Sl$ ; or, as shown in Fig. 17 (c), under the larger critical load,  $Q_2 = 2.618 Sl$ . These critical values of  $P$ , and the corresponding relative deflections shown in the diagram, may be obtained either by a direct study of the forces involved, or by use of the principle of the potential energy.

FIG. 16 (a).

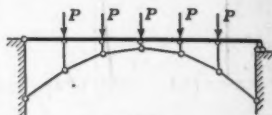

FIG. 16 (b).

If the problem were merely that of simple buckling, only the smaller critical load,  $Q_1$ , would be of interest. Here, however, both critical loads should be considered. The deflections in Fig. 17 (b) and Fig. 17 (c), may be produced by applying instead the horizontal forces shown in Fig. 17 (d) and Fig. 17 (e). Fig. 17 (f) shows a combination of the loads in Fig. 17 (a), Fig. 17 (d), and Fig. 17 (e). Any combination of two forces,  $F_1$  and  $F_2$ , may be expressed by the formulas in Fig. 17 (f), in terms of the values,  $W_1$  and  $W_2$ , and the corresponding values of the deflections,  $u_1$ ,  $v_1$ ,  $u_2$ ,  $v_2$ , in Fig. 17 (d) and Fig. 17 (e), may be computed. These values, substituted in the formulas in

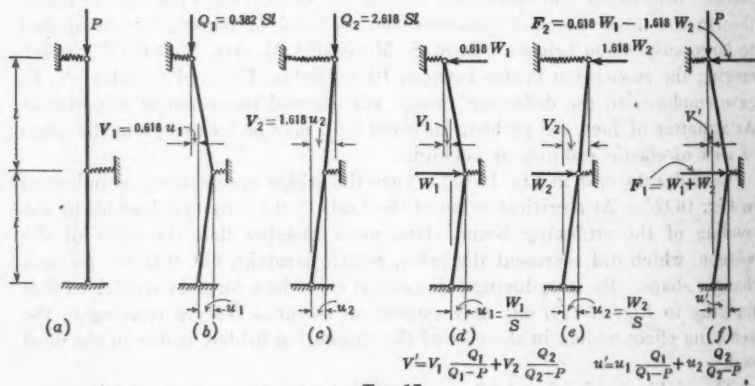

FIG. 17.

Fig. 17 (f), lead to the resultant deflections,  $u'$  and  $v'$ . In these formulas the two critical values,  $Q_1$  and  $Q_2$ , appear. With three links in the structure, and three springs, instead of two links and two springs, there would be three critical loads, and three terms in each of the expressions in Fig. 17 (f). With the

structure turned upside down and the weight,  $P$ , hanging at the bottom,  $P$  again becomes a steadying influence, and the same formulas may be used, only with the sign of  $P$  reversed.

This example, of course, merely indicates that formulas of this kind apply to the suspension bridge. In a paper on buckling,\* however, the speaker has given a general theory, in the light of which this application to the suspension bridge becomes obvious. In the terminology of this paper the suspension bridge is in "heterostatic action". The general formula (Equation (75)†), for "effects" in heterostatic action, such as deflections, moments, or stresses, gives expressions for the deflections of the suspension bridge that are essentially of the same form as those which Professor Timoshenko derived by a direct method.

Professor Timoshenko's achievements relating to the subject of elastic stability are interesting and important, and they point the way toward future research.

WILLIAM HOVGAARD,‡ Esq. (by letter).—The theory of stability of elastic systems has been developed greatly since the beginning of the Twentieth Century, especially in its application to practical engineering, and in this development Professor Timoshenko has taken a leading part. In this paper he has condensed the solution of a number of problems that are of practical interest to designers, not only among structural engineers, but also among naval architects and others. The value of the paper is enhanced by numerous tables which facilitate the application of the formulas. Throughout all the problems the author uses the energy equation to determine the point of transition between the stable and the unstable state of equilibrium, and it is in particular on the form and derivation of this equation that the writer wishes to comment.

In Part III, the fundamental equation of energy, Equation (9), is given the form:

$$T = V_1 + V_2 \dots \dots \dots (26)$$

which expresses the statement that the external work done by the compressive forces,  $T = P\gamma$ , shall be equal to the sum of  $V_1$ , the elastic work done in bending the strut, and  $V_2$  that done in deformation of the elastic medium. The factor,  $\gamma$ , is the deflection of the point,  $A$ , toward the point,  $B$  (Fig. 4), caused by bending. Since  $V_2$  is precisely of the same nature as  $V_1$  and since it is here desired to discuss the principle and not any specific case,  $V_2$  is omitted for the sake of simplicity and the energy equation is obtained for a simple column hinged at both ends and without lateral supports. Denoting the elastic work in bending by  $V$  instead of  $V_1$ , Equation (26) becomes:

$$T = V \dots \dots \dots (27)$$

Using Equation (27), the critical load according to Equation (11), with the omission of the last term in the brackets, becomes the same as Equation (1).

\* "Buckling of Elastic Structures," *Transactions, Am. Soc. C. E.*, Vol. LXXXV (1922), p. 576, especially Part IV, pp. 604-637.

† *Loc. cit.*, p. 619.

‡ Prof. of Naval Design and Constr., Mass. Inst. Tech., Cambridge, Mass.

Another formula which has been used in connection with the problem of the buckling of plates, is obtained by assuming that the work done by the compressive forces is zero, but that the plate buckles sidewise by a small amount. Thus, there will be introduced an additional potential energy of bending,  $V$ , and at the same time the potential energy of compression decreases by an amount,  $V_1$ . Hence, if the potential energy of the system is to remain constant, the equation of energy becomes:

$$V - V_1 = 0 \dots \dots \dots (28)$$

Since both Equations (27) and (28) give the correct result they must be equivalent to each other; but this does not seem immediately obvious. Imagine first that a simple compression displacement,  $\gamma_1$ , takes place in a pin-ended column without any bending, the external work being  $T$ , while, at the same time, an internal work,  $V_c$ , is done by the elastic compression of the column. Since the total axial stress force in the column is equal to  $P$ ,  $V_c = P \gamma_1 = T$ . Assume that the column is deflected a very short distance sidewise in bending, so that its axis is lengthened by an increment,  $\gamma_2$ , and a certain amount of energy,  $V$ , is absorbed in bending, while, at the same time, an amount of energy,  $V_1$ , is released due to the elongation. Equating the external and the internal work:

$$T = V_c + V - V_1 \dots \dots \dots (29)$$

Since  $V_c$  is equal to  $T$ , Equation (29) may be written,  $V - V_1 = 0$ , which is the same as Equation (28).

It is thus shown that Equation (29) is equivalent to Equation (28); but it is not quite obvious that it is also always equivalent to Equation (27). Evidently, this will be true only if  $V_c = V_1$ ; that is, if  $\gamma_1$ , the deflection of  $P$ , is always equal to the elongation,  $\gamma_2$ , because, in that case, Equation (29) reduces to,  $T = V$ . In other words, after the column has been compressed a certain distance,  $\gamma_1$ , it shall bend outward so much that exactly the same amount of compression is again taken out of it. This, then, must be assumed to be the case, but it does not seem clear that it is always and necessarily so.

For this reason Equation (28) seems preferable to the writer both in form and mode of derivation, and he proposes the following proof of it, based on the principle of virtual velocities.

Suppose that a column is simply compressed by terminal axial forces,  $P$ , acting at each end, and that equilibrium is established. In order to test whether the system is actually in equilibrium, assume that one end of the column is fixed and that  $P$  at the other end is moved through a distance,  $\gamma_1$ , so that the column is still further compressed. Here,  $\gamma_1$  is a small quantity of the first order. Since  $P$  remains unchanged, the external work is  $T = P \gamma_1$ . If there is equilibrium, this work must be equal to the internal elastic work,  $V_c$ , due to compression. Therefore,

$$T = V_c \dots \dots \dots (30)$$

In order to determine whether the equilibrium is stable, it is necessary to consider quantities of the second order. The column is still in the compressed

state, but both ends are now regarded as fixed and the column is given a sidewise virtual deflection. This deflection is a small quantity of the first order, but the elongation and the bending strains produced thereby are of the second order. A certain amount of energy,  $V$ , is absorbed in bending and an amount,  $V_1$ , is released due to the elongation caused by bending, but both these quantities are of the second order. Since no external work is done in this case, the condition necessary for stable equilibrium is that  $V > V_1$  and if the column is in the state of transition between stable and unstable equilibrium,  $V = V_1$ , as given in Equation (28). This reasoning is consistent with Equation (29) if in that equation  $T$  is made equal to  $V_c$  and these quantities are regarded as being of the first order, while  $V$  and  $V_1$  are of the second order. The stability of rectangular plates under edge thrust or edge shear is a problem of considerable interest to naval architects, who have not yet made full use of the results achieved in this field of the theory of elasticity. The application of the formulas to ship-plating is complicated, however, by the indefinite mode in which the plates are supported by frames and longitudinals. Furthermore, the presence of riveted seams or butts and the transverse load due to the external water pressures, complicate the problem.

There are at least three cases in which buckling should be considered in the strength of ships. First, when the outer shell or the deck plating is compressed under longitudinal bending of the entire hull; second, when the outer shell plating on the sides is subject to shearing due to forces acting on the entire hull; and, third, when parts of the structure are exposed to excessive local forces, as may occur, for instance, in docking or grounding.

The two first cases are of the greatest importance in lightly built, high-speed vessels, such as fast cruisers and torpedo-boats. In such vessels, the scantlings of the outside plating and of the strength deck are determined primarily with regard to the stresses in longitudinal bending. Generally, a certain maximum calculated stress is allowed or aimed at in the design, but in considering the corresponding factor of safety the strength in buckling or wrinkling of the plating is not generally taken into account. Nor is the choice of spacing of the frames or longitudinals ordinarily influenced by considerations of buckling.

*Example 1.*—Consider the bottom plating of a torpedo-boat in which the transverse frame spacing,  $a$ , is 21 in. and the thickness of the plating,  $t$ , is 0.25 in. The spacing,  $h$ , of the longitudinal girders is 78 in., and it is desired to examine the effect of buckling pressure when the bottom plating is under longitudinal compression, as in the hogging condition. In a panel enclosed between two adjacent frames and two adjacent longitudinals all the edges are regarded as simply supported. Then,  $\frac{h}{a} = \frac{78}{21} = 3.71$ ;  $E = 30 \times 10^6$  lb. per sq. in.;  $\sigma = 0.3$ ; and the flexural rigidity is:

$$D = \frac{E t^3}{12 (1 - \sigma^2)} = \frac{30 \times 10^6 (0.25)^3}{12 \times 0.91} = 42\,900$$

The critical stress is obtained by means of Equation (31):\*

$$p_{cr} = \left( \frac{h}{a} + \frac{a}{h} \right)^2 \frac{\pi^2 D}{t h^3} = \alpha_1 \frac{\pi^2 D}{t h^3} \dots \dots \dots (31)$$

Making the proper substitutions, the value is, approximately,

$$p_{cr} = 15.8 \times \frac{9.87 \times 42\,900}{0.25 \times 6\,084} = 4\,440 \text{ lb. per sq. in.} = 2 \text{ tons per sq. in.}$$

In vessels of this class it is usual to allow a permissible designed stress in compression of about 6 tons per sq. in. in the extreme fibers, corresponding to perhaps 4 to 5 tons per sq. in. in the strakes of plating here under consideration. Hence, it appears that buckling would be very likely to happen, but, although there are cases on record where buckling resulting in permanent strains has occurred, on the whole, it must be regarded as an exception. Another consideration is that elastic buckling may take place quite commonly in vessels of this type without being noticed because the deformation is arrested by adjacent longitudinal members before over-strain occurs, and when the stresses cease, the plating goes back to its original position. The effect in this case is that certain plates, which form part of the flanges of the ship girder, shirk their duty in compression and greater longitudinal stresses are thrown on the remaining strakes. Such incipient buckling has been previously described by the writer.†

Basing conclusions on various tests and on the practice common in bridge construction, it was estimated that the limiting spacing of longitudinal stiffeners for which the plating may be assumed to be fully effective in compression, should be equal to about eighty times the thickness. If this spacing were exceeded it was recommended to reckon as effective only a band of plating directly attached to the longitudinal stiffeners of a width equal to fifty times the thickness, that is, a strip of width,  $25 t$ , on each side. In the torpedo-boat discussed in Example 1, the ratio,  $h$  to  $t$ , is more than 300, but in battleships it may be as small as 80 or less, especially in the strength deck.

It must be borne in mind also that in Equation (31), all the edges are assumed to be simply supported, that is,  $w = 0$  and  $\frac{\sigma^2 w}{\sigma x^2} = 0$ ; but whether the last condition is fulfilled seems doubtful. Probably there is considerable clamping effect along all four edges and in such cases buckling will not occur until a greater stress has been reached.

As regards buckling or wrinkling by shearing the writer has heard of no case in which this has occurred due to the general shearing of the entire hull of a ship. If it did occur, it would probably take the form of wrinkling between transverse frames, but although permanent damage of this kind may not have been observed it is still possible that very light elastic wrinkling may have taken place unnoticed, disappearing as soon as the shearing forces cease to act. In cases where the shearing stresses actually have been excessive, relief

\* "Applied Elasticity," by S. Timoshenko and J. M. Lessells, p. 292.

† "Structural Design of Warships," E. and F. N. Spon, Lond., 1915, p. 27.

may have been obtained by local shearing of rivets in the horizontal seams, resulting in greater stresses being thrown on the flanges of the ship girder. Such shearing of the rivets in the longitudinal seams in the region of the neutral axis is not uncommon and has led to the adoption of triple-riveted seams in certain classes of ships in the region most exposed to shear stresses.

*Example 2.*—It is of interest to calculate the buckling stress in shear for the same panel as considered in Example 1. From Table 9,  $\alpha_1$  will be equal to about 6.0 and since all the other elements are the same as in case of buckling by compression, in which  $\alpha_1 = 15.8$ , the critical buckling stress in shear is,

$$p_{sr} = \frac{6.0}{15.8} \times 4\,400 = 1\,670 \text{ lb. per sq. in.} = \frac{3}{4} \text{ ton per sq. in.}$$

Actually, the maximum calculated shearing stress may reach about 4 tons per sq. in., so that buckling of the plating would seem very likely to occur; but, again, the boundary conditions are probably more favorable than was assumed.

Local buckling and wrinkling are known to have occurred in the docking of ships, both in floor-plates and in the lower parts of bulkheads when excessive pressures have existed on certain docking blocks. The stresses are not readily calculated in such cases on account of the complexity of the structure; furthermore, the pressure on the blocks is difficult to determine. The writer believes that naval architects can learn a great deal from civil engineers, but he believes also that civil engineers could obtain much valuable information by an analysis of shipbuilding practice. Evidently, civil engineering lends itself much better to the application of scientific methods than naval architecture. In ships, the straining actions are far more uncertain and varied in character than in stationary structures, and dynamic forces of great magnitude occur quite frequently.

DR. ING. A. NADAI\* (by letter).—Questions concerning the determination of buckling loads in structural parts subjected to a somewhat complicated system of lateral or axial forces formerly have seemed to be insolvable. In a few cases it was possible to calculate the critical loads under which the equilibrium of an elastic system becomes unstable, but only when the differential equation for the lateral deflection of the structural part could be integrated in finite terms. In many cases it was not possible to express the solution or the integrals of the differential equation by means of known functions. Many problems of practical importance of this kind could be mentioned.

If one inquires more closely, it will be found that in such cases the engineer is not greatly interested in the actual form of the function which solves his differential equation. In other words, it is not so important for him to establish the complete integral of the differential equation of his problem or to determine a special integral satisfying given boundary conditions. All he wishes to know is the lowest value of the critical load which will produce buckling.

From a mathematical standpoint the answer to such questions involves the determination of a certain parameter or constant which already enters into the differential equation. With the ordinary methods this constant, or

\* Research Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

the "critical load", cannot be determined until the form of the solution has been found, that is, until the differential equation has been integrated for the given boundary conditions. This requires, in most cases, the solution of a transcendental equation and the determination of its roots.

In such cases the methods used by Professor Timoshenko have proved successful. As he has shown in a variety of examples of practical importance, it is not at all necessary to write down the differential equation for the deflection of the beam and to search for its integrals. By using certain expressions containing the potential energy of the system of external forces and the energy of elastic distortion, it is possible to calculate an approximate value of the buckling load, without knowing the more exact form of the elastic line of the distorted structural part. Instead of the differential equation and its integration, an energy principle is used to express the condition of stability of the equilibrium of the system. In the case of stable equilibrium of an elastic system, the total sum of the potential energy of the external forces and of the elastic distortions must be an extreme value and a minimum. In other cases, as, for example, in a system which is under buckling load, this sum remains unchanged for certain small, special "variations" of the form of the equilibrium of the elastic bar. Often this energy sum can be treated for the case of the buckling of a system the same as if the system were in a condition of stable equilibrium, that is, by searching simply the form of a function (the elastic line) for which a certain definite integral (the expression of the energy sum) becomes an extreme value.

Perhaps it has not yet been noticed by engineers that, for a given differential equation of a problem, there exist an infinite number of such equivalent conditions, that is, of such definite integrals that have extreme values. From any of these definite integrals, the unknown function can be derived. Consider, for example, the linear differential equation of the second order of a function,  $y = f(x)$ :

$$y'' + \alpha y = 0 \dots \dots \dots (32)$$

which should be integrated under the condition that, for  $x = 0$ ,  $y' = 0$ , and for  $x = l$ ,  $y = 0$ . The integral is, obviously,

$$y = a \cos x \sqrt{\alpha} \dots \dots \dots (33)$$

Under these conditions the integration constant,  $a$ , in Equation (33), is undetermined and, because of the condition that when  $x = l$ ,  $y = 0$ , the parameter,

$\alpha$ , must be found so that  $\alpha l^2 = \frac{\pi^2}{4} = 2.46740$ ; but  $\alpha l^2$  can also be chosen so

that it becomes equal to certain multiples of the quantity,  $\frac{\pi^2}{4}$ . As is well

known, the elementary problem is to determine the lowest load,  $P$ , under which a straight bar of length,  $l$ , clamped at one end, loaded centrally at the other, and allowed to deflect laterally, would lead to Equation (33). The critical load is found by Euler's formula:

$$\alpha l^2 = \frac{P l^2}{I E} = \frac{\pi^2}{4} \dots \dots \dots (34)$$

in which,  $P$  is the load;  $I$ , the moment of inertia of the buckling bar;  $E$ , the modulus of elasticity; and  $l$ , the length of the bar.

The same problem, treated as one of calculus of variation, would require the determination of the function,  $y$ , for which the definite integral,

$\int_0^l [(y'')^2 - \alpha (y')^2] dx$ , becomes an extreme value. This integral contains the sum of the potential energy of the external force,  $P$ , and  $a$ , the elastic energy of bending.

Another possibility would consist in searching for an unknown function,  $y = f(x)$ , from another condition as follows: Assume that  $y$  is replaced by some approximate function,  $\eta = \phi(x)$ , which could contain some constants,  $c_1, c_2, c_3$ , etc. The second derivative of this function and the expression,  $\Delta = \eta'' + \alpha \eta$ , could then be computed.\* If  $\eta$  and  $\alpha$  were the exact values of  $y$  and  $\alpha$ , then  $\Delta$  should become 0 for every value of  $x$ . In general, this will not be the case, the approximation being closer as the values of  $\Delta$ , or of the integral,  $\int_0^l \Delta^2 dx$ , become smaller. A sum of squares can never become negative and, therefore, the best approximation for  $\eta$  and  $\alpha$  is obtained by determining the constants,  $c_1, c_2, c_3$ , etc., that enter into the value of  $\eta$  so as to make the integral a minimum. As seen from this, another requirement for the function,  $y$ , and the parameter,  $\alpha$ , would consist in determining them from the condition that the definite integral of the squares of the quantity,  $\Delta$ , should become a minimum, or:

$$\int_0^l \Delta^2 dx = \int_0^l (\eta'' + \alpha \eta)^2 dx \dots \dots \dots (35)$$

A third possibility would be as follows: Equation (32), if written in the form,  $y'' + \alpha y = 0$ , represents the equation of a simple harmonic motion of an oscillating material point. The independent variable is now the time,  $t$ , and  $y$  is the distance traveled by the point.\* The constant,  $\alpha$ , contains the mass and the restoring force. Substitute  $t$  for  $x$  in Equation (33); then,  $y = a \cos t \sqrt{\alpha}$ ; but  $y$  can now be determined also from another condition, namely, that the definite integral,  $\int_0^{\frac{T}{4}} [(y')^2 - \alpha y^2] dt$ , should become an extreme value. The integral contains the difference of the kinetic and potential energy of the moving point, the upper limit,  $\frac{T}{4}$ , now contains the period,  $T$ , of an oscillation.

If the relation,  $y = a \left(1 - \frac{x^2}{l^2}\right)$ , is used instead of the exact solution expressed in Equation (33); if  $0 < x < l$ ; and if  $y$  is determined from the condition that the integral,  $\int_0^{\frac{T}{4}} [(y')^2 - \alpha y^2] dt$ , or  $\int_0^l [(y')^2 - \alpha y^2] dx$ , should become an extreme value, this leads to the conclusion that  $\alpha = 2.50$ . From the condition that  $\int_0^l [(y'')^2 - \alpha (y')^2] dx$  must become an extreme value, it is found that

\*  $y', y'',$  etc., designate the derivation of  $y$  with respect to the time,  $t$ .

$\alpha = 3$ . As seen from this, derived from the first condition, a value of  $\alpha$  is found which is only greater by 1.3% than its exact value,  $\alpha = \frac{\pi^2}{4} = 2.46740$ , while the second condition would give a greater error of about 20 per cent.

As these examples show, there exists a variety of equivalent expressions (forms of definite integrals) from which the values of critical loads under buckling or—in the corresponding case of dynamics—of the frequencies of vibrating systems can be derived. Those definite integrals which contain derivatives of the lowest order of the unknown function will probably give the values of the critical speed or the critical load with greater accuracy.

It would perhaps be interesting to discuss some of the equivalent expressions of the type mentioned herein, which could be used for the purpose of determining the values of buckling loads. The writer does not know how far such questions have been treated.

Finally, another example will illustrate the usefulness of the method given by Professor Timoshenko. Consider a circular plate of radius,  $r = a$ , clamped along its circumference and exposed to a constant pressure,  $p$ , acting radially in the plane of the plate. The critical value of the pressure that will buckle the plate is given by solving the differential equation:

$$r^2 \phi'' + r \phi' + \left( \frac{p r^2}{N} - 1 \right) \phi = 0 \dots\dots\dots (36)$$

for the slope,  $\phi$ , of the deflected middle surface of the plate. In Equation (36),  $N$  denotes the plate rigidity, or,

$$N = \frac{E h^3}{12 (1 - \nu^2)} \dots\dots\dots (37)$$

in which,  $E$  is the modulus of elasticity;  $h$ , the thickness of the plate;  $\nu$ , Poisson's ratio; and  $r$ , the radial co-ordinate. The solution is found by Bessel's function:

$$\phi = c I_1 \left( \frac{\lambda r}{a} \right) \dots\dots\dots (38)$$

in which,  $\lambda^2 = \frac{p a^2}{N}$ , and for  $\lambda$  any root of the equation,  $I_1 (\lambda_n) = 0$ , can be taken.\* In Equation (38),  $a$  is the radius of the plate. The first positive root of the last equation is  $\lambda_1 = 3.8317$ . The corresponding value of the lowest buckling load is  $p = \frac{\lambda_1^2 N}{a^2} = 14.682 \frac{N}{a^2}$ .

By using the relations,  $x = \frac{r}{a}$ ,  $y = \phi \sqrt{x}$ , and  $\lambda^2 = \frac{p a^2}{N}$ , Equation (36) can be easily transformed into the form:

$$y'' + \left( \lambda^2 - \frac{3}{4 x^2} \right) y = 0 \dots\dots\dots (39)$$

For a corresponding definite integral,  $\int_0^1 \left[ (y')^2 - \left( \lambda^2 - \frac{3}{4 x^2} \right) y^2 \right] dx$ , can be taken, which is now to be made an extreme value. When  $y = c (x^3 - x) \sqrt{x}$ ,

\* The solution seems to have been established first by Bryan; see, also, A. Nadai, "Die elastischen Platten," Springer, Berlin, 1925, p. 249.

this integral gives the first approximate value of the parameter,  $\lambda_1^2 = 16$ , with an error of 9 per cent.

By using a better approximation,  $y = c_1 (x^3 - x) \sqrt{x} + c_2 (x^5 - x) \sqrt{x}$ , the result is  $\lambda_1^2 = 14.702$ . When compared with the exact value,  $\lambda_1^2 = 14.682$ , it can be seen that this is a very good approximation for the buckling load of the plate.

S. TIMOSHENKO,\* Esq. (by letter).—The purpose of the paper was to give a brief discussion of several problems of elastic stability, different from simple column problems and of interest to structural engineers. In all cases it was assumed that the bars were slender and the plates thin, so that buckling occurred within the elastic limit of the material. There are many cases of more complicated conditions in which buckling occurs beyond the elastic limit, and the writer completely agrees with Professor Westergaard's statement that these problems "represent a field for future research, both experimental and analytical."

In the case of trusses, the compressed members are usually in a condition of eccentric compression, due to rigid joints. The magnitude of the eccentricities can be calculated by the methods used in the analysis of "secondary stresses" in trusses. Having these eccentricities, it seems logical to design these members as bars submitted to the simultaneous action of compression and bending. As an example, take the simplest case, when the eccentricities on both ends are equal and in the same direction. The maximum bending moment at the middle is then given by the well-known secant formula:

$$\mu_{\max.} = P_e \sec \frac{l}{2} \sqrt{\frac{P}{EI}} \dots \dots \dots (40)$$

in which,  $P$  is the eccentrically applied compressive force, and  $e$ , the magnitude of the eccentricities.

The maximum compressive stress is:

$$s_{\max.} = \frac{P}{A} + \frac{\mu_{\max.}}{S} = \frac{P}{A} \left( 1 + \frac{e}{r} \sec \frac{l}{2} \sqrt{\frac{P}{EI}} \right) \dots \dots \dots (41)$$

in which,  $r = \frac{S}{A}$ .

In using Equation (41) to determine cross-sectional dimensions, it is important to note that the maximum stress is not proportional to the load,  $P$ , but increases more rapidly than the load. Hence, it is not logical in Equation (41) simply to make  $s_{\max.}$  equal to the working stress,  $s_w$ , when designing the bar. This is explained by Fig. 18 which shows  $s_{\max.}$  as a function of  $P$ , as given by Equation (41). This curve has as its asymptote the vertical line,  $BC$ , such that,

$$OB = P_{cr} = \frac{EI \pi^2}{l^2} \dots \dots \dots (42)$$

Select a working stress that is a certain amount less than the yield-point stress,  $s_y$ , for example, let  $s_w = \frac{s_y}{2}$ . In Fig. 18, this corresponds with the point

\* Prof. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

$D$ , on the curve and it follows that the load is  $P_w$ . It will be seen that, due to the non-linear relation between  $s_{\max}$  and  $P$ , the ratio,  $\frac{P_w}{P_y}$ , is different from the ratio,  $\frac{s_w}{s_y}$ .

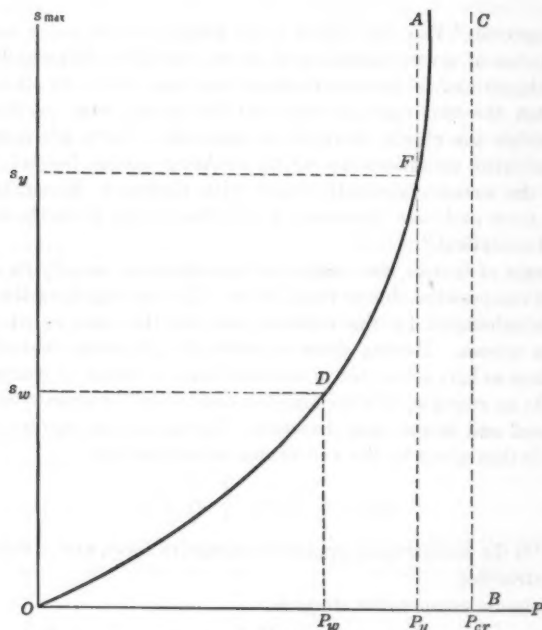

FIG. 18.

While  $s_w$  is one-half  $s_y$ ,  $P_w$  is more than one-half  $P_y$ , and the factor of safety with respect to the beginning of yielding is smaller than 2. In order to arrive at the prescribed factor of safety, let  $s_w$  and  $s_y$  represent, respectively, the working stress for short compressed bars and the yield point of the material, and let  $n$  be the factor of safety. This factor, then, must be such that the maximum stress, given by Equation (41), will equal the yield point when the load,  $P$ , is increased  $n$  times. It is assumed that Equation (41) is accurate enough to describe conditions also when  $s_{\max}$  approaches  $s_y$ . For this limiting condition, Equation (41) becomes:

$$s_y = \frac{n P}{A} \left( 1 + \frac{e}{r} \sec \frac{l}{2} \sqrt{\frac{n P}{E I}} \right) \dots \dots \dots (43)$$

from which,

$$\frac{1}{n} s_y = s_w = \frac{P}{A} \left( 1 + \frac{e}{r} \sec \frac{l}{2} \sqrt{\frac{n P}{E I}} \right) \dots \dots \dots (44)$$

Comparison of Equation (44) with Equation (41) shows that the replacement of  $P$  by  $nP$ , under the radical, takes proper account of the fact that  $s_{\max}$  increases faster than  $P$ .

If  $P$ ,  $e$ ,  $n$ , and  $s_y$  are known, the cross-sectional dimensions may be determined by cut-and-try methods so as to satisfy Equation (44). Manipulation with this equation can be greatly simplified by preparing tables for  $\frac{P}{A}$  for various values of  $n$  and  $\frac{e}{r}$  and for various slenderness ratios of struts. Such

tables were calculated for several cases by K. S. Zavriev\* and an analogous method was proposed by A. Ostenfeld.†

An analogous analysis can be developed for any other condition of eccentricity. With the tables mentioned, compressed members with any given factor of safety can easily be designed. This method of treating compressed members also gives a logical basis for dimensioning lattice-bars of built-up columns. These bars must be strong enough to sustain the shearing force, the value of which is easily derived when the eccentricities in the application of the compressive force are known.

Both methods of reasoning applied by Professor Hovgaard in deriving Equations (27) and (28) are legitimate and both of them reach the same final result. This subject was discussed elsewhere in detail by the writer‡ and he did not consider it necessary to repeat it.

### PRE-DETERMINING THE EXTENT OF A SEWAGE FIELD IN SEA WATER\*

By A. M. RAWN,<sup>†</sup> AND H. K. PALMER,<sup>‡</sup> MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. GEORGE W. FULLER, KENNETH ALLEN, R. F. GOUDEY, WARREN E. HOWLAND, HARRISON P. EDDY, AND A. M. RAWN AND H. K. PALMER.

#### SYNOPSIS

This paper presents a method for pre-determining the probable area and extent of a sewage field in sea water, when the quantity of sewage flow and the direction and depth of discharge below the ocean surface are given. The formulas may also be applied to define the probable limits of a sewage field at any given degree of dilution.

Research by the writers fails to reveal any established numerical relationship between the known or pre-determined factors surrounding an ocean outfall outlet and the probable amount of dilution obtained at the ocean surface over the outlet or of the probable spread of the field. In many instances bacteriological surveys made of the area of ocean pollution at sewer outlets have disclosed the extent of the permissible pollution to be far from what the designers anticipated. The predicted area in such cases was based largely upon an "acres-per-second-foot-of-sewage" factor used as a constant rather than as a variable, dependent on the elements of design and conditions existing at the outfall site.

Health standards, as related to shore waters along ocean beaches, define the limits to which pollution of such waters may be carried without creating a menace to health or a public inconvenience. These standards are often found

\* Published in May, 1929, *Proceedings*.

<sup>†</sup> Asst. Chf. Engr., Los Angeles County Sanitation Dists., Los Angeles, Calif.

<sup>‡</sup> Chf. Draftsman, Los Angeles County Sanitation Dists., Los Angeles, Calif.

to be maintained by frequent reconstruction of the ocean outlet following quarantine of the adjacent shore waters. By means of the formula presented herewith, an attempt is made to eliminate some of the elements of doubt and conjecture regarding the probable spread of a sewage field and to aid in the design of ocean outlets which will not of necessity be abandoned or reconstructed prior to the expiration of their anticipated useful life.

The particular factor that influenced the undertaking of this series of experiments is the contemplated construction of an ocean outfall by the Los Angeles County Sanitation Districts on the California coast line, south of the City of Los Angeles. The information and data assembled during the series of experiments, and the formulas derived from the experimental and research work, are presented for the information of those engaged in similar work or studies.

#### NOTATION

The following notation has been used in the paper:

- $a$  = constant in the equation of the path from a horizontal outlet.
- $A$  = area, in square feet, of the cross-section of the rising column of water at any level ( $y$ ) under observation.
- $B$  = constant.
- $D$  = diameter of the outlet, in inches.
- $E$  = horizontal distance from the center of the rising column to the edge of the sewage field.
- $F$  = constant used in determining velocity in the sewage field.
- $K$  = constant.
- $L$  = length of path between outlet and surface.
- $n$  = number of outlets.
- $P$  = thickness of sewage field.
- $Q$  = quantity of sewage or fresh water.
- $S$  = dilution factor.
- $S_0$  = dilution factor at head of rising column.
- $t$  = time, in seconds.
- $U$  = velocity of ocean current.
- $V$  = velocity of the fresh-water jet, or of diluted sewage in the sewage field.
- $x$  = horizontal distance from the outlet to the center of the rising column at any level,  $y$ , under consideration; or the horizontal distance from the center of the rising column at the surface to any point in the field.
- $X_0$  = radius of virtual ring from which the sewage field spreads.
- $X$  = horizontal distance from the outlet to the center of the rising column at the surface (see Fig. 1).
- $y$  = vertical distance from the outlet to the point in the center of the rising column that is under consideration.
- $Y$  = total depth of salt water above the outlet.

EARLY OBSERVATIONS OF THE BEHAVIOR OF A  
FRESH-WATER JET IN SALT WATER

From preliminary studies and minor experiments with small colored fresh-water jets about  $\frac{1}{4}$  in. in diameter, discharging less than  $\frac{1}{2}$  gal. per min. in clear sea water, the following behavior was indicated. When discharged vertically upward from a submerged outlet a jet was seen to rise very much in the form of a dense cloud of smoke; it rolled and billowed in much the same manner, taking finally a shape which approximated an inverted cone with its base resting at the surface of the water and its apex at the point of discharge. Repeated trials indicated that the cone was uniformly constant in dimension and appearance for like conditions of discharge.

From a jet of fresh water discharged horizontally below the surface of the salt water the path of the fresh water appeared to approximate that of a projectile, except that it curved upward and was retarded by the turmoil occasioned by the billowing of the fresh water in the same manner as smoke billowing from a stack. A nozzle was fixed at a depth such that, when the jet was discharged vertically upward, it just reached and broke the surface of the salt water. The writers demonstrated that the same quantity of water from the same nozzle, discharged horizontally at the same depth, would not reach and break the surface of the salt water as a well-defined jet. This indicated that, other conditions being equal, the absorption of sea water into the sewage—or the degree of intermingling of the two waters—was greater for a horizontal than for a vertical discharge outlet.

With the jet pointing vertically downward, the path of fresh water gave the appearance of an inverted fountain with the head fluctuating or varying slightly in elevation. The fresh water traveled, sometimes, all to one side of the jet and frequently, in its upward path, completely surrounded the downward jet. The upward path then took the same approximate form as that from a vertical discharge line, except that it was not quite so concentrated in color and for a like amount of discharge presented a somewhat larger ring as it broke the surface. For a jet inclined  $45^\circ$  upward, conditions appeared to be about an average between that for a vertical and a horizontal discharge.

A cap in the form of a funnel with the spout closed, was lowered over the vertical jet until the edge of the funnel was below the point of outlet. The fresh water then gave the appearance of passing over an inverted weir, the upward path from the edges of the weir being about the same form as the rising column from a vertical jet, but with greater diffusion of fresh water into salt water and a larger field where the fresh water broke the surface of the salt water.

The observation of the behavior of the streams of fresh water from the miniature jets in the salt water formed the basis for the design of an apparatus to be used in the subsequent studies. It was determined from these meager observations that it would be necessary to be able to measure actual dilution at the surface, as produced under varying conditions of depth, quantity, velocity, and direction of discharge.

## DESCRIPTION OF METHODS AND APPLIANCES

The first observations were made in tubs of salt water and in the quiet lagoons at Alamitos Bay, California. They indicated little that was conclusive because no method was provided for measuring the value of the dilution factor at the time the stream reached the surface of the salt water or during its spread over that surface.

The site chosen for carrying the experiments to a conclusion was a basin in Los Angeles Harbor about 2 acres in extent, protected on two sides by land and, with the exception of a small entrance, on the other two sides by fairly tight sheeted wharves. Few steamers passed the entrance, and the only other disturbance due to wave action was occasioned by fishing boats and yachts brought into the basin for repairs. Equipment was mounted on a large raft moored in the basin which permitted the experiments to be made without reference to the tides. Depths of 13 ft. were obtained at high tide with 9 ft. possible at all times. The arrangement is shown in Fig. 1.

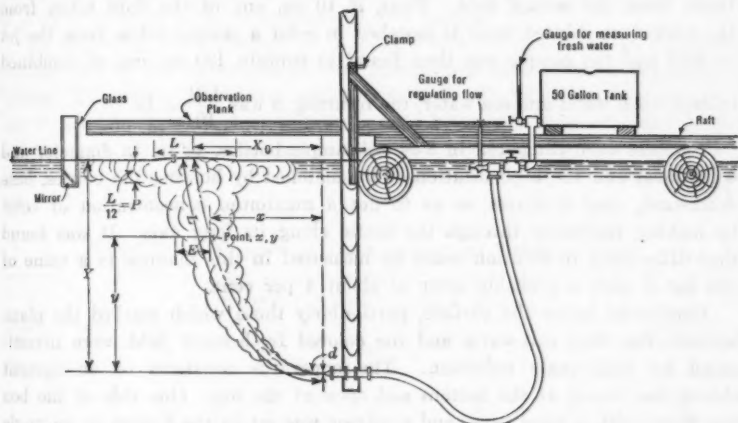

FIG. 1.—EXPERIMENTAL APPARATUS.

A fresh-water tank (a 50-gal. oil drum), was mounted on its side on the raft; the contents could be discharged through a  $1\frac{1}{2}$ -in. flexible hose, 12 ft. long. Pipe couplings, nipples, and reducers, could be attached to the end of the hose, permitting discharge through varying sizes of nozzles, which were ordinary pipe nipples ranging from  $\frac{1}{4}$  in. to  $1\frac{1}{4}$  in. in inside diameter. A few experiments were performed with  $1\frac{1}{2}$ -in. and 2-in. nozzles, with a section of  $2\frac{1}{2}$ -in. fire hose as a discharge line. The permanent end coupling on the hose was attached to a 1-in. by 6-in. board, 16 ft. long, which could be clamped to an upright post on the raft with the nozzle at any desired depth.

Flow from the drum was controlled by a globe valve located about a foot below the lowest elevation of the drum. Thus, the variation in flow due to change in head, as the drum emptied, was minimized. As a check on the

uniformity of flow a gauge glass was placed in the line below the valve, and was kept, as nearly as possible, at a constant head by adjusting the valve opening from the drum.

The drum was carefully calibrated and the rate of flow during any one experiment was determined by measuring the quantity of water discharged during that experiment. Time was measured to the nearest second and the fluid surface drop in the tank was indicated by the fall in a gauge glass in the outlet just above the globe valve.

Eosine Y was introduced into the fresh water as a coloring agency, the proportions being about  $\frac{1}{2}$  grain per gal. for shallow-water experiments when resulting low values of  $S$  were to be measured and as much as 2 grains per gal. for either deeper experiments or those in which the field spread was to be measured.

The value of  $S$  at any time was measured by diluting with sea water a measured sample of the tank fluid until it compared in color with the sample taken from the sewage field. Thus, if 10 cu. cm. of the fluid taken from the tank were diluted until it matched in color a sample taken from the jet or field and the sample was then found to contain 120 cu. cm. of combined colored fresh water and sea water, the resulting  $S$  was  $\frac{120}{10} = 12$ .

Samples were compared in 8-oz. oil-sample bottles,  $1\frac{1}{2}$  in. in diameter and 6 in. long, and the high dilutions were matched by holding the bottles, base downward, over a mirror so as to get a maximum concentration of color by looking indirectly through the bottle along its long axis. It was found that differences in dilution could be measured in this manner to a value of 150 for  $S$  with a probable error of about 4 per cent.

Conditions below the surface, particularly those which marked the plane between the clear salt-water and the colored fresh-water field, were investigated by right-angle reflection. The apparatus consisted of an upright oblong box closed at the bottom and open at the top. One side of the box was fitted with a glass pane, and a mirror was set in the bottom at an angle of  $45^\circ$  with the glass side. The possibilities of such an instrument are apparent.

The paths of the smaller streams of fresh water were found to be subject to some variation as a result of slight currents in the sea water, and in order to measure the horizontal co-ordinate of the path of a horizontal jet with a minimum of possible error, a double jet was placed at times on the nozzle. It consisted of a "tee" and the two jets discharged horizontally in opposite directions. The distance between the centers of the two rising columns was measured at the surface; from this was subtracted the distance between the two nozzle ends and the remainder was divided by 2, giving the required distance without reference to variation in the path which was the same for both jets. Interference between two rising columns below the surface and the spread of a double field was investigated with the same apparatus slightly modified.

The spread of the field on the surface was determined by observing the time when the edge of the field passed fixed points along the edge of the raft and along a plank cantilevered over the water at right angles to that edge.

As a check on results obtained from the foregoing experiments and in order to fix with greater accuracy the upper limits of the curves, values of  $S$  were determined for four known outlets in the vicinity of Los Angeles, namely, those at Los Angeles Hyperion Outfall, Long Beach, Santa Monica, and Santa Barbara. One at Catalina Island was investigated, but the sewage was found to be so diluted on reaching the water surface that samples taken would not yield results.

In the existing outfall investigations the salt content of each sample was measured. A solution of silver nitrate was prepared and standardized by titrating 2 cu. cm. of ocean water with it; 2 cu. cm. of each of the samples was then titrated in the same manner and when there was sufficient salt in the raw sewage to effect results, it also was titrated. By this means values of  $S$  up to 35 or 40 could be determined with accuracy.

To determine the thickness of a sewage field the difference in electrical conductivity of sea water and diluted sewage was noted with a Wheatstone bridge. The galvanometer was adjusted with the electrodes on both arms of the bridge immersed in clear salt water well below the layer of sewage. On raising one arm of the bridge the galvanometer would give a kick as the electrodes entered the diluted sewage. A dilution of 25 could be detected in this way.

#### VERTICAL JETS

It was apparent that there were fewer factors affecting the dilution from vertical jets than from other types, so they were studied first. A series of 222 observations was made at depths ranging from 1.2 to 10.5 ft. and using  $\frac{1}{8}$ -in.,  $\frac{1}{4}$ -in.,  $\frac{3}{4}$ -in., 1-in., and  $1\frac{1}{4}$ -in. nozzles. The number of experiments at various depths for each size of outlet are shown in Table 1.

If for any fixed depth the results of each experiment are plotted with values of  $Q$ , in gallons per minute, as ordinates and  $S_0$  as abscissas, the equation of the curve takes the form:

$$S_0 Q^{0.67} = f(y) \dots \dots \dots (1)$$

and this constant is the same for all sizes of nozzles. Subsequent comparison with results at the existing Long Beach Outfall while 3 000 gal. per min. of sewage was being discharged at a depth of 9.5 ft. and where the resulting  $S_0$  was small, showed that the equation took the form:

$$(S_0 - 1) Q^{0.61} = f(y) \dots \dots \dots (2)$$

The factor  $(S_0 - 1)$  is used instead of the factor,  $S_0$ , in order to avoid the anomalous case arising from the discharge of a large quantity of sewage at shallow depth, under which condition the value of  $S_0$  might become less than unity, which would correspond to a concentration of the sewage. Since  $(S_0 - 1)$  indicates the number of units of sea water per unit of sewage, there is a logical reason for its use.

In Fig. 2 results are plotted at the three depths at which the major number of experiments were taken, and the result of the experiment described at Long Beach is also shown.

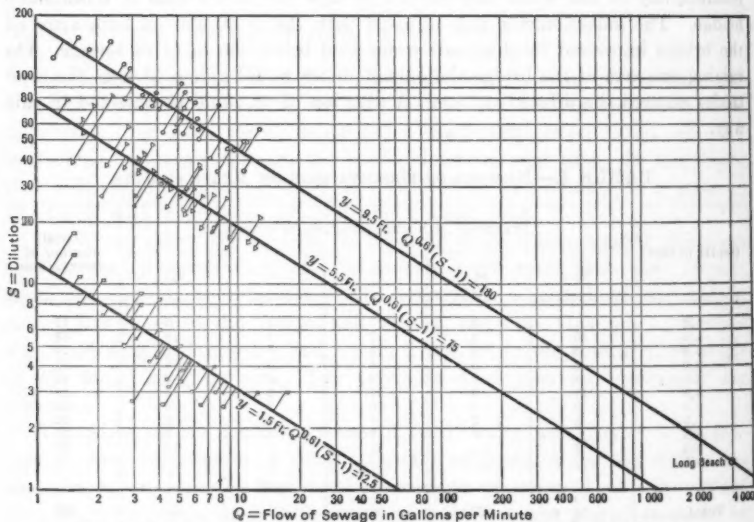

FIG. 2.—RELATION BETWEEN DILUTION AND QUANTITY AT CONSTANT DEPTHS.

#### HORIZONTAL JETS

This type of discharge is complicated by the fact that the rising column follows a path similar to that of a projectile, except that it curved upward. The direction of the path is modified by the inertia of the salt water picked up by the rising column, the tendency being to reduce its horizontal component. A total of 388 experiments was made, using horizontal jets, the numbers at each depth, with different sizes of nozzles, being shown in Table 2.

It was apparent from the beginning that the value of  $S_0$  was greater from the horizontal jets than from the vertical, other conditions being equal, and this group of experiments indicated that for this case Equation (1) should be written:

$$(S_0 - 1) Q^{0.61} = f(L) \dots \dots \dots (3)$$

The first requisite in the solution of Equation (3) was to determine the length of the rising column between the point of discharge and the salt-water surface. This length is, in turn, dependent on the equation of the curve of the path of the rising column. In order to avoid, as far as possible, error introduced by lateral currents in the sea water, the horizontal co-ordinate,  $X$ , was measured with the use of the double nozzle heretofore described.

Comparison of results using different quantities from a given size of nozzle fixed at a constant depth lead to the relationship:

$$x = K V^{\frac{2}{3}} \dots \dots \dots (4)$$

in which,  $K$  is a constant for that depth.

Comparing the values of  $K$  obtained at various depths for one size of nozzle, leads to the equation:

$$K = B \sqrt[3]{y} \dots \dots \dots (5)$$

in which,  $B$  is a constant for that size.

Furthermore, comparing the values of  $B$  for nozzles of different sizes, indicates that it has a progressive increase expressed in the equation:

$$B = \sqrt[3]{D} \dots \dots \dots (6)$$

Combining Equations (4), (5), and (6), and substituting for  $\sqrt[3]{V^2 D}$ , the constant,  $a$ , Equation (4) becomes,

$$x = a \sqrt[3]{y} \dots \dots \dots (7)$$

which is a cubical parabola with the origin at the nozzle.

The formula for the length of this path is too cumbersome to use in practice, but the two following approximations will give the length with sufficient accuracy:

Case 1, when  $\frac{Y}{X} > \frac{1}{3}$ ,

$$L = Y + (0.8a)^{\frac{2}{3}} - \frac{0.1685 a^2}{\sqrt[3]{y}} \dots\dots\dots (8)$$

Case 2, when  $\frac{Y}{X} < \frac{1}{3}$ ,

$$L = X \left\{ 1 + 0.9 \left( \frac{Y}{X} \right)^2 \right\} \dots\dots\dots (9)$$

The exact formula and the two approximations (Equations (8) and (9)) were developed by Mr. Gordon Ward, of the California Institute of Technology.

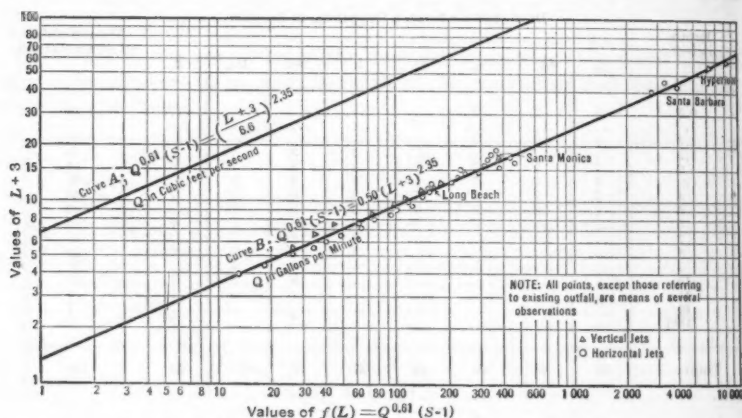

FIG. 3.—RELATION BETWEEN DILUTION AND LENGTH OF PATH.

#### RELATION OF DILUTION, $S_0$ , TO LENGTH OF PATH, $L$

Equation (2) for vertical jets becomes identical to Equation (3) for horizontal jets if  $L$  is substituted for  $y$ . A value for  $f(L)$  was computed for each horizontal and vertical experiment by means of Equation (3) and was plotted with  $f(L)$  as the abscissa and  $L$  as the ordinate. In Fig. 3 the results of all values for  $f(L)$  for any one depth were averaged, and the resultant was plotted as a single point on the curve. With horizontal jets the length of path being a complex function of the depth and velocity, it was impossible to regulate any experiment so that the length,  $L$ , would equal a pre-determined value. Therefore, instead of the observations being segregated into groups of single lengths as with vertical jet experiments, they were averaged within a narrow range of  $L$  values. All values within a range of 0.5 ft. were combined in order to determine the average. The values for Santa Monica and Hyperion were not averaged, but were plotted directly; those for Long Beach and Santa Barbara were the resultant averages of several groups of experiments.

When first plotted, the results lay on a curve, and it was necessary to add 3 ft. to the length of path, which resulted in the equation,

$$(S_0 - 1) Q^{0.61} = 0.5 (L + 3)^{2.35} \dots \dots \dots (10)$$

in which,  $Q$  is measured in gallons per minute. For large discharges it is more convenient to measure  $Q$  in cubic feet per second in which case the coefficient may be readily changed.

#### JETS DISCHARGING VERTICALLY DOWNWARD

In some cases outfall pipes are carried on wharves and the pipe is clamped to a pile so as to discharge the jet downward some distance below the surface of the water. The fresh water then acts in a manner similar to an inverted fountain and the distance to which the water flows downward before turning up, is approximately  $0.5 V$ . This distance is only approximate because the so-called inverted fountain is very unstable, the "head" constantly descending and rising. At Santa Monica, where this system of discharge is used, it was noted that the sewage came to the surface in waves, the flow at times almost ceasing, followed by a "crest" when a large quantity would boil up.

The resulting dilution is apparently that due to the total length of path from the end of the outlet down to the turning point and back to the surface, but in fairly large outlets it is probable that little dilution occurs on the downward path, so that the effective length would be only from the bottom of the downward jet to the surface.

#### JETS DISCHARGING UPWARD AT 45 DEGREES

Experiments were conducted with jets discharging  $45^\circ$  from the vertical and the results indicated that the length of path,  $L$ , was the mean of the lengths for vertical and horizontal jets, other conditions being equal. No formula is given for this case. However, it appears that the mean of vertical and horizontal formulas will indicate the value for  $S_0$  for inclined jets within reasonable limits.

#### DIAMETER OF A RISING COLUMN AT THE SURFACE OF THE SALT WATER

In making the experiments, the time required for the jet to reach the surface was measured to the nearest second; furthermore, the diameter of the column was measured just as it reached the surface and before the field began to spread. This was somewhat indefinite as the column of water, billowing upward, was not exactly round, and it was difficult to determine a mean diameter as it broke the surface of the salt water. The average of a large number of observations, however, indicated this dimension to be approximately one-third the length of the path,  $L$ . (See Fig. 1.)

In the case of a vertical jet the quantity passing any horizontal plane is  $QS$  and the velocity at that level is,

$$V = \frac{QS}{A} = \frac{4QS}{\pi} \left( \frac{3}{y} \right)^2 = \frac{36QS}{\pi y^2} = \frac{dy}{dt} \dots \dots \dots (11)$$

Therefore,

$$t = \int_0^y \frac{\pi y^2}{36QS} dy \dots \dots \dots (12)$$

Since  $S$  is a complex function of  $y$ , this integration (Equation (12)) was performed mechanically. A comparison of the observed and calculated time of rising demonstrated that the observed time was approximately 0.6 of the calculated time, indicating that the assumed area,  $A = \frac{\pi}{4} \left( \frac{y}{3} \right)^2$ , was too great and that the virtual diameter of the column was more nearly  $\frac{y}{4}$  for vertical jets, or  $\frac{L}{4}$  for horizontal jets.

By virtual diameter is meant the diameter of a theoretical column with uniform velocity at all points in any given cross-section, and of such size that the time of rise will be equal to the observed time. In actual cases the outer parts of the column contain rolling water with an upward velocity relatively slow as compared with the center of the column.

For large sewers the diameter of the nozzle should be added to  $\frac{y}{4}$  or  $\frac{L}{4}$  to obtain the true diameter of the column. The importance of this added factor varies inversely with the depth of discharge below the water surface.

#### THICKNESS OF THE SEWAGE FIELD

As the dilute sewage in the rising column reaches and breaks the surface of the salt water its tendency is to spread laterally in all directions over the heavier salt water. The plane of contact between the salt water and the lighter mixture of salt and fresh water is not clearly defined, owing to the natural tendency of the two fluids to intermingle. The average of many observations indicates a value of  $\frac{L}{12}$  for the field thickness and that this thickness remains uniformly constant over the entire apparent field (see Fig. 1). Measurements of the thickness of the fields at the Long Beach and Los Angeles Outfalls confirmed this value.

As the column of sewage rises and mixes with salt water, the velocity of the particles is progressively retarded and the straight line motion is converted into a rolling motion similar to a large column of smoke, the rolling masses gradually becoming larger until they reach the center of the column. On account of this motion of the masses there is no abrupt change in the direction taken by the individual particles where the column breaks through the surface, although the center of the masses will change direction.

The vertical velocity at the top of the rising column is,

$$V = \frac{Q S_0}{\frac{\pi}{4} \left( \frac{L}{4} \right)^2} \dots \dots \dots (13)$$

In still water the area of the annular cross-section,  $A$ , of the field at any distance less than  $E$  from the center of the column (see Fig. 1), will be represented by the formula,

$$A = 2 \pi x P \dots \dots \dots (14)$$

The virtual diameter at the top of the rising column is  $2 X_0 = \frac{L}{4}$ , and the lateral velocity at the head of the rising column will be represented by,

$$V = \frac{Q S_0}{\pi P \left(\frac{L}{4}\right)} \dots \dots \dots (15)$$

Assuming that no loss of energy occurs in the change from vertical movement in the rising column to horizontal movement as the field spreads, by Equation (13) and Equation (15),

$$\frac{Q S_0}{\pi \left(\frac{L}{4}\right)^2} = \frac{Q S_0}{\pi P \left(\frac{L}{4}\right)}$$

or,

$$P = \frac{L}{16}$$

This indicates that the observed velocity of the horizontal motion in the field spread is less than the theoretical value, the latter being determined by assuming no loss in energy as vertical motion is changed to horizontal. Increased turbulence at the column head indicates energy loss at that point, and it is believed that the ratio, 12 : 16, may be fairly representative of such loss. Therefore, the value for  $P$  is assumed to be (see Fig. 1),

$$P = \frac{L}{12} \dots \dots \dots (16)$$

#### SIZE OF THE SEWAGE FIELD

As the fresh water spreads the dilution continues, but since the turbulence is much less than in the rising column the rate of dilution diminishes correspondingly. It was observed that the colored fresh water moved over the salt water in concentric waves, each wave being followed by an interval of apparently clear salt water. These waves continued for some distance from the head of the rising column, and gradually merged to form a field of uniform color. This fact is noted to illustrate the difficulty of securing a single representative sample. Those taken from the same location in the field at different times, other conditions being equal, indicated that the dilution remained constant, within the limits of error of observation, at that location.

Experiments made with a view to obtaining the progressive increase in dilution from the head of the rising column to the edge of the apparent field, did not yield results that were as consistent as those indicating the dilution over the rising columns. This was probably due to the manner in which the sewage left the column head in waves. However, such experiments did show progressive increase in dilution as the distance from the head increased, and the time required for the sewage to travel a given distance was exceedingly uniform for like conditions. The latter was found to be expressed by the equation,

$$t = \frac{2}{3 F} x^{\frac{3}{2}} \dots \dots \dots (17)$$

Differentiating Equation (17),

$$\frac{dx}{dt} = \frac{F}{\sqrt{x}} = V \dots \dots \dots (18)$$

The quantity of diluted fresh water passing a ring is  $QS$  and the area of such annular cross-section, by Equation (14), is  $2\pi Px$ , thus the velocity is,

$$V = \frac{QS}{2\pi Px} \dots \dots \dots (19)$$

Equating this value to Equation (18) and transposing terms:

$$S = \frac{2\pi P F \sqrt{x}}{Q} \dots \dots \dots (20)$$

At the head of the column from which the field expands,  $x = X_0$  and  $S = S_0$ ; substituting these values in Equation (20),

$$F = \frac{Q S_0}{2\pi P \sqrt{X_0}} \dots \dots \dots (21)$$

and substituting this value for  $F$  in Equation (20),

$$S = S_0 \sqrt{\frac{x}{X_0}} \dots \dots \dots (22)$$

Observations of existing fields and a number of experiments indicate that

$X_0 < \frac{L}{8} + \frac{D}{24}$ . However, the use of this value,

$$X_0 = \frac{L}{8} + \frac{D}{24} \dots \dots \dots (23)$$

in Equation (22) is recommended.

In a confined channel with approximately parallel sides the cross-section of the field can increase only by thickening. The kinetic energy cannot increase and, therefore, as the velocity decreases with the increasing dilution, it is evident that the field must thicken, and, as soon as the thickness equals the depth of the water in the channel, no further dilution is possible. It is evident, therefore, that a constricted channel makes a poor location for a sewer outlet, and where it is the only available location the initial dilution should be as high as possible.

Some currents are nearly always present in the ocean, and in order to consider their effect on the field it is necessary to consider the velocity of spreading. The two particularly important considerations are the distance the field will travel directly against an ocean current and the distance it will travel directly with the current, until a certain value of  $S$  is attained.

The maximum distance the sewage will travel against the current can be expressed as,

$$e = x - x' = x - Ut \dots \dots \dots (24)$$

in which,  $x'$  equals the distance the ocean current will travel in time,  $t$ , at a velocity,  $U$ , and  $e$  is the maximum distance from the center of the column head

to which the sewage can travel against the ocean current. Under conditions expressed in Equation (24),  $V = U$ . Then, from Equation (18),  $U = \frac{F}{\sqrt{x}}$ , and,

$$x = \left( \frac{F}{U} \right)^2 \dots \dots \dots (25)$$

From Equation (17),

$$U t = \frac{2}{3} \left( \frac{F}{U} \right)^2 = x' \dots \dots \dots (26)$$

Substituting the values of  $x$  and  $x'$  from Equations (25) and (26) in Equation (24),

$$e = \left( \frac{F}{U} \right)^2 - \frac{2}{3} \left( \frac{F}{U} \right)^2 = \frac{1}{3} \left( \frac{F}{U} \right)^2 \dots \dots \dots (27)$$

in which, the value of  $e$  is independent of the value of  $S$ .

The distance the sewage will travel with the current will be expressed by the relation,

$$e = x + U t \dots \dots \dots (28)$$

#### MUTUAL INTERFERENCE FROM MULTIPLE OUTLETS

The theory has been advanced in the past, and incorporated into the actual design and construction of numerous ocean outlets, that, other conditions being equal, the use of multiple outlets is advantageous.

An inspection of Equation (10) for  $S_0$  would indicate that such an assumption is true, because the value of  $S_0$  for  $\frac{Q}{n}$ , for a given depth, is greater than the value of  $S_0$  for  $Q$  and the distance that sewage must travel to attain a definite value for  $S$  is a function of  $\left( \frac{S}{S_0} \right)^2$ .

#### *Interference Between Rising Columns Below the Salt-Water Surface.*—

Two vertical outlets were attached to the discharge hose so as to permit simultaneous discharge from both at equal depth and at constant distance between centers of rising columns. As long as the depth of discharge below the surface was less than three times the distance between the two outlets, the observed and calculated values of  $S_0$  were the same. However, when the depth of discharge below the surface exceeded three times the distance between the two outlets, the two rising columns interfered below the salt-water surface, decreasing the area of the columns in contact with pure salt water. This resulted in the observed value for  $S_0$  being less than the theoretical for each column alone. At extreme depths, where the ratio of depth to distance between centers was great, the observed values approached the theoretical value for one outlet discharging the combined flow of the two.

A series of experiments was performed in which two horizontal jets were directed toward each other. The resulting observed values of  $S_0$  in this instance approached very closely those for the foregoing experiment, with two vertical jets at equal depths. This is reasonably explained by the fact that

the two horizontal velocities directed toward each other were neutralized, the path of each was shortened, and the two columns mingled shortly after discharge and rose together as a single vertical column.

Six slots, 1 by 1-in., were cut in the rim of a can, which was inverted and placed over a vertical nozzle. This divided the flow from the nozzle into six small columns, and at shallow depths, where these columns did not interfere in rising, the resulting observed value for  $S_0$  was that due to each small stream alone; but after interference became effective, at greater depths, the advantage was nullified.

Under the circumstances, very little horizontal velocity was imparted to the fresh water flowing through the orifices, the fresh water escaping as if it were flowing over inverted weirs with an acceleration due to the difference of the specific gravity of the two fluids and equal to  $\frac{g}{40} = 0.8$ .

A similar experiment was performed by inverting a can over a vertical nozzle, except that, in this instance, no slots were cut into the edge of the can. Under these circumstances the fresh water rose in the form of a hollow column, all the dilution taking place on the outer surface thereof. As the depth of discharge was increased the ratio of the observed value of  $S_0$  with the diffuser, to the calculated value without the diffuser, decreased from 1.5 at a depth of 2 ft. to 1.3 at 6 ft. and 1.08 at 10 ft.

*Merging of Fields.*—Ordinarily, when multiple outlets are used, the fields will merge a comparatively short distance from the rising columns. The merging of the individual fields may result in a thickening of the major field, an increased lateral velocity of spread, or a combination of both. The following data indicate that the increased lateral velocity predominates, although there is probably some thickening of the major field.

In calm water, with no currents, the major field can be considered as a number of individual fields each roughly corresponding in shape to a sector of the circular area of the major field with the column head near the apex. The condition obtaining in each individual field, under such a circumstance, was roughly reproduced by discharging a jet from a horizontal nozzle close to the surface, thereby imparting to the field a horizontal velocity in the direction in which the field would normally expand if its natural spread were laterally obstructed by other forces.

A tabulation of the results obtained from this experiment indicates that  $X_0$  is about twice the  $X_0$  value obtained when the field was permitted to expand equally in all directions.

In Equation (22), doubling the value of  $X_0$  likewise doubles the value of  $x$  if  $\left(\frac{S}{S_0}\right)$  remains constant. In the foregoing experiment the field was roughly circular and  $x$  represented the diameter. Under normal conditions of spread, without currents present,  $x$  will represent the radius. It follows therefore, that since the diameter of the field in the experiment was about twice the radius of the normal field the two are roughly equivalent.

This leads to the conclusion that even if the individual fields were still more distorted, approaching the shape of circular sectors, the assumption of equivalent areas would still hold. Results of investigations at the Hyperion Outfall indicate that to be the case.

The area of the major field, from such conclusions, will be  $n$  times the area of each individual field and its radius, or the distance the sewage will travel in calm water is obtained from the value of  $x$  in Equation (22), thus,

$$x = X_0 \left( \frac{S}{S_0} \right)^2 \sqrt{n} \dots \dots \dots (29)$$

Due to the increased velocity of spread in the major field the time for  $Q$  to reach the limit,  $E$ , of the major field is the same as for  $\frac{Q}{n}$  to reach the limit of its individual field.

Let the total flow through all the outlets be equal to,

$$Q' = n Q \dots \dots \dots (30)$$

$$X_0' = X_0 \sqrt{n} \dots \dots \dots (31)$$

$$F' = \frac{Q' S_0}{2 \pi P \sqrt{X_0'}} \dots \dots \dots (32)$$

Then, substituting Equations (30) and (31) into Equation (32):

$$F' = \frac{n Q S_0}{2 \pi P \sqrt{X_0' \sqrt{n}}} = n^{\frac{1}{2}} \frac{Q S_0}{2 \pi P \sqrt{X_0'}} = n^{\frac{1}{2}} F \dots \dots \dots (33)$$

From Equation (17), the time required to reach the outer limit of the combined field is equal to:

$$t' = \frac{2}{3 F'} (x')^{\frac{3}{2}} \dots \dots \dots (34)$$

and substituting  $F'$  in Equation (33):

$$t' = \frac{2}{3 n^{\frac{1}{2}} F} x^{\frac{3}{2}} n^{\frac{1}{2}} = \frac{2}{3 F} x^{\frac{3}{2}} = t \dots \dots \dots (35)$$

#### STRATIFICATION

It has been found that when water is undisturbed by wind or wave action, a difference of 2.5° Fahr.\* in its temperature is sufficient to cause stratification. The equivalent of this difference is shown in Fig. 4, in which temperature of sea water is plotted against the specific gravity of the sewage for different values of  $S$  at 60° Fahr. From this, it may be seen that raising the temperature of sea water from 60° to 62.5° Fahr., reduces the specific gravity from 1.02540 to 1.02479, the latter being equivalent to the specific gravity of sewage at 60° Fahr., diluted to  $S = 105$ .

This indicates that if  $S$  is less than 105 the mixture will tend to come to the surface. Actual experiment shows, however, that mixtures with a much higher value of  $S$  will come to the surface, probably assisted by the inertia imparted by the initial velocity.

\* "Solving Sewage Problems," by Fuller and McClintock, p. 157.

After reaching the surface the lighter fluid spreads laterally over the sea water and its tendency to remain stratified is exceedingly persistent. Oceanographic evidences of stratification in clear sea water are common in places where only slight changes in specific gravity are apparent. Observations have disclosed that stratification temporarily exists where the heavier water forms the upper stratum, the layers thus being in a state of unstable equilibrium. They remain so until disturbed sufficiently to cause a re-adjustment to stability with the heavier water at its proper level.

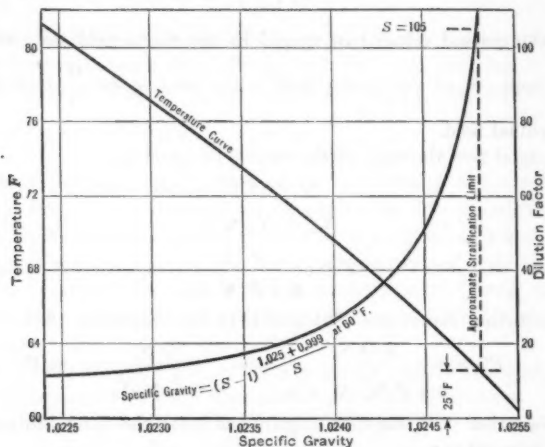

FIG. 4.

It is concluded, therefore, that the sewage field may not be expected to thicken before it has traveled such a distance from the column head as is needed to obtain a value in excess of 100 for  $S$ . The probable tendency will be for the sewage to remain distinctly stratified until a value of  $S = 200$ , or more, is reached; at which time (see Fig. 5), the specific gravities of the sea water and the dilute sewage are so nearly alike as to tend to merge, causing field thickening and consequent great dilution.

Wind and wave action or other disturbance will hasten the mingling of the thin sheet of sewage with the sea water and will have a pronounced effect on the breaking up of stratification; therefore, the most pronounced apparent fields will be observed during the periods of greatest calm.

In bacteriological surveys conducted about the Los Angeles City Outfall at Hyperion, a presumptive count of not to exceed 10 *B. Coli* per cu. cm. of sample taken is considered as marking the edge of the polluted area. Applying Equation (22) to the actual sewage field as found at Hyperion indicates that the value of  $S$  at the outer limit of the field is 212. Time as well as dilution may well be responsible for the bacterial destruction, and it is altogether probable that the sea water exercises a bactericidal effect on the sewage. It must be apparent that a presumptive count of 60 000  $\pm$  *B. Coli* per cu. cm. of sewage cannot be reduced to 10 per cu. cm. of sewage and sea water by dilution alone

in so short a distance from the column head as is usually found in bacteriological surveys.

It is undoubtedly true that, after the breaking up of stratification, the field thickens materially, reducing the lateral velocity, increasing the dilution, and accelerating the bactericidal possibilities of the sea water, and that, therefore, the place at which stratification breaks down marks approximately the outer limits of the field. This limit may be some distance beyond that place, however, and the actual value of  $S$  at its limits is much greater than Equation (22) would indicate at such location. For practical purposes, however, it is considered sufficient to neglect this thickening and apply Equation (22) on the assumption that  $S$  equals from 200 to 225.

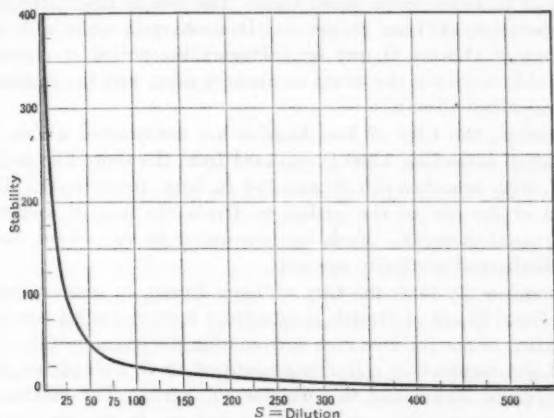

FIG. 5.—RELATION BETWEEN DILUTION AND STABILITY.

Following the assumption that the field stratification breaks down at a value for  $S$  of 200 +, care should be taken to provide sufficient depth of water at the onshore field limit to permit of material field thickening; that is, the depth of sea water at the shoreward limit of the field should be greater than the probable value for  $P$ .

#### CORROBORATION AND CORRECTION FROM RESULTS OBTAINED AT EXISTING OUTFALLS

Reference to Fig. 3 indicates that the upper limit of Curve A follows, within reasonable limits, the results obtained by measuring the actual value of  $S_0$  obtained at four existing California outfall sewers.

At Long Beach, the ocean outfall consists of a 36-in. cast-iron pipe extending 850 ft. seaward along the ocean bed and discharging 8.5 ft. below mean sea level through a vertical riser.\* The flow of sewage is continuous and during the series of experiments it varied from 6.7 to 10.5 cu. ft. per sec. The point of discharge is located in exceedingly calm water, and conditions over

\* Replaced in 1928 by 42-in. cast-iron outfall into 32 ft. of sea water, because of adjacent shore pollution.

this outfall approach more nearly those under which the experiments at San Pedro were performed than at any other outfall site investigated.

At Santa Monica, the ocean outfall consists of a 24-in. pipe supported by the Santa Monica Pleasure Pier.\* At the end of the pier it discharges vertically downward through a 20-in. pipe to a depth of 13.4 ft. below mean water level. During the period of observation, 7.5 cu. ft. per sec. was flowing, resulting in a velocity through the down pipe of 4 ft. per sec. and for the stage of the tide at that time, a value of  $L$  of 14.5 ft.

At Santa Barbara, sewage is discharged from a pumping station through a 42-in. reinforced concrete pipe laid in the ocean bed, the direction of discharge from the end of the outfall pipe being nearly horizontal and discharging the sewage 37 ft. below mean water level. The flow is intermittent; with one pump in operation 10.87 cu. ft. per sec. is discharged, while with two pumps the discharge is 15.2 cu. ft. per sec. During the period of observation one pump was able to empty the sump in about 4 min., and the interval between pumping was about 10 min.

At Hyperion, the City of Los Angeles has constructed a 7-ft. reinforced concrete outfall extending 5 300 ft. seaward from the shore line and terminating in a Y, with branches 320 ft. and 108 ft. long, respectively. This Y was constructed at the end of the outfall to divide the flow of sewage into two streams of equal quantity. Each leg terminates in an upward riser, so that sewage is discharged vertically upward.

On September 29, 1926, the City of Long Beach, in co-operation with the California State Board of Health, conducted a bacteriological survey to determine the extent of the polluted area surrounding the ocean outfall. The extent of the field was assumed by a limiting count of 10 *B. Coli* per cu. cm. of seawater sample and was found to comprise 507 acres. The maximum sewage flow during the survey amounted to about 10.5 cu. ft. per sec.; or a polluted area of 48.3 acres per cu. ft. per sec. of sewage discharged. In this value of  $Q$  the writers differ with the city officials of Long Beach who state that the maximum was 15.3 cu. ft. per sec. Flow was computed by measuring head loss in passing a Republic flow meter disk, the recording apparatus being out of order at the time.

Equations (1) to (35) are not applicable to the determination of the size of a field under conditions existent at Long Beach. They would indicate a field far too large and one in which bacteriological destruction would occur long before the calculated outer limit of the field at  $S = 200$  would be reached. Furthermore, they would indicate that a very thin layer of mixed water would have to maintain itself as an independent stratum for a period extending into days. Influenced by the tidal currents into and out of the Long Beach Inner Harbor Entrance, sewage from the Long Beach Outfall would reach the outer limits of the actual field, as found, in 4 to 6 hours.

At the same time that the City of Long Beach was conducting the bacteriological survey the writers made a separate survey of dilutions and surface velocities within a radius of 200 ft. of the outlet. The sewage is discharged

\* To be replaced in 1929 by connection to Los Angeles City System because of adjacent shore pollution.

between the two breakwaters which protect the Inner Harbor Entrance and about 200 ft. east of the channel into the Inner Harbor; it is, therefore, subject to an eddy current. Measurements of the dilution were made in three directions from the column head, from which it was found that the value of  $S$  was  $2.8 x^{0.31}$ ,  $0.58 x^{0.32}$ , and  $2.5 x^{0.32}$  in the respective lines of travel. The differences were due to the effect of the eddy current. Substitute in Equation (29), the known value of  $S_0 = 2$ , a mean value of  $S = 1.2 x^{0.5}$  and  $n = 1$ ; then,  $x$  cancels and  $X_0 = 2.8$ . By applying the same values in Equation (23),  $X_0$  is found to be equal to 2.6 which agrees with 2.8 within the limits of error allowed for the observation.

A rough check on the thickness of the field was obtained from the velocity at which the flow of sewage left the column head. This was made by observing the time required for chips of wood to float past fixed points in one direction from the outlet. The observations follow the formula,  $t = 0.08 x^{1.58}$ , which, by differentiation, results in the equation:

$$V = \frac{7.9}{x^{0.58}} \dots \dots \dots (36)$$

The field thickness,  $P$ , may be obtained by first combining Equations (19) and (36) and then substituting the known values,  $Q = 14.3$  and  $S = 1.2 x^{0.50}$ . For  $x = 15$  ft., the value of  $P$  is found to be 0.42 ft., and for  $x$  200 ft.,  $P = 0.36$  ft. Assuming the mean velocity of the sewage stratum to be 0.8 of the surface velocity, as in float measurements, the field thickness at 15 ft. becomes 0.53 ft. as compared to 0.75 ft. obtained from Equation (16). This observation of field thickness is noted for the purpose of illustrating the shallow depth of the sewage field.

Twice each year the City of Los Angeles conducts a bacteriological survey in the vicinity of its ocean outfall at Hyperion, which is intended to determine the area of ocean pollution. Owing to the fact that shortly after the construction of the outfall numerous leaks of considerable magnitude appeared at the joints between concrete pipe sections and that the leaks were not repaired until about April, 1927, there are only five of the surveys which interpret conditions as they should exist with the sewage discharge confined to definite, known outlets at or near the seaward end.

TABLE 3.

Date.	Q, in cubic feet per second.	Observed area of field, in acres.	Acres per cubic foot per second.	Number of outlets.	Depth, in feet.	$S_0$ .	Computed area, in acres.
January 11, 1925..	120	720	6.0	1	57	10.5	710
May 17, 1927.....	200	555	2.7	3	56	14	524
October 4, 1927....	170	986	5.8	2	55	11.5	(986)
February 29, 1928..	197	834	4.2	4	52	15	1 090
May 23, 1928.....	205	1 075	5.2	4	52	14.5	1 170

In Table 3 are the results of these five surveys, together with the theoretical results supplied by application of Equations (1) to (35) to conditions as they existed on the dates of the survey.

The comparison of the field spread in each case (see Table 3) is made on the assumption that the value of  $X_0$  is alike in each case, that it is correct within the reasonable limits of error, and that the outer boundary of each field is fixed by a value of  $S = 212$ . This was the value of  $S$  at the field boundary as determined by Equations (1) to (35) for the survey conducted October 4, 1927.

The advantage of initial dilution is well indicated by a comparison of these three fields with each other and with those at Long Beach. Between February or March, 1925, and April, 1927, the line leaked badly and could readily be compared with a line having a large number of small outlets. Each bacteriological survey conducted during this period indicated a smaller area of pollution per second-foot of discharge than is shown by any one of the five surveys given in Table 3.

At Deer Island, in Boston, Mass., Harbor, about 1920\* the sewage from a population of 700 000 was discharged horizontally in 30 ft. of water through fourteen rectangular outlets, 18 by 30 in. in size, distributed through a distance of 120 ft. Observations showed that the value of  $S_0$  was 21 and that 300 ft. away from the outfall pipe, sewage could not be visually detected. Several hundred feet away, chemical analysis showed about 100% sea water.

Assuming a rate of 100 gal. per capita daily, from the tributary population, the maximum total flow through the Deer Island Outfall would amount to 108 cu. ft. per sec., or 7.7 cu. ft. per sec., flowing through each outlet. The corresponding length of path should be 36 ft. and, assuming that the outlets are arranged in pairs discharging in opposite directions so that rising columns do not interfere,  $S_0 = 19$  theoretically. For  $x = 300$ ,  $S = 110$ , and for  $S = 212$ ,  $x = 2100$  ft.; the field area is 317 acres, or 2.94 acres per sec-ft., corresponding to a field limited by the same conditions of final dilution as the observed field at Hyperion. If the observed value ( $S_0 = 21$ ) of the initial dilution is used, the field limit, where  $S = 212$ , is found to be at  $x = 1715$  ft. and the area is 212 acres. As far as can be determined from data available, Equations (1) to (35) indicate a field on the side of safety.

#### PROBABLE ERROR

The probable error in the value of  $S_0$ , as determined from several of the vertical observations at constant depths, amounts to approximately 4 per cent. If a second variable is introduced, which in this case is the length of path, it would cause this to be multiplied by  $\sqrt{2}$ , making the resulting probable error about 6 per cent.

Since  $x$ , the distance to the outer boundary of the field, is inversely proportional to the square of the initial dilution, it is subject to an error of 12%, and the area of the field to an error of 25 per cent. Therefore, while so much depends on the value of  $S_0$ , it is a useless refinement to compute its value, and it can be found from Fig. 7 within the limits of error.

All the experiments at San Pedro Harbor were performed in very quiet water, and at Long Beach, the water at the outfall discharge is almost equally

\* Rept. of Special Sewage Disposal Comm., Los Angeles, Calif., August 10, 1921.

as smooth. At Santa Barbara there are small swells and the outfalls at Santa Monica and Hyperion are in the open ocean.

It has been considered axiomatic that, other conditions being equal, discharge into rough, disturbed water would result in greater dilution than discharge into calm water. The experiments at San Pedro indicated this clearly, in that relatively larger values of  $S_0$  were obtained with the use of  $\frac{1}{4}$ -in. and  $\frac{3}{8}$ -in. nozzles, than with the large sizes. The explanation for this is that, even in the more sheltered area, there were always present, currents of sufficient magnitude to effect results from these small streams of discharge, and these had little effect on the larger ones.

Extending this reasoning to nozzles of a size likely to be used in outfall sewer construction, it may be seen that on a calm day little, if any, increase should be found over the theoretical value in the dilution. When pollution is fixed by its effect on neighboring bathing beaches, calm weather conditions should be especially taken as a criterion for obvious reasons.

#### APPLICATION OF EQUATIONS (1) TO (35)

If the horizontal jets are to be used, the length,  $L$ , may be found from Equations (8) and (9) by introducing the value of  $x$  given in Equation (7); or, as circumstances warrant, may be taken from Fig. 6. For vertical jets,  $L = y$ .

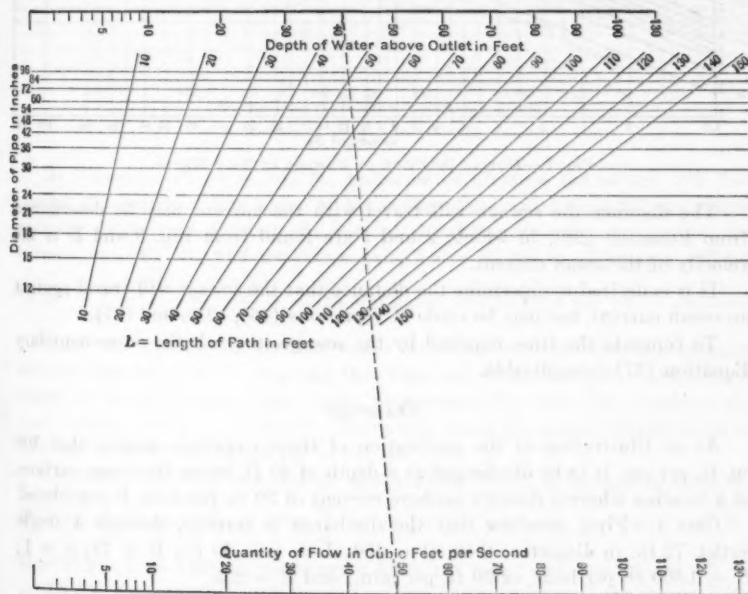

FIG. 6.—LENGTH OF PATH FROM OUTLET TO WATER SURFACE FOR HORIZONTAL OUTLETS.

The initial dilution,  $S_0$  may be found from Equation (10), or Fig. 7. (It should be noted that in Equation (10),  $Q$  is in gallons per minute.) The total

quantity of water coming to the surface is  $Q S_0$ , of which,  $Q (S - 1)$  is salt water.

The distance to which the sewage will travel away from the outlet, if there are no currents present, is found from Equations (23) and (29). This distance may also be taken from Fig. 8 with  $S = 225$ . For any other value of  $S$  multiply  $x$  by  $\left(\frac{S}{225}\right)^2$ . In some cases,  $x$  and  $t$  may exceed the limits of Fig. 8, but then the time element will be so great that other factors will enter and make the formulas inapplicable.

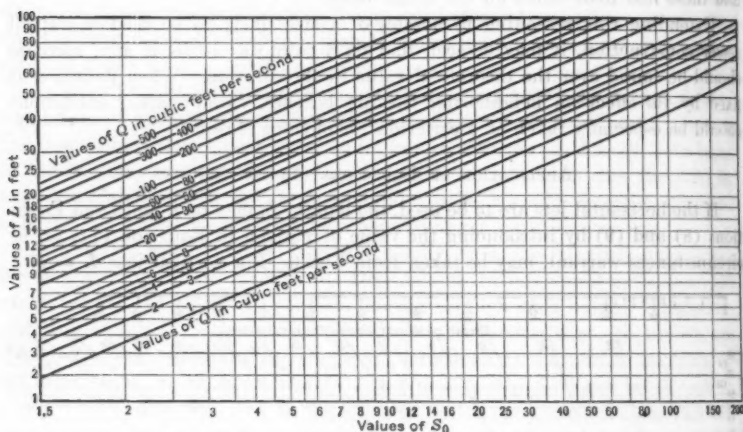

FIG. 7.—INITIAL DILUTION OF SEWAGE IN SALT WATER.

The distance the sewage will travel with the current may be determined from Equation (28), in which,  $x$  and  $t$  are found from Fig. 8 and  $U$  is the velocity of the ocean current.

If it is desired to determine the distance that the sewage will travel against an ocean current, use may be made of Equations (16), (21), and (27).

To compute the time required by the sewage to reach the outer boundary Equation (17) is applicable.

#### EXAMPLES

As an illustration of the application of these equations assume that 100 cu. ft. per sec. is to be discharged at a depth of 40 ft. below the ocean surface, at a location where a directly onshore current of 30 ft. per min. is considered.

*Case 1.*—First, consider that the discharge is vertical, through a single outlet, 72 in. in diameter; then,  $Q = 100$ ;  $L = y = 40$  ft.;  $D = 72$ ;  $n = 1$ ;  $U = 1800$  ft. per hour, or 30 ft. per min.; and  $S = 225$ .

From Fig. 8 the radius of the field at  $S = 225$  is more than 10 000 ft., so it will be necessary to compute  $x$  and  $t$ . Ordinarily, this is not worth while as other factors will tend to limit the field, but the computation is carried out as an illustration.

From Fig. 7,  $S_0 = 5.8$ . By Equations (23), (29), (16), (21), and (17):  $X_0 = 8.0$ ;  $x = 12\,000$  ft.;  $P = 3.3$  ft.;  $F = 9.9$ ; and  $t = 24.5$  hours, respectively. Hence,  $Ut = 44\,500$  ft., and, from Equation (28),  $e = 56\,500$  ft., which is the theoretical distance.

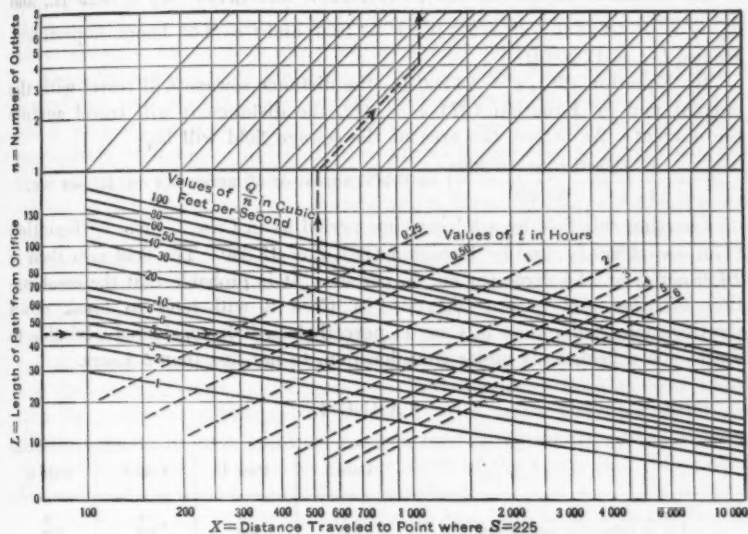

FIG. 8.—MEAN RADIUS OF SEWAGE FIELD.

By Equation (27),  $e = 131$  ft., which is the distance the sewage will flow against the current. The shape of the sewage field will be roughly an ellipse with the major axis equal to the sum of the distances with and against the current, or  $56\,630$  ft., and the minor axis,  $2x = 24\,000$  ft. The area will be,

$$A = \frac{\pi}{4} \left( \frac{56\,630 \times 24\,000}{43\,560} \right) = 24\,500 \text{ acres, or } 245 \text{ acres per cu. ft. per sec.}$$

It is very probable in the case under consideration, that the thin stratum will not exist as such for long and that time will limit the field. Assuming 5 hours as the field limit, then, from Equations (17) and (28), respectively,  $x = 4\,150$  ft. and  $e = 13\,150$  ft. From this value the area is found equal to 1990 acres, or 19.9 acres per cu. ft. per sec.

Case 2.—Assuming the use of two vertical 54-in. discharge nozzles, let

$$Q = 100 \text{ cu. ft. per sec.; } n = 2; \frac{Q}{n} = 50 \text{ cu. ft. per sec.; } y = L = 40 \text{ ft.};$$

$$D = 54 \text{ in.; } U = 1\,800 \text{ ft. per hour, or } 30 \text{ ft. per min.; and } S = 225.$$

To prevent interference between the rising columns below the surface, the two outlets should be at least  $\frac{40}{3} + 4.5 = 17.8$  ft. apart. The value of  $S_0$ , in this case becomes 8.4. This factor is not needed in the computation, but is

mentioned to emphasize the effect of  $S_0$  on the size of the sewage field. By Fig. 8,  $x = 7,600$  ft. The time being in excess of 6 hours, is not shown in Fig. 8 because the size of the field will probably be limited by other factors.

By means of Equations (23), (16), (21), and (17):  $X_0 = 7.25$  ft., and  $X_0 \sqrt{n} = 10.25$  ft.;  $P = 3.3$  ft.;  $F = 12.6$ ; and  $t = 9.55$  hours, respectively. Hence,  $U t = 17,200$  ft.

By Equation (28),  $e = 24,800$  ft., the distance sewage will travel with the current and by Equation (27)  $e = 212$ , the distance it will travel against the current. As before, the area of the sewage field will be,

$$A = \frac{\pi}{4} \left( \frac{25,012 \times 15,200}{43,560} \right) = 6,900 \text{ acres, or } 69 \text{ acres per cu. ft. per sec.}$$

Limiting this field by a 5-hour time period as in Case 1, then, by Equation (17),  $x = 4,850$  ft., and by Equation (28),  $e = 13,850$ . The field area then is 2,450 acres, or 24.5 acres per cu. ft. per sec. It is probable that the combination of time and greater dilution in Case 2 will tend to break down stratification earlier than in Case 1; nevertheless, it is considered advisable to limit such a field, as is under consideration, to not less than 5 hours.

$\frac{A}{Q}$ , in acres.....	12.50	6	1.4	0.9

If horizontal outlets are used, the computation is the same as for vertical outlets, except that it is first necessary to determine the length,  $L$ , of the rising column from Fig. 6, or by means of Equations (8) or (9). Equation (9) applies only to shallow depths with high velocities at the outlet, where the horizontal distance from the outlet to the point where the column reaches the surface is equal to or greater than three times the depth. For most cases Fig. 6 will suffice instead of Equation (8). Four other cases are given in Table 4.

## DISCUSSION

GEORGE W. FULLER,\* M. Am. Soc. C. E. (by letter).—The authors have presented interesting observations with equations corresponding to a variety of assumptions as to the travel of sewage in sea water. Of particular interest is the application of equations to conditions at existing outfalls. It would be advantageous to extend such applications to other outfalls.

From the standpoint of pollution of bathing beaches or shellfish layings it is probable that sewage fields are moved for greater distances at times of heavy wind storms than is generally realized. Public health aspects make it particularly desirable to diffuse the sewage as extensively as practicable and thus eliminate the likelihood of any sewage field at all. Such a result is related to the use of multiple outlets which have substantial submergence, and to the release of sewage under conditions by which its velocity of discharge is quickly and almost completely checked, as well as to its release in numerous small streams whereby quick and thorough dispersion is promoted.

The writer's observations indicate that there is no more adequate design for the discharge of sewage into brackish water than the arrangement provided for the Passaic Valley trunk sewer, designed to serve a population of 1 600 000 and discharging sewage into Upper New York Bay near Robbins Reef Light. The 150 nozzles or diffusers, located about 50 ft. below mean low water and distributed over an area of about 3 acres, release the sewage with a swirling outward motion so that it leaves the periphery of the nozzle in a thin ribbon. Dispersion of the sewage is practically complete.

This paper is also of interest to engineers who have to do with the disposal of sewage in the Great Lakes or other large bodies of fresh water where there is opportunity for the discharge to pollute bathing beaches or water-works intakes. There are different factors, of course, in such a situation as compared with outfalls in sea water. Stratification conditions are different and the effect of tides is absent, which in estuaries like New York Bay never allow the water at various depths to come to a complete standstill at the same time. Furthermore, in the Great Lakes, the effect of wind at times may be such as to cause the movement of sewage fields for relatively great distances, thus showing the need of effective dispersion.

KENNETH ALLEN,† M. Am. Soc. C. E. (by letter).—The phenomenon of the course and diffusion of sewage discharged from submerged outlets is one that has rarely received close study, although the general results have been long recognized. The authors have attacked the problem in such a way that, under given conditions, the form of the issuing jet and its spread over the surface of sea water may be approximately predicted. This is believed to be an important advance over previous investigations along these lines.

The experiments and conclusions drawn therefrom are, however, limited to sea water, and in the application of the deduced formulas it is possible that the inexperienced engineer might not appreciate the important influence of

\* Cons. Engr. (Fuller & McClintock). New York, N. Y.

† San. Engr., Sanitation Comm., New York, N. Y.

salinity and the direction, form, and diffusion of the sewage stream. In inland cities the phenomena accompanying the discharge of sewage from submerged outlets in lakes and rivers will differ radically from those to be observed in salt water.

The effect of salinity was brought out very clearly in experiments made by the writer for the Metropolitan Sewerage Commission of New York in 1909. Owing to the configuration of the harbor, the flow of upland water brought down by the Hudson River and the action of the tides, the percentage of sea water was found to average 74.8 at West Bank Light in the Lower Bay and 33.7 in the Hudson River off Fort Washington Point. The extreme readings noted at those points during the year were 93.2% at West Bank Light on November 5, and 0% at Fort Washington Point on April 8. Conditions varied, therefore, from those of fresh water to those of nearly pure sea water.

Several series of experiments were made to learn more of the action of sewage discharged into waters of different specific gravities.

*Experiments on Flotation.*—Croquet balls were weighted until they balanced in water of a specific gravity of 1.000, and then released in water of known specific gravity at a given depth.\* The time required for the balls to rise to the surface was noted with a stop-watch. (See Table 5.)

The results, while not entirely consistent, give a fair idea of upward velocities of smooth solids released in waters of different density that will not be reached by a diffusing liquid. Bottles, released in a similar way, rose even more rapidly, on account of their smoother surfaces.

*Laboratory Experiments in Diffusion.*—A total of thirty-one experiments was made to observe the action of a dyed sewage or water when discharged from a pipette, or small tube, in waters of different salinity. Alcoholic solutions of eosin and fluorescein and aqueous solutions of bluing, permanganate of potash, and uranine were tried. The dye, especially the bluing, was found to increase the specific gravity slightly, and it was feared that alcohol might affect diffusion. Permanganate of potash was likely to be decolorized by organic matter. It was finally decided to use uranine ( $C_{20}H_{10}O_5Na_2$ ) which, in a strong solution, is a deep red, but becomes a brilliant green on dilution, readily detected in a Nessler tube in a 1 : 20 000 000 dilution. A dye called "Special Scarlet" was used later and was found to be a very serviceable and less expensive substitute.

These experiments indicated clearly the effect of specific gravity and the way in which a drop or a jet diffused. Some of the forms observed were beautiful as well as interesting: Waves of floc; rings like smoke rings; funnels; and cones and wavy threadlike lines, rising or falling, and diffusing rapidly or slowly. The diffusion of 2 cu. cm. of a 1% solution of uranine added gently to the surface of 200 cu. cm. of waters of varying salinity in beakers and jars began in a few minutes, was complete in an hour with tap water, and took 48 hours in a mixture containing 25% of sea water, while it had not occurred

\* The salinity of sea water varies in different parts of the ocean, but for this region chlorine of 18 000 parts per million, corresponding to a specific gravity of 1.025, was assumed as constituting 100 per cent.

with a 75% mixture of sea water in a week's time. (See Table 6.) Salinity, therefore, was shown to have a marked effect on diffusion.

*Experiments in Diffusion in the New York City Aquarium.*—These experiments, twelve in number, were made to confirm the results obtained in the laboratory before conducting others on a larger scale in the open water. The tank was 4 ft. high, 4 ft. wide at the top, narrowing to about 3 ft. at the bottom, and 8 ft. long, with an overflow a few inches below the top. The dye and water were fed from a funnel and by a tube to a nozzle, the depth and direction of which were adjustable. Nozzles of  $\frac{1}{4}$  in.,  $\frac{3}{8}$  in., and  $\frac{1}{2}$  in. were used.

TABLE 5.—EXPERIMENTS TO DETERMINE UPWARD VELOCITY OF SMOOTH SOLIDS.

Experiment No.	Number of tests.	Specific gravity of water.	Vertical distance traveled, in feet.	Average velocity, in feet per second.
1	13	1.0215	1.47-1.51	0.500
2	10	1.016	1.70	0.455
3	15	1.007	1.62	0.352
4	15	1.009	1.62	0.301
5	4	1.0195	10.0	0.635
6	10	1.0215	10.0	0.49

Without going into the details of these experiments, some of the results were as follows:

- With a horizontal jet a considerable current may be induced at a slight depth without apparent effect on the surface itself.
- With a  $\frac{1}{4}$ -in. horizontal jet of fresh water in fresh water, under a head of 1.0 ft., the axis of the jet remained horizontal, enlarging in diameter to 3 in. at a distance of 1.25 ft. from the nozzle and to 6 in. at a distance of 3.0 ft. from the nozzle, and then diffusing slowly. After substituting a jet of sewage, the diameter 3.0 ft. from the nozzle was 12 in.
- In the case of a  $\frac{1}{4}$ -in. upward jet of fresh water at a depth of 3.0 ft. in fresh water under a head of 2.5 ft., the jet formed a concave cone 5 in. in diameter 1.0 ft. from the nozzle and spread in a thin layer at the surface. By the end of 5 min. diffusion was quite uniform to a depth of 1.5 ft.
- With a  $\frac{1}{4}$ -in. horizontal jet of sewage in fresh water near the bottom of the tank, 3.4 ft. below the surface and under a head of 0.15 ft., there was a gradual descent of the jet to the tank bottom which it covered with a blanket about 2 in. thick, with very little diffusion, in 3 min. The temperature of the sewage was 62° Fahr., with a specific gravity of 1.001. The temperature of the water was 61° Fahr., and its specific gravity was 1.000.
- With a  $\frac{1}{4}$ -in. jet (nearly horizontal) of sewage in harbor water, at a depth of 3.3 ft. and under a head of 0.15 ft., a temperature of sewage, 62° Fahr., specific gravity, 1.0015, and a temperature of water, 58° Fahr., the effluent rose promptly in an upward curving cone, reaching the surface in 1 min., where it spread out. At the end of 3 min. the supply of dye was cut off and by the end of 5 min. there remained but a thin green layer at the surface.
- For a  $\frac{1}{4}$ -in. horizontal jet of sewage in harbor water, as in Result (e), under a head of 1.0 ft., the diameter in a plane 1.0 ft. above the nozzle was 8 in. (see Fig. 1). The horizontal component of

the jet did not appear to affect the time taken to reach the surface.

- (g) With a  $\frac{1}{4}$ -in. upward jet of sewage in harbor water, at a depth of 2.5 ft., and under a head of 1.0 ft., the sewage rose promptly to the surface with little diffusion and then spread in a thin layer. The diameter 2 ft. above the nozzle was 6 in.
- (h) At a  $\frac{1}{4}$ -in. downward jet of sewage in harbor water, under a head of 1.0 ft., the jet rose as a column of greater diameter and with more rapid diffusion than in Result (g) and spread at the surface. Diffusion was increased materially by a slight agitation of the water.

\* Experiments by Dr. Payne B. Parsons, Bacteriologist, Metropolitan Sewerage Comm. of New York.

The results of these experiments are generally confirmed by the work of the authors and by a similar apparatus, but their analysis has been carried to a point where the path of a jet of fresh water in sea water may be more closely predicted.

*Experiments on Diffusion in New York Harbor.*—Nine experiments were made by placing a dye in the surface water of the harbor, or at sewer outlets, to observe the rate at which sewage might be expected to become diffused and dispersed under different conditions. These were followed by twenty-one experiments to observe the result of discharging dyed water at various depths and locations in the harbor.

In three experiments at the outlet proposed at that time for the Bronx Valley Sewer, in the Hudson River, off Mount St. Vincent, dyed water was pumped at rates of 17 to 25 gal. per min., to depths varying from 5 to 25 ft. through a  $\frac{1}{4}$ -in. hose. The velocity of the river water varied from 0 to 3 ft. per sec., and its specific gravity varied from 1.010 to 1.013. The detection of dye at the surface was uncertain at slack water from depths greater than 16 ft., or in a current of  $2\frac{1}{2}$  ft. per sec. from depths greater than 9 ft.

Nine similar experiments were made at various points in New York Bay, Gravesend Bay, and the Upper East River. These indicated that:

- (a) With a difference in specific gravity of 0.004, dyed water will rise in quiet harbor water from depths of 10 to 26 ft. at a mean rate of 0.10 to 0.14 ft. per sec., and be visible at the surface.

- (b) With a difference in specific gravity of  $0.004\frac{1}{2}$ , it will rise from a depth of 18 ft., at a mean rate of 0.17 ft. per sec. and be visible at the surface.
- (c) With a difference in specific gravity of 0.016, it will rise from a depth of 27 ft. in a current of  $1\frac{1}{2}$  ft. per sec., at a mean rate of about 0.10 ft. per sec., and be visible at the surface.
- (d) In moderate currents dyed water may be expected to be visible at the surface if discharged at depths of 15 to 20 ft., but that the rate of ascent is variable. The limit from which it can be discovered under the most favorable conditions appears to be about 40 ft. In sea water (specific gravity,  $1.021\frac{1}{2}$ ), with a current of 0.3 ft. per sec., diffusion is very gradual at first, but proceeds more rapidly later.

Two similar experiments, but on a larger scale, were made in the Upper Bay, near the site of the Passaic Valley Sewer outlet off Robbins Reef, which has since been built.

In the first experiment, 16 500 gal. of a 1:2 750 solution of uranine in tap water was discharged 40 ft. below the surface through a  $2\frac{1}{2}$ -in. hose, at a rate of 205 gal. per min., giving a velocity of 14 ft. per sec. The specific gravity of the harbor water varied from 1.0115 to 1.0135.

In the second experiment, 56 000 gal. of tap-water containing 290 lb. of uranine, forming a solution with a specific gravity of 1.003, was pumped from a pontoon through an 8-in. pipe, at a rate of about 2 320 gal. per min., or with a velocity of 14.8 ft. per sec., to a depth of approximately 40 ft., the pontoon and discharge pipe rising as the experiment progressed. The specific gravity of the harbor water was 1.015, and the velocity of its current, as observed by submerged floats, averaged: 0.45 ft. per sec. at a depth of 3 ft.; 1.03 ft. per sec. at a depth of 20 ft.; and 2.85 ft. per sec. at a depth of 50 ft.; from which the mean velocity at the point of discharge was taken as 2.2 ft. per sec.

In spite of these large volumes no evidence of the discharge was observed in either case, although it had been detected once before in one of the smaller experiments at this point and at the same depth. The inference was that diffusion occurred rapidly due to subsurface currents at the time of the larger experiment, and that the rise of sewage to the surface probably depends more on the velocity of such currents than on the volume of sewage discharged.

It is clear that salinity of a body of water receiving sewage is an important factor in its diffusion, as it also is in its oxidation, its effect on precipitation, its decomposition, its general appearance, and its accompanying odors. The sewage of the City of Washington, D. C., discharged in 30 ft. of fresh water in the Potomac River and that of Hamburg, Germany, discharged at a depth of 30 ft. in the Elbe, is difficult to discern at the surface, while that from the Boston and New York outlets forms a field on the surface that is often clearly visible, well defined, and extensive. It was noted in the New York experiments with dyes that the edge of the field on the windward side was most clearly defined, while the more rapid diffusion took place on the leeward side.

From what has been said it is evident that diffusion is promoted by locating inlets in deep water of low salinity, but having a high velocity of flow. Discharge should be horizontal and from multiple outlets. The submerged outlets from Deer Island in Boston Harbor, with fourteen horizontal orifices, and the one hundred and fifty outlets of the Passaic Valley Sewer, in which the upward-flowing stream is dissipated by spiral flanges, are excellent examples of effective diffusion and dilution of an effluent in salt water.

As the visibility of sewage fields in calm weather is largely due to the oily surface film known as "sleek", it is obvious that for the sake of appearance, oily wastes should be kept out of effluents so far as practicable: First, by

control and treatment at the source of industrial wastes of this nature; second, by providing municipal collection of crank-case wastes from garages; and, third, by installing skimming tanks on the line of outfall sewers. Other points that might be emphasized are the very great effect of turbulence of current on diffusion, and the variable effect of winds on the shape and extent of the sewage field.

Table 7\* shows how the sewage discharged at the Deer Island and Moon Island outlets in Boston Harbor concentrates near the surface, as indicated by the increasing salinity or percentage of sea water and saturation with dissolved oxygen with increasing depth.

R. F. GOUDEY,† ASSOC. M. AM. SOC. C. E. (by letter).—The authors are to be congratulated on their presentation of basic data derived from unique and ingenious experiments, which now definitely removes "judgment" as the sole factor to be considered in choosing sizes and lengths of ocean outfall sewers. Although the paper abounds in involved mathematical discussion, which most sanitary engineers shun, an impartial and critical analysis indicates the logic behind the important and significant conclusions which the authors have drawn from their experimental data.

Disposal of sewage and the degree of prior treatment required in connection with ocean disposal need particular study in Southern California, because of general unfavorable conditions, as compared with the Atlantic Coast. Instead of a Gulf Stream, with good currents relatively close to shore, as prevails along the Atlantic, California's main current, the Japan Current, runs more than 1 000 miles from shore. The littoral currents are wind-induced, low in velocity, variable in direction, and undependable for sewage disposal. The wind direction, likewise, is variable, due to changing from land to ocean breezes daily. For instance, during the night the land breezes prevail from north to east, and, finally, work around to the southeast in the early morning. With the overcoming of the land breezes by the ocean winds during the forenoon, the prevailing and strongest winds of the day come from the southwest. Toward evening, they veer toward the north, when the land breezes dominate. Except during stormy periods, when the winds are either from the north or southeast, this continual routine of "boxing the compass" accounts for the lack of uniformity in dependable shore currents. For these reasons, the authors are correct in using calm periods as critical.

A rather high standard of ocean disposal has naturally resulted in Southern California, as its coast line alternates with wide sandy beaches, which are ideal for bathing, and rocky bluffs, which are fast being utilized for picturesque home sites. Experiments to correlate bio-chemical oxygen demand, dissolved oxygen, and chlorides, with sewage fields, failed to establish a sensitive relationship or a law. Experience indicates that the sewage field loses its identity as badly discolored water at a *B. Coli* index of 10 per cu. cm., and this is the standard now used by sanitary engineers in California. It is believed to be a reasonably fair basis as compared to the accepted drinking water

\* Determinations by Dr. Payne B. Parsons, abstracted from the Report of the Metropolitan Sewerage Comm. of New York, 1912, Chapter III.

† San. Engr., Bureau of Water and Power, Los Angeles, Calif.

standard, considering relative quantities of water imbibed for drinking purposes, compared with that imbibed during bathing, nor does the figure differ from the *B. Coli* content common to natural streams having no unfavorable hygienic record. Adoption of less stringent standards, say, 50 *B. Coli* per cu. cm., which might safely be allowed during "slips", is not of much economic importance, because of the closeness of the two zones. Further requirements of ocean disposal dictate that there should be no odor in the vicinity of the outlet, nor sewage litter stranded alongshore.

In the earlier outfalls in Southern California, the length from shore was set arbitrarily, even in the case of large outfall sewers, such as that for Los Angeles. The lengths of the more recent outfall sewers have been gauged from the behavior of *B. Coli* fields of pollution determined from pre-existing outfalls. The outlets are generally made to discharge from up-turned ells lying on the ocean floor, in order to avoid their becoming clogged with shifting sand, and to prevent the transmission of water hammer.

Table 8 gives a few examples of long outfalls in California that have a vertical discharge.

The outfall is rather long, compared with those one would design by use of the formulas given by the authors.

For small communities, the ease of using pure and protected wrought-iron pipe as large as 18 in. in external diameter, has not caused any particular hardship, in achieving the lengths of outfalls actually used. Although the life of such outfalls may not be more than twenty-five years, for growing cities, they represent an easy way to obtain a serviceable outfall for a fairly long term of years.

TABLE 8.—LONG OUTFALLS WITH VERTICAL DISCHARGE.

\* Downward discharge.

In larger cities, the cost per foot has been as much as \$150, and, in some proposed projects, the cost has been variously estimated up to \$500 per ft. Obviously, any factors that may shorten the outfall, or establish its performance in advance, deserve analysis. Investigations to perfect ocean disposal

are quite as important as the efforts of inland communities to refine their high-grade treatment processes. Along recreational and residential shores, the ocean should not be regarded as a crude dumping ground for sewage.

There are certain factors not stressed in this paper which probably have quite a bearing on the performance of ocean disposal outlets. From the time sewage leaves the outlet until it reaches the surface, dilution and diffusion appear to yield an extremely rapid and extensive purification. The greater the oxygen content of the water, and, conversely, the less the oxygen demand of the sewage, the less will be the area of surface pollution. The quantity of dissolved oxygen in sea water varies according to the temperature of the water and the amount of vegetable life in it, which at certain times even causes supersaturation with oxygen of 5 or 10 per cent. The oxygen demand value of the sewage varies with its age and treatment. The behavior of outfalls discharging settled sewage is, in actual practice, much better than those discharging crude or screened sewage.

Added dilution would give lower ratios of dissolved oxygen in the sea water to the oxygen demand of the sewage. Furthermore, the degree of treatment given to the sewage is an important factor in the length of outfall sewer which will be required to keep the sewage-polluted field offshore. Further research into these phases is desirable.

Sludge deposits in the vicinity of outfalls exert high oxygen demand, and, consequently, must cripple seriously the capacity of the ocean to oxidize and dilute the sewage being discharged from the outlet. The apparently large area needed for dilution at the old Long Beach outfall could be easily explained by the high oxygen demand of the sludge, which cut down the dissolved oxygen in the sea water, limiting the organic matter that it would handle.

The authors noted a discrepancy in the actual and theoretical diameter of a rising column of sewage. It is conceivable that this may be occasioned either by the diffusion rate of salt in the sea water as it penetrates the sewage, or the swelling action may be caused by escaping dissolved gases in sewage, which at times might become as much as 20 parts per million expressed as oxygen, and might exert a material buoyant effect distorting the original line of travel. However, the ocean salt would increase dilution, and the sewage gas would shorten the time for initial dilution. There does not seem to be sufficient evidence to warrant a conclusion that the bacteria die in about 5 hours. In fact, there is evidence indicating that the time may vary from less than 1 hour to more than 5 hours. An excellent field of research would be the study of destruction of bacteria in ocean water, including such factors as temperature, oxygenation from dilution, sunlight, and time for various degrees of dilution.

The paper, as presented, has been a great help in extending knowledge on the behavior of ocean outfalls, because it places values on certain factors that heretofore were vague. For instance, in the matter of depth; even for small outfall sewers, Fig. 8 shows that 1 cu. ft. per sec. of sewage, if discharged at a depth of 30 ft., would travel horizontally, from a point above the outlet, 100 ft.; if discharged in 10 ft. of water, the distance of travel would

be 2 300 ft. This certainly has a considerable bearing on locating the outfall to obtain the minimum length for the greatest depth possible.

A second point is the desirability of discharging sewage from a horizontal outlet, at a greater velocity than would ordinarily be obtained. The length of outfall can be practically cut in half by obtaining reasonable velocities of discharge. It may be that, by pumping the sewage through a 15 or 20-ft. lift and discharging it through a nozzle, the capitalized cost of pumping would be far less than the cost of an outfall twice its length.

The desirability of multiple outlets is confirmed by these experiments. In the past there has been a debate among engineers as to whether multiple outlets are actually better than single outlets. Table 4 seems to afford conclusive proof of the desirability of multiple outlets. With high-velocity discharge, they would be relatively simple to add to many existing outlets that need better dilution and more satisfactory disposal.

WARREN E. HOWLAND,\* Esq. (by letter).—The writer would like to inquire whether the experiments from which Equation (17) was derived, were conducted as illustrated by Fig. 1. That is, was the spread of the field on the surface determined "by observing the time when the edge of the field passed fixed points along the edge of the raft and along a plank cantilevered over the water at right angles to that edge"?

If  $t$  in Equation (17) refers to the time required for the colored water to reach a distance,  $x$ , from the point of discharge, it seems to the writer that the formula and the equation derived from it:

$$V = \frac{\alpha}{x^{0.50}} \dots \dots \dots (37)$$

refer merely to conditions that occur when the fresh water is first discharged into the salt water rather than to conditions after the time when the flow may have become steady. Is not the condition of steady flow of greater interest than the transitory condition of initial flow? Might not the two conditions be entirely dissimilar?

The authors describe a series of observations made at Long Beach, Calif. They state that a rough check on the thickness of the field was made by "observing the time required for chips of wood to float past fixed points in one direction from the outlet". Presumably, the condition studied was more nearly that of steady flow. From these observations they conclude that:

$$V = \frac{\alpha}{x^{0.58}} \dots \dots \dots (38)$$

In this case, the exponent of  $x$  is 0.58 instead of 0.50 as in Equation (37). Is this to be considered as a reasonable check, or does the difference between the two values represent an actual difference between steady flow and initial conditions, or are the experiments that lead to the two equations entirely incomparable?

The authors have not made themselves entirely clear as to the method used in computing the extent of the sewage field in the case of current flow. In the example given to illustrate Case 1, they find that in quiet water the sewage

\* Asst. Engr., State Dept. of Health, Hartford, Conn.

would travel 12 000 ft. before attaining a dilution of 225; but the time required to travel this distance would be 24.5 hours. In the case of current flow, the original point in the water, hypothetically, is then 44 500 ft. away from the new point where sewage is entering. Is it to be supposed that the dilutions and the relative velocities at corresponding distances from the point in the water where the sewage originally entered are the same as they would be if the sewage were still coming in at this original point?

Apparently, the authors made this assumption when they added 12 000 and 44 500 to obtain  $e = 56\,000$  ft., which is given as the total distance traveled by the sewage, presumably to attain a dilution of 225. This value of  $e$  is further corrected to 13 150 to conform to the hypothetical conditions as stated, but the alteration suggested does not seem to correct the error of the original assumption.

To state the question differently: Is not the case of sewage inflow into a moving current somewhat similar to the discharge of fresh water from a slowly moving boat? In the latter case a narrow band of brackish water is left behind and it immediately spreads sidewise, mixing with the salt water. The water at each point in the center of the spreading band is continually attaining a greater dilution by mixing as well as by actual removal of the fresh water once present. The writer believes that the contours of equal dilution, under such conditions, would be narrow ellipses or, perhaps, egg-shaped figures, but the dimensions might be difficult to compute.

The paper is of interest to sanitary engineers in Connecticut in their work of guarding health at bathing beaches.

HARRISON P. EDDY,\* M. AM. SOC. C. E. (by letter).—It seems rather unfortunate that the authors chose the conditions surrounding the Deer Island Sewer Outlet in Boston Harbor to assist in corroborating their theory on pre-determining the extent of a sewage field in sea water; they were evidently misinformed as to the design features of the outfall itself. The data to which they have applied their theory are in error in two respects: The depth of outlet, which they call 30 ft., and the size of outlet, which they call 18 by 30 in.

The sewage is discharged from fourteen outlet openings increasing in size toward the outer end.† The diameters of these openings, which are approximately elliptical (with the exception of the outermost, which is a 48-in. circle), vary from 25 by 44 in. to 13 by 23 in., respectively. The mean area of the fourteen openings is, therefore, 640 sq. in., instead of 540 sq. in., as assumed by the authors.

From plans of the Metropolitan Water and Sewerage Board it is found that six of the outlets are at a depth of about 50 ft. below mean low water, while the other eight openings range in depth from 30 to 46 ft., with an average depth of 38 ft. Thus, the mean depth of the fourteen outlets is 43 ft. below mean low water, instead of 30 ft.

Had the authors used the correct values for depth and area of outlet, their statements in regard to the application of the formulas to the Deer Island Outfall would probably have read as follows: The length of path should be

\* Cons. Engr. (Metcalf & Eddy), Boston, Mass.

† "The Metropolitan Sewerage Works," by R. W. Loud, *Journal*, Boston Soc. of Civ. Engrs., October 8, 1923, p. 325.

52 ft., and  $S_0 = 42$ , theoretically. For  $x = 300$ ,  $S = 262$ ; and for  $S = 212$ ,  $x = 195$ ; and the field area is 2.7 acres, or 0.025 acre per sec.-ft. If the observed value ( $S_0 = 21$ ) of the initial dilution is used, the field limit at  $S = 212$  is found to be at  $x = 783$  ft. and the area, 44 acres.

These results differ radically from those which were obtained by the authors and which were deemed to corroborate their theory. The initial dilution obtained by applying the formulas to the corrected data is twice that of the observed initial dilution, and the equations, therefore, are decidedly not on the safe side in this instance. However, it may well be that the authors' Equations (1) to (35) are not applicable to such a complicated outfall, in which the outlet openings are of various sizes and are located at different depths.

In order to compare the results obtained by observation with those to be expected from an application of the authors' theory, a study has been made of some tests at the Nut Island Sewer Outlet in Boston Harbor.\* This outfall consists of two 60-in. pipes discharging vertically, but at the time of the tests only one outlet was in use.

In order to determine the degree of dilution that takes place and the condition of the sea water before the sewage reaches the surface, several samples of water were taken immediately over the outlet in use on October 14, 1915. Samples were collected at the same time in the line in which sewage was flowing from the outlet and at various distances therefrom, as well as samples of harbor water from points outside the path of sewage from the outlet. The tests were made when the rate of discharge was approximately 1 380 000 gal. per hour, and when the depth of water over the outlet was about 30 ft.

Observed dilutions have been derived from the free ammonia content of samples collected at various points. For example, the initial dilution ( $S_0$ ) is obtained from the free ammonia content of the sewage (17.600 parts per million), the surface of the harbor above the outlet (1.753 parts per million), and the harbor water outside the path of sewage from the outlet (0.120 part per million). From these figures,  $S_0 = 11$ . In a similar way, the dilution near the outer limit of the sewage field, at a point 1 400 ft. from the outlet, where the free ammonia content of the water was 0.330 part per million, has been found to be 83.

The velocity of the ocean current has been estimated from the time (1.37 hours) required for floats to travel from a point 1 400 ft. from the outlet to 3 500 ft., because the limit of the sewage field, as determined by observation and analysis, seemed to be approximately 1 400 ft. from the outlet. Within the sewage field, floats of course would be influenced by the dispersion of the sewage over the harbor surface.

Table 9 gives a comparison of the results obtained by computation, using Equations (1) to (35), with those obtained by chemical analysis and observation at the Nut Island Outfall.

In the case of the Nut Island Outfall the authors' formulas yield results well on the side of safety, except for  $t$ . In the latter instance the computed value checks fairly closely with the observed value.

\* Rept. of the Mass. Dept. of Health, 1915, p. 347.

TABLE 9.—COMPARISON OF COMPUTED AND OBSERVED VALUES.

Factors.	Computed value.	Observed value.
Initial dilution, $S_0$ .....	5	11
Time of travel, $t$ , in hours, from head of rising column to edge of field..	2.0	1.5
Distance, $e$ , that sewage will travel with current, in feet.....	4 810	1 400

Another comparison between results obtained by observation and by the use of the authors' formulas is afforded by tests made by the State Department of Health at the sewer outlet of New Bedford, Mass., on August 9 and September 24, 1915.\* The New Bedford Outfall,† which has a diameter of 60 in., discharges vertically through a single outlet at a depth of 30 ft. below low-water mark. The quantity of sewage flowing through the outlet at the time of the tests is not definitely known, but a flow of 100 gal. per capita per day has been assumed for the total population of the city in 1915 (109 568). The observed initial dilution has again been derived from free ammonia content, the determinations used, being as follows:

	Free ammonia, in parts per million.
Sewage .....	18.202
Sea water above outfall:	
August 9, 1915.....	1.276
September 24, 1915.....	0.207
Sea water outside area affected by sewage:	
August 9, 1915.....	0.110
September 24, 1915.....	0.044

When applied to the data given for the New Bedford Outfall, Equations (1) to (35) yield a value of  $S_0 = 9$ , while the values of  $S_0$  derived from free ammonia content are 15 for August 9 and 111 for September 24. Here, again, the result obtained by the formulas is well on the side of safety. In fact, if the conditions found at the New Bedford Outlet on September 24 are at all usual, the authors' formulas would have been practically useless. On the other hand, it will be observed from the two tests cited that there is a wide variation in the value of the initial dilution above the New Bedford Outlet at different times, and many similar tests would have to be made before definite conclusions could be reached as to a fair average value of the observed initial dilution.

From the foregoing it is evident that caution must be exercised in using formulas for predetermining the extent of a sewage field in sea water, although they may well be used as guides to judgment.

A. M. RAWN‡ and H. K. PALMER,§ MEMBERS, AM. SOC. C. E. (by letter).—  
The writers acknowledge with thanks the discussions of their paper. Some

\* Rept., Mass. Dept. of Health, 1915.

§ Chf. Draftsman, Los Angeles County Sanitation Dists., Los Angeles, Calif.

of these discussions require no comment other than to state that they are helpful in pointing out the limitations to be set about the formulas and that they contribute additional information supplementing the original investigation or allied to it.

Mr. Howland raises a question regarding the time factor used in developing the formula for spread of the sewage field. The writers state that the time used was that of the initial spread. It was found that the edge of the field advanced with the same relative velocity as that of the continuing field; that is, the velocity of flow past a given point on the raft or plank was reasonably constant for constant conditions. So long as the field thickness remains constant, which observations indicate to be true, this would necessarily be so.

It is quite impossible to obtain a series of observations yielding consistent values of the exponent of  $x$  in the equation,

$$V = \frac{F}{x^n} \dots \dots \dots (39)$$

because the forces causing the spread of the field are small and slight disturbances materially affect the velocities.

Fig. 9 shows a series of four sets of curves drawn by assuming a field to be spreading in concentric circles of equal dilution in absolutely still water. They are drawn with the same value of  $C$  for all functions. This emphasizes clearly the effect of the exponents. In actual cases these lines would not intersect at one point, but would be parallel to the lines shown. At any distance,  $x$ , from the center the quantity of diluted water passing the ring would be  $QS$ , and the velocity would be as given by Equation (19). Combining constants, this equation becomes:

$$V = C \frac{S}{x} \dots \dots \dots (40)$$

which involves three variables and is indeterminate unless assumptions are made.

Kinetic energy is proportional to the quantity and the square of the velocity and by properly combining all constants an equation may be written:

$$KE = C_1 S V^2 \dots \dots \dots (41)$$

A new variable is introduced in Equation (41) and the equation remains indeterminate. By making further assumptions, certain permissible values may be shown.

*Case 1.*—Assume that  $V$  is constant (see Fig. 9 (a)); then:

$$KE = C_2 x \dots \dots \dots (42)$$

and,

$$S = C_3 x \dots \dots \dots (43)$$

in which,  $x$  equals the horizontal distance from the center of the rising column at the surface to any point in the field. According to Equation (42), kinetic energy increases with distance, which is an impossible situation as there is no source of energy.

Case 2.—Assume that the kinetic energy is constant (see Fig. 9 (b));  
then:

$$S = C_4 x^{\frac{2}{3}} \dots \dots \dots (44)$$

and,

$$V = \frac{C_5}{3\sqrt{x}} \dots \dots \dots (45)$$

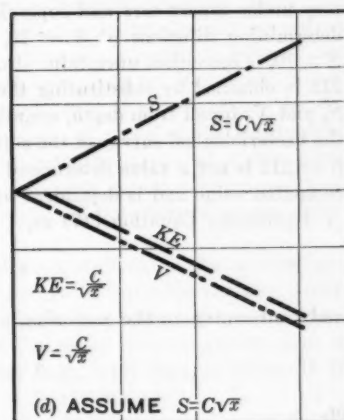

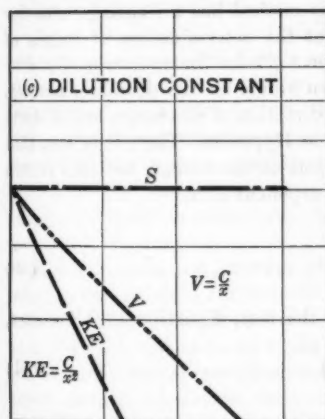

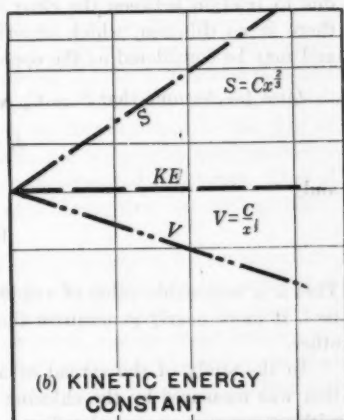

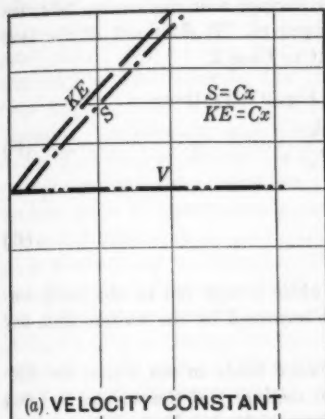

FIG. 9.—CURVES OF DILUTION, VELOCITY, AND KINETIC ENERGY.

This is an ideal condition in which there would be no loss of energy. It constitutes the upper limit for the velocity and the exponent of  $x$  lies somewhere between 0.33 for the second assumption, and 1.00 for the third assumption.

Case 3.—Assume that the dilution is constant (see Fig. 9 (c)); then:

$$K E = \frac{C_6}{x^2} \dots \dots \dots (46)$$

and,

$$V = \frac{C_7}{x} \dots \dots \dots (47)$$

In this instance, the kinetic energy decreases rapidly as might be expected, due to friction between the clear sea-water surface and the sewage field; but there is no dilution, which experiment disproves. It does not fit the facts and may be considered as the opposite limit to Case 2.

Case 4.—Assume that  $S = C_8 \sqrt{x}$  (see Fig. 9 (d)); then:

$$K E = \frac{C_9}{\sqrt{x}} \dots \dots \dots (48)$$

and,

$$V = \frac{C_{10}}{\sqrt{x}} \dots \dots \dots (49)$$

This is a reasonable value of velocity, and while it may not be absolutely correct, it more nearly generalizes the facts determined by the writers than any other.

In the study of the spread of actual sewage fields in sea water, the dilution was measured by the chlorine titration method and the writers feel that without extreme care and refinement, such as might be obtained in a laboratory under expert care and supervision, this method has a limiting value for determining dilutions of  $S = 75$ , and that the determination of values of  $S > 40$ , is somewhat uncertain. In Equation (22) the limiting value for  $S = 212$  is obtained by substituting three known values in the equation, namely,  $S_0$  and  $X_0$  found from depth, quantity, and direction of discharge, and  $X$  from the bacteriological survey of the actual field at Hyperion. Thus, it is seen that  $S = 212$  is not a value determined by analysis of the sewage, but that it is a computed value and is dependent upon the exponent of  $x$ .

Expressing Equation (17) as,

$$t = \frac{1}{n F} X^n \dots \dots \dots (50)$$

and conforming to the reasoning given in the text, Equation (22) becomes,

$$S = S_0 \left( \frac{x}{X_0} \right)^{2n} \dots \dots \dots (51)$$

or,

$$x = X_0 \left( \frac{S}{S_0} \right)^{\frac{1}{2-n}} \dots \dots \dots (52)$$

Stating the value of  $n$  equal to 1.5, as in the text, this becomes,

$$x = X_0 \left( \frac{S}{S_0} \right)^2 \dots \dots \dots (53)$$

but if  $n = 1.6$  then,

$$x = X_0 \left( \frac{S}{S_0} \right)^{2.5} \dots\dots\dots (54)$$

Again referring to the computed field at Hyperion, by use of Equation (22) the field is found to have a limiting value of  $S = 212$ . Had the exponent, 0.417 (corresponding to the value of  $n = 1.583$ ), been used instead of 0.50, the value of  $S$  expressed by Equation (22) would be 135. The value,  $S = 212$ , was attained by assuming  $S_0$  equals 14, and, as long as the value of  $S_0$  is nearly this, it can be seen that it makes little difference whether the exponent 0.417 or 0.50 is used. For larger values of  $S_0$  the  $x$  distance obtained from the use of the smaller exponent will be less than that if 0.50 is used. Therefore, the formulas and diagrams given in the text err on the side of safety, if at all, and the writers feel that their use is justified until extensive experiments offer the substitution of other coefficients and exponents. One of the best series of measurements, using nineteen floats, gave an average equation of  $t = 0.097x^{1.53}$ .

In determining the behavior of a sewage field influenced by an ocean current, the writers have assumed that dilution is due to the relative motions of that field and the underlying moving salt water; and that in the process of initial dilution or during the rise of the sewage to the sea-water surface the surrounding sea water will impart enough of its motion to the sewage so that the horizontal component of the rising cone just below the ocean surface will equal the velocity of the ocean current.

Mr. Eddy has pointed out the erroneous assumptions made as to the design of the Deer Island Outfall. The writers acknowledge the correction and since receiving Mr. Eddy's notes have procured a complete copy of the plans of this Outfall, as well as the descriptive paper by Mr. R. W. Loud. Despite the fact that the writers were materially in error regarding this design, their statements relating to the probable distance of travel of the sewage field are not greatly in error. In his analysis of the Outlet in operation, Mr. Eddy has incorrectly made assumptions as to the probable initial dilution and final distance of travel in calm water, having overlooked the effect of mutual interference of the jets.

Fig. 10 shows the probable pattern of cross-sections of the sewage jets, taken at the sea-water surface and at 15 ft. and 30 ft. below the surface. Interference between the jets begins to occur 30 ft. below the sea-water surface (see Fig. 11) and there is really more of the rising column surface area in contact with the surrounding water at the 30-ft. level than at either 15 ft. below, or as the combined rising columns reach the surface.

By the time the sewage reaches the surface it is substantially one flat jet (see Fig. 10(a)), and while the experiments and observations from which the formulas were derived, were not carried sufficiently far to assure an accurate determination of the value of  $S_0$  for this particular case, there follows from the formula a relationship between the area of the rising column exposed to the surrounding sea water and the value of  $S_0$  at the surface. Taking into account the merging of the columns approximately 30 ft. below the salt-water surface, and the decreased periphery at about this elevation (see Table 10) the writers

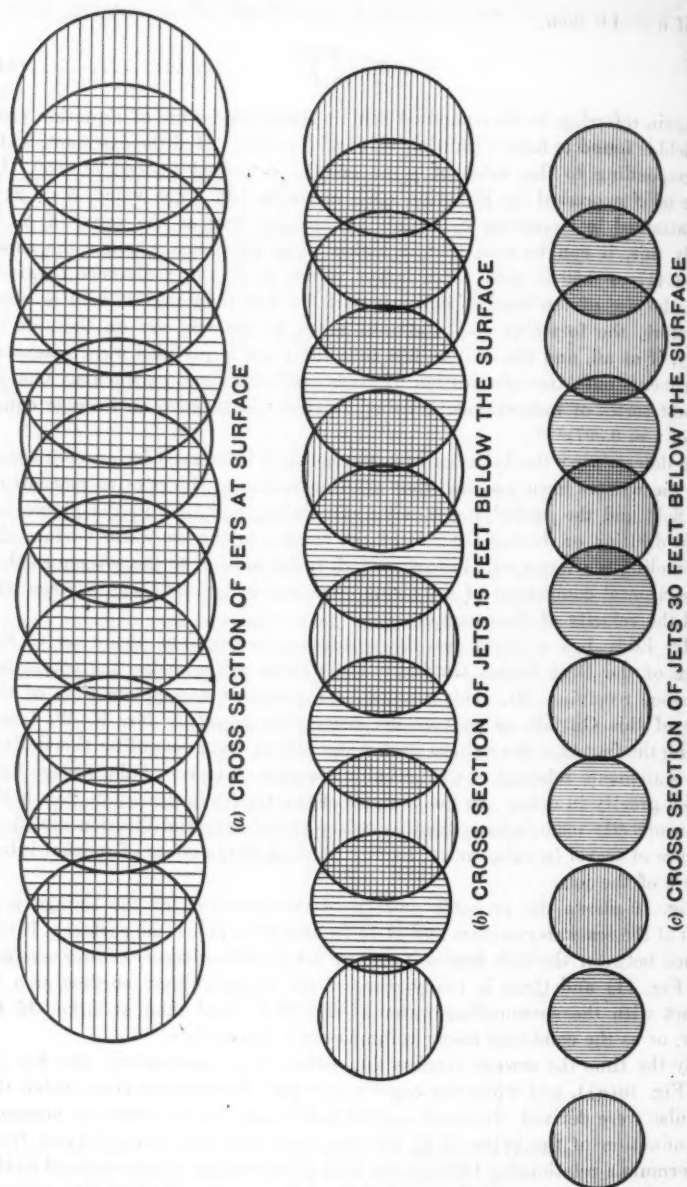

FIG. 10.—HORIZONTAL CROSS-SECTIONS OF JETS SHOWING PROPANE BEHAVIOR OF 116 CUBIC FEET PER SECOND OF SEWAGE ISSUING FROM DEEP ISLAND OUTLET DURING ITS INITIAL DILUTION.

would state that the probable value for  $S_0$  under conditions of flow as indicated by Figs. 10 and 11 is 25 as compared to 21 used by the writers and 42 by Mr. Eddy.

TABLE 10.—COMPARISON OF ACTUAL WITH THEORETICAL PERIPHERY.

Actual periphery, in feet. (1)	Theoretical periphery, in feet. (2)	Ratio, Column (1) Column (2). (3)	Remarks. (4)
255	664	0.37	Cross-section of jets at surface.
230	531	0.44	Cross-section of jets 15 ft. below surface.
256	354	0.73	Cross-section of jets 30 ft. below surface.

Analysis of the Deer Island Outlet indicates that 116 cu. ft. per sec. will not flow from fourteen outlets, but only the first eleven as illustrated in Fig. 11. This is also indicated in Mr. Loud's paper,\* which describes an examination made in 1922, when a considerable deposit was found in the outer part of the discharge pipe, and one of the discharge openings was seen to be entirely choked with grease. An analysis of the hydraulics of the Outlet with especial reference to the value of the salt-water equivalent, will disclose why probably only eleven outlets will function under a flow of 116 cu. ft. per sec.

Table 11 is an analysis of the values of  $S_0$  and  $S$  obtained at the Nut Island Outfall, as indicated by the ammonia and chlorine content of the samples. The table is included because of reference in Mr. Eddy's comments. It illustrates clearly the difficulties attending the study of the spread of the field, as well as of obtaining accurate samples for computation of the value of  $S_0$ . The progressive dilution in the field is erratic by either test, the chlorine content analysis seemingly giving the better results. The float velocities noted, are quite contradictory unless currents not noted by the observers were present, in that the velocity of 120 ft. per hour is obtained near the outlet where the combined velocities of sewage and bay current would be present, and 4 000 ft. per hour near the outer edge of the field where only the bay currents should be appreciable.

It is likely that, with the numerous conflicting currents in Boston Harbor, the Nut Island sewage field cannot be used to corroborate the formula for the spread of the field in calm water or where pronounced and unvarying known ocean currents are present.

The writers' experiences in obtaining samples for values of  $S_0$  lead them to believe that the discrepancy between the observed and calculated values of this factor in Table 11, may be the result of obtaining samples at or near a ring of turbulence, surrounding the column head. This ring is indicated by a standing wave and at it the sewage undergoes a high increase in dilution; so that samples taken in or immediately outside the ring will yield erratic results.

The writers experienced great difficulty in obtaining samples directly from the head of the rising columns of sewage outlets in operation, principally because of the difficulty of rowing a boat into the column head. It is espe-

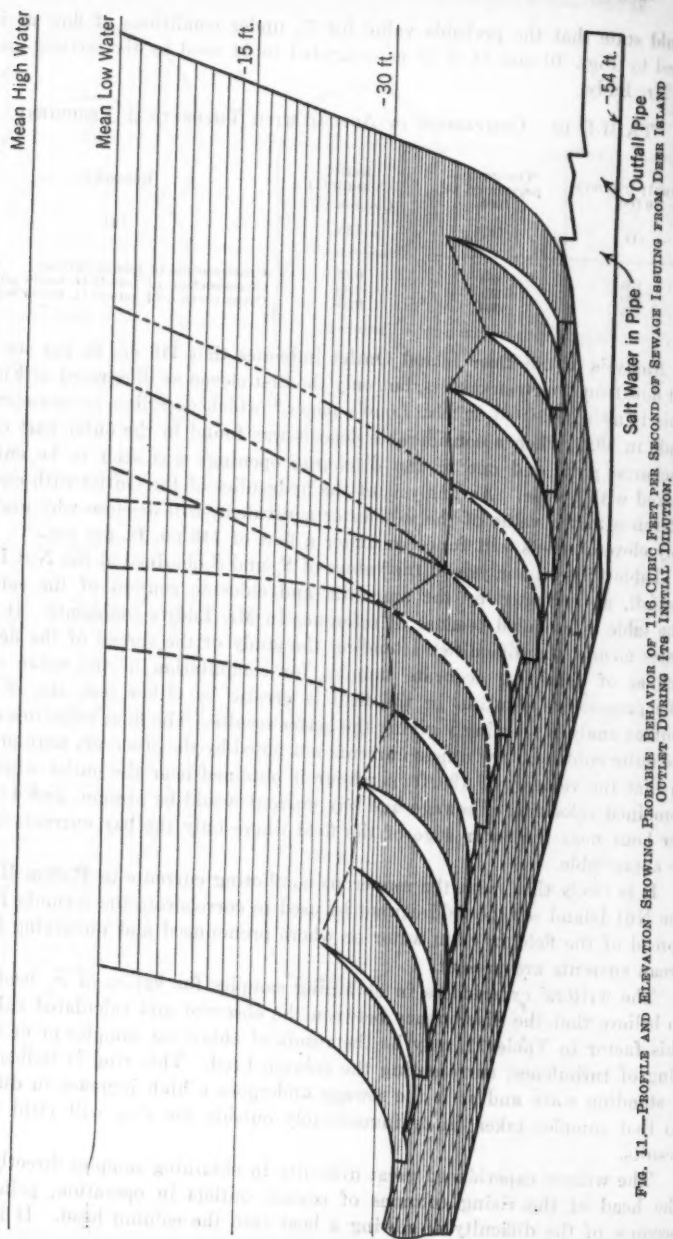

FIG. 11.—PROFILE AND ELEVATION SHOWING PROBABLE BEHAVIOR OF 116 CUBIC FEET PER SECOND OF SEWAGE ISSUING FROM DEER ISLAND OUTLET DURING ITS INITIAL DILUTION.

cially difficult to cross the ring of turbulence surrounding the column head. It is still more difficult to obtain samples from the rising column below the sea surface, and it is quite possible, even approaching a probability, to obtain specimens from either location that are extremely erratic, even if carefully taken. The rising column of sewage is not a homogeneous mass of sewage and sea water until it has moved at least a short distance from the column head. Fully 10% of all the samples taken in the experiments with small controlled outlets, was discarded by the writers as being too erratic for use.

Mr. Eddy refers to two tests at New Bedford, Mass., on August 9 and September 24, 1915. Depending upon the position of the tide, the theoretical value of  $S_0$  with a flow of 17 cu. ft. per sec. would vary between 9 and 15. The test of August 9 gives a value of  $S_0 = 15$  and that on September 24,  $S_0 = 111$ . The test of September 24 is probably the result of obtaining an extremely dilute portion of the cone which, as has been stated, is not a homogeneous mass at the time it reaches the surface. A long series of observations of this value at the New Bedford Outlet would probably disclose a great many instances departing radically from the calculated value.

Mr. Fuller's description of the operation of the diffusers on the Passaic Valley Outlet and Mr. Goudey's comments on sewage from high velocity outlets, are in line with the writers' idea of the proper design for ocean outlets. Care, however, should always be taken to prevent mutual interference of rising columns, the tendency of which must be to decrease the extremely important factor of initial dilution.

To Mr. Allen's comment upon the limitations to be set about the formula, the writers wish to add that the formulas are useless, or nearly so, unless all the factors influencing the rise and spread of the sewage field are carefully predetermined.

Paper No. 1751

### MEASURING MATERIALS FOR CONCRETE\*

BY WILLIAM MAYO VENABLE,† M. AM. SOC. C. E.

#### SYNOPSIS

The paper deals with those variations in workability, strength, and solidity of concrete from batch to batch, which result from unavoidable variations in the water content and gradations of the aggregates as received for use. It considers especially how the different methods of measuring the ingredients tend to increase or to reduce the difficulties of securing uniform results.

The bulking of samples of sand from twenty-two localities when measured by different methods was determined experimentally in order to ascertain the best method of measuring. Briquettes were made with all these sands, using different proportions of cement and water, in order to ascertain how the method of measurement affected the uniformity of the results. Both the strength and the solidity of these briquettes were determined.

Interesting results of these tests are here discussed, including the function and practical control of the mixing water. It is shown that the chief function of the mixing water is to make it possible to pack the other ingredients of the concrete in the least possible space; and that when the quantities of cement, sand, and stone to be used in any batch have been determined, such a quantity of water should be used as will make it possible to compact the mix into the smallest volume.

#### EFFECT OF WATER

Mixing of concrete has been thoroughly discussed, and the basic principles are well understood, although there remain differences of opinion as to the best procedure in applying these principles in design. However, a design depends on the properties of the materials to be used; and the greatest difficulties in the design of concrete arise from uncertainties regarding these properties.

\* Published in August, 1929, *Proceedings*.

† Mgr., Development Dept., Blaw-Knox Co., Blawnox, Pa.

Concrete ready to place consists of a mechanical mixture of at least four different materials—stone or coarse aggregate, sand or fine aggregate, cement, and water. For a definite combination of perfectly dry materials and a little water only, the mixture cannot be compacted as much as when thoroughly dry. The bulk increases not because of the volume of the water, but because the water films on the grains prevent them from rolling or slipping on one another. This "bulking" at first increases with the quantity of water, until there is sufficient water to begin to lubricate the particles instead of to bind them. Thereafter an increase in water makes it possible to compact the mass more with certain mixes than can be done, even by pressure, with a perfectly dry batch. Then the voids between the grains are completely filled with water. If any more water is used, the bulk is increased accordingly.

If the quantities are measured out separately, and the fineness or the void spaces, or both, in any one of the three materials varies somewhat from batch to batch, the optimum quantity of water for maximum compactness will likewise vary. In practice it is impossible to procure stone and sand that do not vary and, consequently, there is always an element of uncertainty as to the mix. It is desirable, therefore, that the measuring methods be such as to compensate, as far as possible, for variations in the physical properties of the materials as received on the work, so that the resulting mixture has a minimum of void space to be filled by water, and has enough water—but no more than enough—to insure "workability". Such methods of measurement are available.

Most of the water used in mixing concrete is necessary only to lubricate the mass. Sometimes only 20% is required for chemical purposes, the other 80% remaining after the concrete hardens, until finally it dries out and is replaced by air. On ordinary poured concrete work, it is desirable to use only enough extra water to give maximum compaction.

#### CONCEPTS OF CONCRETE

Thus, the final mixture of stone, sand, cement, and water, may be considered in several different ways, as follows:

- (a) A mixture of "total dry materials" with water. This does not indicate directly a desirable method of measuring each of the ingredients separately.
- (b) A mixture of "combined aggregate" (sand and stone) with cement grout. This usually occurs first to the practical man when he attempts to interpret the water-cement ratio theory, and has not yet grasped the importance of the other materials which enter into the mix. The strength of concrete is not approximately the same as the strength of grout of the same water-cement ratio.
- (c) A mixture of "coarse aggregate" (stone) with cement mortar. Usually, experience leads to the adoption of Method (c).

#### BULKING AND SEGREGATION

Whenever granular materials are mixed with water, two phenomena may be observed, their relative importance depending on the quantity of water used, and the conditions of placing or of compacting the mix. These are (1) bulking, and (2) segregation, due to the settling or moving of large particles faster than small ones when there is too much water.

For stone, the bulking due to dampness is negligible. For sand, it varies with the fineness and other physical properties and with the water content, sometimes amounting to 15% for relatively coarse sand, or to 50% for a very fine sand. The moisture content for maximum bulking varies between 3% and 12% of the weight of the sand. Cement behaves like very fine sand, and bulks much more than 50% with small percentages of water; but this is negligible since cement is always measured dry, usually by weighing. Sand, however, as received on the work, almost always is moist or wet, the variation seriously affecting its practical measurement.

Segregation and its effects are best shown by simple experiments. In a glass tube, say, 1½ in. in diameter and 4 ft. long, pour dry sand to a depth of about 3 in. Empty it out, fill the tube with water, and pour the sand back. The larger grains will settle faster than the smaller and the sand will reach a greater depth than in the dry.

If the same experiment is performed with cement, a similar result will be observed, except that perhaps several hours will be required for the smallest particles to settle. The cement should be mixed with some water before the final pouring, to insure that the fine and coarse grains are completely separated before settling. Allow the settled cement to harden, for a day, then remove and examine it. It will have practically no strength, the top forming merely a "mud", called "laitance", and the bottom part being soft and brittle.

Something like this occurs in mortar when an excess of water is used, but the segregation of the cement is not nearly as complete, because the distance that each particle must settle is small. A mixture of 1 volume of cement to 1.2 volumes of water makes an utterly worthless "neat" cement briquette, but a similar water-cement ratio in concrete gives considerable strength, although such a mixture is by no means recommended.

The plain fact is that to secure workability much more water is required to compact the sand and cement than to compact the cement alone. Neat cement is quite "workable" with 40% of its bulk of water, but between twice and three times this quantity is commonly required to "work" a mixture with sand and stone added.

Tamping or jarring, if it is to improve the concrete at all, does so by loosening the ingredients from positions where points rest against surfaces into positions where surfaces are in contact. It is desirable that all surplus water and air escape, leaving the grains packed together as tightly as possible, provided the water does not carry with it any cement, or cause partial segregation of the fine particles of cement from the coarse particles in the mixture. Obviously, the amount of such segregation or washing out increases with the quantity of water removed; therefore, it is desirable to use the minimum water to secure the initial condition of workability necessary for compacting the concrete. Even then the mass may not be plastic. It is only plastic when the various grains are surrounded by enough water to permit them to roll on one another without excessive surface friction.

#### CONSTANT MORTAR

In short, although water is necessary for workability, any excess is injurious: First, because it increases the volume; and, second, because it

causes segregation of the cement. Concrete usually, although not always, is placed under conditions which render it very difficult to remove surplus water without injurious segregation. Therefore, the practical problem is how to assure the use of only the necessary quantity of water in each batch. This is really much more important than that any one material shall be kept constant in quantity, although in every respect successive batches should be as nearly alike as possible.

In making concrete, the general practice is to measure separately four materials, water, cement, sand, and stone, and to mix them. The man doing the measuring must set each measuring device to secure the correct final result. Frequently, this is difficult and it is desirable to specify the mixture in such a way that practical measurements are simple. The chief practical difficulties, with which the specifications may not have been concerned, are:

- (a) Moisture already in the sand must either be eliminated or allowed for in measuring. This may vary excessively from batch to batch.
- (b) The coarse aggregate may not be uniform, and, consequently, the proportion of sand to stone desired in a batch may vary. As compared with these difficulties, other problems of measurement are of minor importance.

The easiest way to overcome these difficulties practically, aside from any theoretical considerations which influence the design of the mix, is to conduct the measurement so as to produce a constant volume of uniform mortar for each batch. Then if and when necessary, the quantity of stone used therewith can be varied. Constant mortar is necessary for constant concrete, regardless of what the strength or other properties of that concrete are to be.

#### SANDS AND THEIR DIFFERENCES

Sands commercially available for concrete work differ exceedingly in the matter of fineness and grading of particles. For the purpose of ascertaining how the physical properties affect the accuracy of various methods of measurement, the writer procured samples of commercial sands from different parts of the United States, and tested them in different ways. The sieve tests (Table 1) were conducted as follows: First, after thoroughly drying, 100 cu. cm. of each sample was measured, by pouring into a graduate, without shaking or otherwise compacting, and was weighed (Table 1, Column (3)). It was then separated by sieving, the various grades (beginning with the finest) being poured back into the graduate and the total volumes read (Columns (4) to (10)). Thus, of Sample No. 18, originally 100 cu. cm., 1.0 cu. cm. passed the finest sieve (100-mesh); 14.5 cu. cm. were retained on the next coarser sieve (48-mesh) which poured into the graduate gave a total reading of 15.5 cu. cm. The final reading was 103 cu. cm., showing that, by screening, this sand increased in volume 3 per cent.

This increase takes place with all natural sands, but differs greatly among the samples (Table 1). This is due, in large part, to differences in the shape, as well as in the size of the grains, the Pittsburgh sand with 3% increase having rounded grains, and the Boston sand with 25% increase having grains of irregular figures with sharp edges and corners.

The differences in the relative proportions of fine grains in natural sands is shown graphically for some of the samples, in Fig. 1. Although the average diameter of grains in Sample No. 6 (Table 1) is about eight times that in

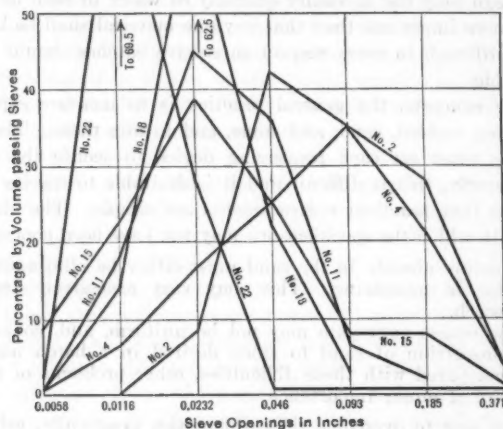

FIG. 1.—VARIATION IN SAND GRADINGS.

Sample No. 22, both are satisfactory for concrete. Evidently, the fineness sieve test alone, gives insufficient information to compare the suitability of various sands for concrete mortar.

The amount that sand "bulks" when moistened depends on the degree of moistness and the fineness of the sand; the finer the sand, the greater the bulking. A good idea of the extent of this bulking may be gained from Fig. 2.\* The sieve analyses corresponding are given in Table 2. The Allegheny

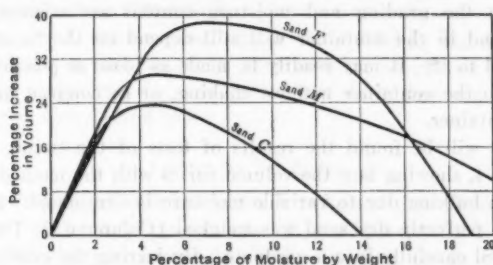

FIG. 2.—CURVES SHOWING THE BULKING OF THREE DIFFERENT SANDS DUE TO VARIOUS PERCENTAGES OF MOISTURE.

River sand, Curve M, is the same as Sample No. 18 in Table 1. As moisture was added the bulking effect on this Pittsburgh sand increased rapidly, reaching a maximum of 27% for 4% of water. Thus, to get the equivalent of 1 cu. ft. of dry sand requires a measuring box of 1.27 cu. ft. capacity if the sand has 4% moisture, and is measured loose. Where sand is taken from open stock piles, using volume measurement and allowing for bulking, it is generally practicable to get the specified quantity in a batch, without variation of more than 5 per cent. If, however, some of the batches are very wet or very dry, and the others moderately wet, as in a pit or bin, the variation may amount to more than 15% in the Pittsburgh District.

#### SATURATED SAND

However the measurement is made, great accuracy in each batch can be expected only if the moisture content is kept uniform, batch after batch.

\* "The Bulking of Moist Sands: Effect of Phenomenon on Strength and Yield of Concrete," by Arthur A. Levison, *Public Roads*, July, 1924, Vol. 5, No. 5, p. 21.

There are two attainable conditions of uniformity. One is to use perfectly dry sand; in actual work this can be attained only by artificial drying, which is expensive. The other is to have the sand saturated with water, or to measure it under water.

Even when the grading and moisture content are constant, the total quantity of sand in the container will still depend on the tamping or compacting applied to it. It may readily be made as loose as possible, by simply pouring it into the container without shaking, or as compact as possible by jarring the container.

In Table 3 will be found the results of tests of the twenty-two samples listed in Table 1, showing how the volume varies with the method of measurement when the bulking due to variable moisture is eliminated. In each case, 100 cu. cm. of perfectly dry sand was weighed (Column (2), Table 3). The sand was poured carefully into a graduate. By jarring the graduate the sand could be compacted to the volume given in Column (3), but no more. Pouring the same sand into another 100-cu. cm. graduate, half full of water, caused it to assume the volume given in Column (4), and rapping the graduate with the submerged sand caused it to compact to the volume given in Column (5). If the sand were poured suddenly into a very deep tube, filled with water, the larger grains settled first and the final volume was that given in Column (6).

TABLE 3.—VARIATION OF SAND VOLUMES AND VOIDS BY DIFFERENT MEASUREMENTS.

22	146.8	95.0	108.0	90.0	112.8	58.0	42.0	38.9	46.3	35.7	48.7	0.771

Each of these five different conditions of measurement will give consistent results. That by measuring the sand loose, but completely saturated with water (Column (4)), is the simplest in practice, the measurements being reproducible on a commercial scale to within 0.5%, batch after batch, with the commercial sand used in Pittsburgh.

The net volume of sand grains only, as determined by the water displaced (Column (7)), shows that the voids vary between 30 and 44 per cent. By segregation the grains may be arranged so that more than one-half the space is void (Samples Nos. 14 and 15).

#### GROUT TO BE ADDED

Now suppose that just sufficient grout is to be added to fill the voids in the sand; at once the question would arise: In what way shall the voids be measured? Will the percentages in Table 3 suffice, or do these correctly represent the quantity of grout to be used? The smallest voids (when the sand is most compact) are indicated in Columns (9) and (11), and the voids of loose measurement in Columns (8) and (10). Are the voids increased beyond both these amounts when grout is added and, if so, to what extent? Without the answer to this question no determination of voids will show how much cement and water will be required to fill them properly.

Grout is not a simple liquid, but a liquid with solid grains in suspension. The amount required to "fill" the voids depends not on the voids in the sand, as measured by the water test, as much as on the volume of cement already mixed with the water to form the grout. When grout—or even dry cement—is mixed with sand, some of the particles of cement (with a diameter as large as one-eighth that of the average sand grain) prop the grains apart, thus increasing the voids to be filled, while others occupy the spaces between the grains and thus diminish the voids. Therefore, a thorough mixture of perfectly dry sand and perfectly dry cement cannot be compacted so that it will have no voids. Perhaps for any commercially available sand and cement 15% of void space is the minimum.

Moist cement and sand cannot be thoroughly compacted unless there is at least enough water to fill all the voids in the compacted mass. At least 15% of the final volume, therefore, must be water, as this is necessary to overcome surface tension among the particles and thus permit them to adjust themselves to fit snugly against one another. The quantity of water required to fill the voids completely depends not on the quantity of cement, nor on the voids in the sand measured separately by any method whatever, but on the voids in the cement and sand when mixed together in that condition of closeness permissible for "workability" for placing in the forms.

#### SOUNDNESS OF BRIQUETTES

To ascertain the effect of varying quantities of sand, cement, and water on the soundness and strength of mortar, a number of sample briquettes were made and tested, and the results are given in the accompanying diagrams.

As it was desired to investigate only the effect of varying the proportions, it was essential to use cement and sand of uniform quality. The cement for the briquettes came out of the same sack. All the washed Allegheny River sand was from the same stock pile, thoroughly dried and sifted. To secure uniformity of size only material passing a 0.0232-in. screen and retained on a 0.0116-in. screen was used.

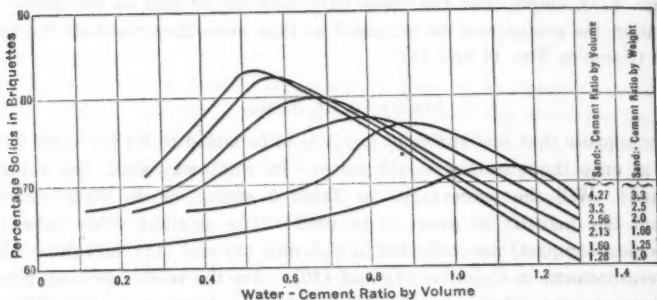

FIG. 3.—SOUNDNESS OF BRIQUETTES FOR VARIOUS RATIOS OF SAND TO CEMENT AND WATER TO CEMENT.

In turn, 100 grammes of this sand was mixed with 10 grammes, 20 grammes, etc., of cement, and with enough water to give water-cement ratios, by volume of 20%, 30%, etc. Each briquette was made in the ordinary standard mould, the materials being pressed in as tightly as possible with the fingers. It was weighed and the residual materials were weighed to check, so that the exact weights of water, cement, and sand in each briquette could be computed. It was assumed that water equal to 10% of the weight of the cement eventually combined chemically to form solid material. The percentage of solid matter to the total volume of each briquette could then be calculated.

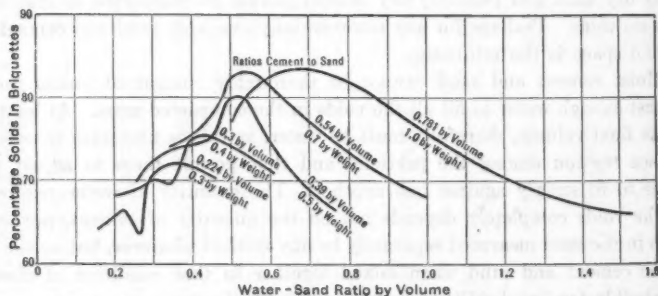

FIG. 4.—SOUNDNESS OF BRIQUETTES FOR VARIOUS RATIOS OF CEMENT TO SAND AND WATER TO SAND.

The results are given graphically in Figs. 3 and 4. With equal weights of sand and cement (Fig. 3) the soundest briquette was that containing about 52% as much cement as water, by volume. That is, it could be compacted farther in the mould than with more, or with less, water. Thus, with a sand-

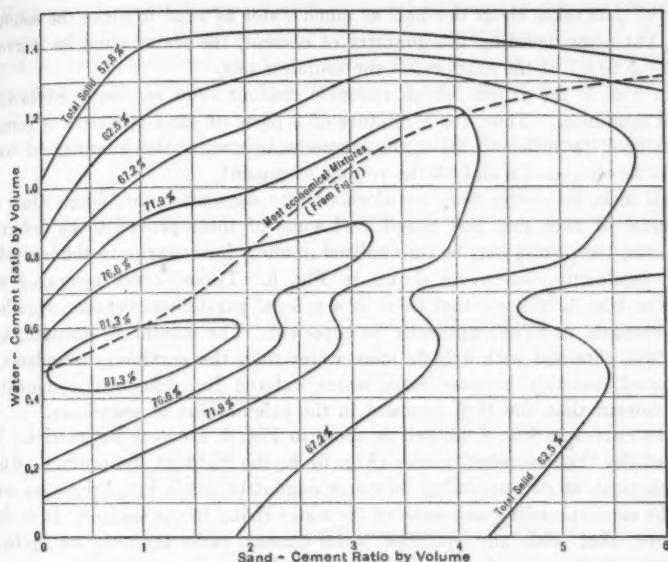

FIG. 5.—PERCENTAGE OF TOTAL SOLIDS IN BRIQUETTES OF VARIOUS MIXTURES.

cement ratio of 2 by weight, or 2.56 by volume, the water-cement ratio required to produce the densest briquette was about 0.8, while with only one-third as much cement as sand (sand-cement ratio of 4.27), it required a water-cement ratio between 1.1 and 1.2 to compact to the utmost.

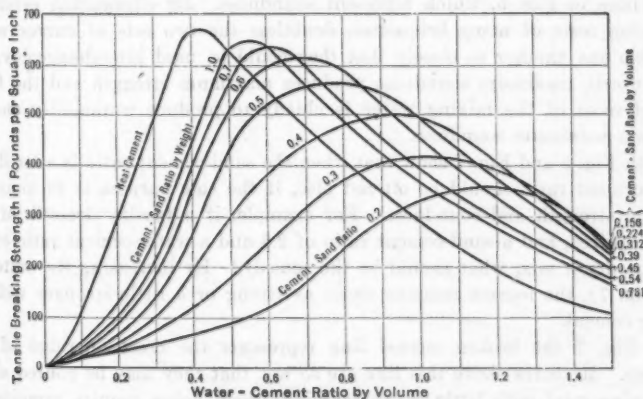

FIG. 6.—“IDEAL” CURVES SHOWING THE RELATIONSHIP BETWEEN WATER-CEMENT RATIO AND TENSILE STRENGTH FOR DIFFERENT RATIOS OF SAND TO CEMENT.

By comparison, Fig. 4 interprets the same experimental data using the water-sand ratio, instead of the water-cement ratio. Thus, a cement-sand

ratio of 0.39 takes about one-half as much water as sand to make the soundest mix, but after doubling the quantity of cement, the water must be increased from 0.5 to 0.7 of the sand to get the soundest mix.

In Fig. 5, the graphs which resemble contour lines represent mixtures of equal soundness. Thus, for a mixture of 3 parts of sand to 1 part of cement, by volume, in order to make the soundest briquette, the quantity of water should be between 0.8 and 0.9 the volume of cement.

All these briquettes were tested about fifty days after moulding. Only one briquette of each mix was tested, and some of these proved to be defective. However, the results may be rationalized to allow for vagaries in the individual tests, producing the curves shown in Fig. 6. These curves compared with those in Fig. 3, indicate that there is a general parallelism between soundness and strength, as might naturally be supposed. The maximum strength, however, was obtained with a little more water than the maximum soundness, as computed, possibly because more water entered into chemical combination with cement than the 10% assumed in the calculations of soundness.

The curves in Fig. 6, as well as those in Fig. 3, are very instructive. The part of the "neat cement" curve (Fig. 6) to the right of the ordinate, 0.6, is hypothetical, as corresponding mixtures cannot be made into briquettes without the cement settling and some of the water rising to the surface. It is clear, however, that with any specified water-cement ratio there is an optimum quantity of cement and sand that will give the greatest strength.

#### STRENGTH TESTS

Another aspect of the same relationship is shown in Fig. 7. Discrepancies between the curves and observations are mostly for the mixes that are too wet for high-grade concrete. The strength curves in Fig. 7 should be compared with those in Fig. 5, which represent soundness. By eliminating errors by averaging tests of many briquettes, doubtless the two sets of curves would resemble one another so closely that they could be used interchangeably. In other words, maximum soundness produces maximum strength and the function of most of the mixing water is chiefly to produce workability enough to attain maximum soundness.

Both Fig. 5 and Fig. 7 show that when the sand-cement ratio is altered, the water-cement ratio should be altered also, if the sole purpose is to maintain uniform strength and soundness. For example, if a tensile strength of 400 lb. is required, and a sand-cement ratio of 2.5 and a water-cement ratio of 0.8 give too dry a mix, what should be the remedy? By increasing the water to 0.9 (Fig. 7), the mortar remains about as strong or a little stronger without adding cement.

In Fig. 7 the broken curved line represents the crest or ridge of the contours. Mixtures above this line are so wet that they may be poured about reinforcing steel with little or no tamping; those below require tamping or pressure to secure the strength recorded in the tests. This line is reproduced in Fig. 5, for comparison. Any mixture below this line will have its strength increased by adding water only; any mixture above it will increase in strength by reducing the water content, providing in each case the tamping is sufficient.

Mixtures of a specified strength will be found only within the corresponding contours. Obviously, the cheapest mix is the one requiring the least cement. Therefore, the proportions of the cheapest workable mix are found at the intersection of the broken line with the contour line representing the strength required.

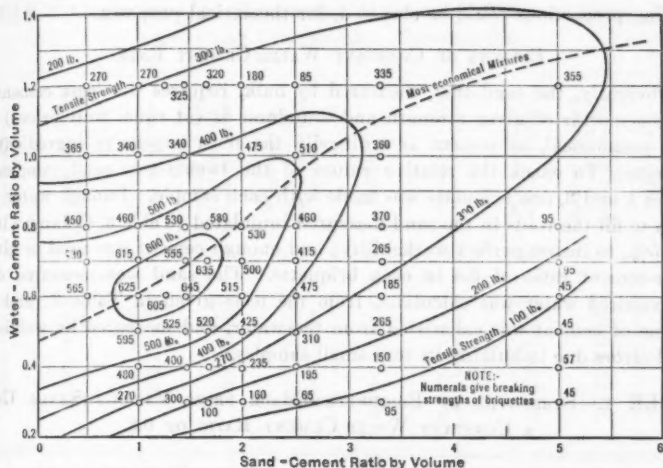

FIG. 7.—RELATIONSHIP BETWEEN SAND-CEMENT AND WATER-CEMENT RATIOS FOR BRIQUETTES OF VARIOUS TENSILE STRENGTHS.

The use of the water-cement ratio for determining the quantity of water is, of course, arbitrary. A water-sand ratio plotted from the same data (Fig. 8) is just as applicable. If the sand were supplied in perfectly dry condition, so

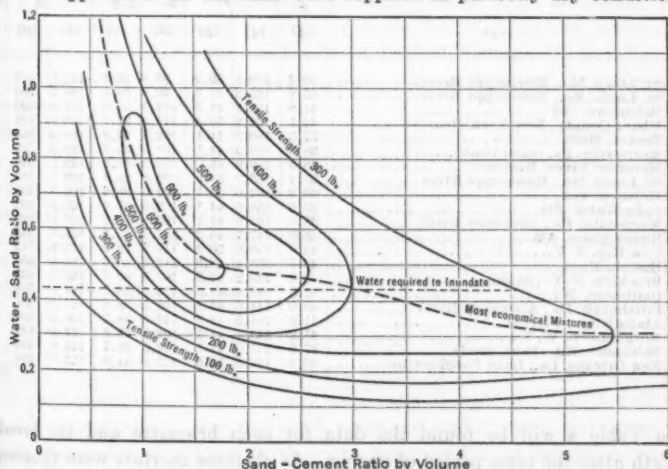

FIG. 8.—RELATIONSHIP BETWEEN SAND-CEMENT AND WATER-SAND RATIOS FOR BRIQUETTES OF VARIOUS TENSILE STRENGTHS.

that all the water may be measured separately, Figs. 7 and 8 are equally convenient. If, however, the sand is not dry, and not uniform, some advantages, as will be shown, accrue from the use of the form of Fig. 8.

All the tests on which Figs. 2 to 8 are based were made with a specially prepared sand, to secure such uniformity of materials that the effects of varying proportions could be observed, for theoretical purposes.

#### EFFECTS OF CONSTANT WATER-CEMENT RATIO

Obviously, the sand that, measured by bulk, requires the least cement, to make a mortar of given strength and soundness is (at equal unit prices) the most economical, as cement is ordinarily the most expensive ingredient in concrete. To check the relative values of the twenty-two sand samples of Tables 1 and 3, one briquette was made with each sample. Enough water was taken to fill the voids in the sand measured inundated (Table 3, Column (10)), plus 5%, to insure perfect workability; and enough cement was used to give a water-cement ratio of 0.8 in each briquette. The sand was measured dry; the required water was calculated from the tests given in Table 3; and the volume of cement was calculated from the water, and measured by weight to avoid errors due to bulking in very small samples.

TABLE 4.—STRENGTHS OF BRIQUETTES MADE FROM VARIOUS SANDS USING A CONSTANT WATER-CEMENT RATIO OF 0.8.

In Table 4 will be found the data for each briquette and its breaking strength after the same period of curing. As all these mortars were thoroughly "workable", they should show approximately equal strength, if maintaining a

constant water-cement ratio could produce that result, regardless of the differences in the sand. From the percentages of cement to sand, by volume (Table 4, Column (10)) it will be seen that almost all these mixtures were richer than 2 of sand to 1 of cement.

#### CONSTANT CEMENT-SAND RATIO AND ITS RESULTS

In Table 5 are given the strengths of a series of briquettes made of a mixture of  $2\frac{1}{2}$  parts of submerged sand without any extra water, and 1 part of cement (both by volume), or a cement-sand ratio of 0.4; in other words, the table indicates the result of ignoring the water-cement ratio altogether, using in every case not a constant quantity of water, but the quantity necessary to saturate the sand. The water-sand ratio in Table 5, Column (2) is taken from Table 3, Column (10), and the water-cement ratio in Column (3) is computed therefrom.

In general, all these mixes are leaner in cement, than those in Table 3; they have from 80 to 60% as much cement, and less actual water, although the water-cement ratio is higher. Of course, since only one briquette was made for each test, no individual result can be considered reliable. It is remarkable, however, that the variation in breaking strengths of briquettes made by using constant proportions of inundated sand and cement, by volume, as indicated in Table 5, are so nearly alike.

#### NATURAL VARIATIONS IN SANDS

When sand has been measured under water, extra water may be added in any desired quantities. Table 6 gives the results of tests of briquettes all made with the same carefully screened sand, measured under water, and mixed with various quantities of cement, with extra water added in definite quantities. It shows clearly how the strength falls off usually as more water is added, when

the mix is lean (Column (3)), but that when the mix is very rich (Column (6)), water must be added to make it workable enough to obtain sound briquettes.

A similar effect occurs with natural sands used in concrete, the chief difference being that there it is necessary to begin adding water with leaner mixes. These tests were made to throw light upon the effect of moderate variations in the quality and the dryness of materials in order to ascertain the best methods of measurement in the actual work—not in the laboratory only.

Now, if the sand varies in physical properties and hence in total void spaces per measured batch, an element of uncertainty is introduced. The method of measurement may be such as to magnify or minimize the importance of this; and, obviously, the latter will be the best to adopt.

Using six successive batches of Pittsburgh sand, which were dumped out and weighed after measurement, the maximum variation in the weight of the batch was 0.5%; and the maximum variation in the water content was 2 per cent. The mean variation was much less, two batches (1 800 lb.) weighing within 1 lb. of each other. Thus, in the six batches, the voids varied not more than 2 per cent.

TABLE 6.—STRENGTH, IN POUNDS PER SQUARE INCH, OF BRIQUETTES MADE WITH INUNDATED SAND.

\* Too dry to be workable.

#### WATER REGULATION

If, however, the sand came from different sources, the variation would be greater. Then, it would be best to ascertain the extra water to be added for each sand. However, for such differences as may occur from batch to batch it is important to realize that varying the water in saturated sand in proportion to the voids is beneficial. The variation in the sands in Table 5 was extreme, but the results, except for those samples which contained deleterious materials, were remarkably uniform. Measuring the sand under water tends to produce more uniform results in the mortar than weighing the batches dry and adding uniform quantities of water.

Having determined by computation and experiment the proportions of materials that produce concrete of any desired strength and consistency, and

in order to use the sand available (which may vary in moisture content, fineness, and voids), for producing concrete that is uniform, batch after batch, it is essential to:

- (a) Eliminate the effect of moisture already in the sand on the accuracy of measurement; and,
- (b) Regulate the quantity of water used in each batch so as to maintain the workability of the mix with as little excess water as practicable.

#### PRACTICAL MEASUREMENT OF SAND

Sand may be measured by bulk or by weight; moist as received on the job; dry or saturated. Some years ago the usual method was by loose bulk as received; that is, moist. There was a time when ingredients for test specimens upon which specifications were based, were measured loose and moist. For some years, however, laboratory tests have been made generally with dry rodded sand, corresponding in compactness to Column (3), Table 3, and often from 15 to 30% more compact than the same sand as received on the job. Thus, the old specification 1 : 3 : 5 with loose sand would correspond to 1 : 2.5 : 5 with dry rodded sand (laboratory conditions). Much confusion resulted and not a little injustice was done contractors by adhering to the specifications for loose measurement in the field while demanding results and costs based on rodded measurement in the laboratory.

Happily, this discrepancy has been recognized and for the most part specifications are now drawn to permit measurements on the work corresponding to those used in the laboratory. If bulk measurement is permitted, allowance for bulking of sand in the measuring containers is usually permitted also. When the bulking is determined experimentally, the error introduced is rarely more than 5% in the total quantity of sand.

Such a variation in a batch is not in itself a serious matter ordinarily, if the other materials remain constant. Thus, from Fig. 7, with the water-cement ratio constant a variation of 5% in the sand-cement ratio will have scarcely any effect on the ultimate strength. Again (Fig. 8) with the water-sand ratio constant a variation of 5% in the sand-cement ratio will have small effect on the strength. There is a more serious error, however, if the water contained in the sand varies considerably. It may be 3 to 8% of the total weight, or 7 to 20% (a difference of 13%) of the total volume of the sand, while the bulking may remain almost constant. Therefore, the water-cement ratio may easily vary by 30% when the sand-cement ratio varies only 5 per cent. Thus, the variation of 30% in the quantity of water that may enter a batch is excessive; some batches will be too wet, and others too dry. The concrete cannot be handled uniformly; and, moreover, one batch may be twice as strong as another.

The facts that only in occasional batches will the wide variations occur, and that by care in handling (avoidance of pits where sand may become water-logged) a fair degree of uniformity may be attained, render it possible to use moist bulk measurement for sand with fairly good results. On the larger and better conducted jobs the water content is checked frequently, and

allowance is made in measuring additional water to be used. This, however, is subject to serious error from batch to batch.

Weighing is slightly more accurate than volume measurement, with allowance for bulking. An extreme variation of from 3 to 8% in moisture content, by weight, means only 5% in the sand; and making allowance for moisture by tests from time to time reduces the inaccuracy. Weighing makes it impossible to have those extreme variations in actual quantity of sand—15 to 30%—that may occur in bulk measurement when some of the sand is moist, but some is water-soaked, or practically dry. However, it cannot compensate for using a variable quantity of water due to ordinary fluctuations in the water content of moist sand, which are always appreciable and sometimes excessive with material exposed to the weather.

#### SATURATING THE SAND

Accurate measurement requires that sand shall be either dried out, or saturated with water at the time of measurement. This is essential, not only for accurate measurement of the sand itself, but more particularly, by ascertaining how much water goes into the measured batch with the sand, for determining the proper quantity of water to be added.

Drying sand is both troublesome and expensive, and measuring it moist introduces a probable error of 15%, or more; whereas measuring it under water gives a constant volume of sand and of water per batch. Hence, this latter method is by far the best. The additional water required must be determined, and then kept constant.

In the case of the Pittsburgh sand (Table 3, Sample No. 18), the sand measured loose under water (Column (4)) has the same bulk as if measured dry. This is true for Sample No. 13 also. Other samples, however, differ in this regard, so that it becomes necessary to determine the proportions on the basis of volume in the state actually adopted in the measuring devices, and not on any other.

The percentages of voids when sand is submerged (Table 3, Column (10)), may readily be determined. However, although this percentage varies from 35.2 to 48.8, of the twenty-two samples only two have voids exceeding 43.6 per cent. Therefore, usually the quantity of water required to saturate will be less than that in Fig. 8; and ordinarily it is necessary to add water in excess of that included with the saturated sand, in order to keep the mix workable when cement and stone are introduced. The containers used in the tests in Table 3 were small; larger apparatus would give percentages of voids somewhat less.

#### BATCHES TO CAPACITY OF MIXER

Where concrete is placed in forms, the volume turned out by the mixer frequently exceeds the amount for which forms can be prepared, and the mixer need not be run to capacity, or need be operated only part of the time. For other structures, such as massive masonry construction or concrete roads, the job capacity frequently is fixed by the mixer capacity. In any event, however, it is most economical to run the mixer at its full capacity when

running at all. The best procedure in measuring materials to mix full-sized batches is as follows:

Determine from the specifications, as nearly as possible, how much sand per batch may be used to work the mixer to capacity. The measuring device should then be adjusted to fit, and such variations as are necessary to get just the mix desired should be made by adjusting the stone (measured by bulk, with or without compensation for variable voids), the cement (measured by weight), and the excess water (measured by bulk). These adjustments are much easier to make than changes in the sand-measuring device (which must be water-tight) and permit the mixer to run at nearly full capacity.

If, however, sack measurement for cement is required, the sand container must be set for the quantity corresponding with the number of sacks of cement in the batch, after determining what volume of sand in the saturated condition is compatible with the proportions specified.

#### EQUIVALENCE OF DRY AND SATURATED SANDS

The actual procedure must depend on how the specifications are worded, or interpreted. The method will be illustrated by assuming several different kinds of specification:

(a) Suppose the specifications, based on the use of saturated sand, read:

"The sand shall be measured by bulk saturated with water, and the water filling the voids shall be included in the batch. There shall be used in each batch \* \* \* pounds of cement for each cubic foot of sand as measured. Surplus water, constant in quantity for each batch, shall be added, as may be determined by the engineer to be necessary to secure the desired workability.

"To the sand, cement, and water specified in this section shall be added the coarser aggregate or aggregates (there may be several) elsewhere described."

A specification thus drawn leaves the workability entirely in the control of the engineer. It is entirely fair and can be enforced without hardship. There will be no "over-run" or "under-run" of cement unless there is dishonesty, or the coarse aggregate departs from specifications as to voids.

(b) If the specification is based on laboratory tests with sand measured in a "dry rodded" condition, it may read:

"The proportions specified for sand, cement, and water entering the various grades of concrete are based upon dry rodded sand of the grade specified (which should be the same as the sand commercially available for the work). In measuring the sand, correction must be made to insure that the actual quantity, regardless of the moisture in it, shall be equivalent in weight to the quantity specified, were it measured in a dry rodded condition."

Then it is easy for the engineer, or the contractor, to calculate the number of cubic feet of saturated sand that are exactly equivalent to dry rodded sand. The procedure is as follows:

Pack into a water pail (of Weight *a*) as much perfectly dry sand as can possibly be gotten in, by tamping or rodding. The weight of the bucket and sand, even full, will be Weight *b*. Empty out the sand so that none will be lost, pour it back slowly after the bucket has been a little more than half filled with water, allowing the surplus water to overflow. Be careful not to shake the bucket nor to waste any sand. When the bucket is exactly level

full of sand and water, the weight of the remaining sand will be  $c$  and that of the pail and saturated sand will be  $d$ . Weigh the bucket full of water only (Weight  $e$ ). Then,

$$\text{Weight of bucketful of rodded sand} = b - a;$$

$$\text{Weight of sand only in bucket of sand and water} = b - a - c;$$

$$\frac{\text{Volume of saturated sand to be taken}}{\text{Volume of rodded sand specified}} = \frac{b - a}{b - a - c}$$

The weight of water included in the saturated sand is  $d + c - b$ , and the proportion of voids in the sand (filled with water) is  $\frac{d + c - b}{e - a}$ .

If the process of measuring saturated sand is carried out properly the ratio of water to saturated sand is practically constant, whether measured in a 4-qt. pail, or in a receptacle 1 cu. yd. in capacity.

(c) The specifications are based on measurements of perfectly dry sand, shoveled loosely into a measuring box.

In this case, proceed exactly as in Case (b), using loose sand instead of rodded sand for the first two weighings.

(d) If the specifications state "the sand shall be measured by bulk, in the condition received on the work, loosely shoveled into a measuring box of known cubical contents", they are inaccurate. It would pay the contractor to have sand either dried or water-soaked before delivery, if such specifications are to be enforced.

(e) The specifications call for the sand to be weighed with or without an allowance for moisture content. Suppose that "the mixture shall consist of sand, cement, water, and stone, the sand and cement to be mixed in the proportions of 2 to 1, by weight". In this case, if saturated measurement is permitted (as it ought to be), proceed as follows:

Take a bucket, Weight  $a$ , and a quantity of perfectly dry sand, Weight  $b$ , more than sufficient to fill it. Half fill the bucket with water, and then fill it with sand until it overflows. Weigh the dry sand left over, Weight  $c$ . Finally, empty the bucket and fill it with water, calling the weight,  $d$ . Then,

$$\frac{d - a}{62.4} = \text{volume of bucket in cubic feet}$$

$$\frac{62.4 (b - c)}{(d - a)} = \text{dry weight of 1 cu. ft. of saturated sand}$$

Let  $r$  = the specified ratio of sand to cement, by weight (in the example stated,  $r = 2$ ). Then, for every cubic foot of saturated sand used, take  $\frac{62.4 (b - c)}{(d - a) r}$  lb. of cement.

If cement is to be measured by the sack (of 94 lb. net), for every sack of cement take  $\frac{r \times 94 \times (d - a)}{62.4 (b - c)}$  cu. ft. of saturated sand.

The ratio,  $\frac{62.4 (b - c)}{(d - a)}$ , or its reciprocal, can be determined once for all, and it will not vary as much as the probable fluctuation in the water content of the sand as delivered on the job. Consequently, this method is more accurate than weighing the sand as the supposed specifications require. It is, in fact, a method of weighing which avoids the use of scales by employing the principle of specific gravity and approximate constancy of voids when sand is submerged.

#### MEASURED BY WEIGHT

Practical constructors who have used bulk cement by weighing, report that the physical properties of brands, all passing standard specifications, cause a very considerable difference in the readiness with which various cements flow through gates when being measured. The finer ground material arches more quickly under pressure and is more dusty when the arches break. When mixed with air only, the dry bulk of a given weight varies exceedingly, not only with a different, but with the same, brand of cement.

Cement differs so much in volume, according to the degree of pressure applied and time allowed in compacting, that this type of measurement should never be used. Cement should always be measured by weight. As a sack of cement is filled at the factory by automatic weighing machinery, the contents may be taken as 94 lb., and as equal to 1 cu. ft. With the sack as a unit, specifications of 1 : 2 : 4 mean 1 sack of cement, 2 cu. ft. of sand, and 4 cu. ft. of stone, or multiples of these quantities, to each batch.

With cement shipped in bulk, it is necessary to weigh out each batch independent of the cubic foot as a unit. Weighing also enables the batch to be made of a size to work the mixer to capacity. This distinct advantage recommends the weighing of cement into batches even when it is received in sacks.

#### THE MEASUREMENT OF STONE

Because the sand in the mortar props the stones apart, the voids as determined by water test will always be smaller than the spaces actually to be filled with mortar to produce sound concrete. Experiment will show, however, how much the necessary increase should be. The amount of mortar required depends in part on the fineness of the sand, and in part on the fineness of the stone. In any event, one thing is certain—the greater the percentage of voids in the stone the more mortar will be required to fill them; and the most economical sample of stone or gravel will have the smallest percentage of voids, provided the smallest fragments of the stone are not too small.

The stone may be measured either by bulk or by weight, for it does not vary in volume when moist, as does sand. Stone may vary considerably, however, in the shape and size of fragments, and consequently in the voids. The percentage of voids in coarse aggregate by water test may vary from a maximum of 55 to a minimum of 35 per cent. Assume, merely for illustration of the relative merits of batching by bulk and by weight, that stone received on a given job varies from 40 to 50% in voids, by water test, and weighs in the solid, 200 lb. per cu. ft.

The proportioning must be based on filling all the voids in the coarsest stone—50% of the stone volume, plus whatever increase is due to the size of the sand grains. Table 7 shows the actual voids, when the percentage of voids varies.

TABLE 7.—VOLUMES OF BATCH, SOLID STONE, AND VOIDS, IN CUBIC FEET.

Batch.	PERCENTAGE OF VOIDS IN STONE.		
	50	45	40
(a) Batch of 2 000 Lb.:			
Actual volume of batch.....	20	18.8	16.8
Solid stone.....	10	10	10
Voids.....	10	8.8	6.8
(b) Batch of 20 Cu. Ft.:			
Actual volume.....	20	20	20
Solid stone.....	10	11	12
Voids.....	10	9	8

Of course, there must also be some addition for the propping action of the sand grains, to be determined by experiment, but it is evident that when bulk measurement is used, and the stone has 40% voids, the batch has 9 cu. ft. more solid stone, and still is more workable than one with 50% voids. Clearly, therefore, where fixed proportions are specified, it is better to measure the stone by bulk rather than by weight, and thus to place a premium on securing the most suitable material. To measure stone by weight when it is paid for by the ton tends to produce concrete of equal cost per yard, but not necessarily of equal quality, and certainly not at the lowest expenditure in finished product for value received.

#### PROPORTIONING MORTAR FOR VARYING STONE

There are several ways of varying the quantity of stone from batch to batch so as to have the batches of stone equal not in volume nor in weight, but in voids.

One is to require the stone to be screened into several grades, to measure fixed quantities of each grade separately, and finally to mix these grades. The providing of several different grades of stone at the job, and a corresponding number of separate volumetric batches has much to recommend it. In many cases, however, it is more economical in the long run to use this aggregate as it comes from the crusher or the washing plant, and to include more mortar per batch rather than to go to the expense of special preparation of stone. When it has been stored in large stock piles, there may be considerable variation in voids owing to segregation caused by the larger fragments rolling down and collecting at the bottom.

When it is not desired to separate the stone and measure each grade separately, it is practicable to allow for variations in voids by combining bulk measurement with weight measurement. The principle is this: A certain amount of mortar is sufficient for a batch of stone having maximum void

spaces possible from the source of supply. Suppose, that this maximum is 50%, and that it is permissible to use such stone in a 1:2:4 mix on a given job. However, when the stone is better graded, it would be allowable to use more of it, say 1:2:4.5, because the voids are less. The problem then is, how to distinguish between the proper mixes from batch to batch as the work is carried on.

This is readily done by using a bulk measuring batcher mounted on scales. It is set for 4 parts of stone, by volume. When filled, the stone is weighed, the scales indicating automatically how much additional stone may then be introduced, by weight. On a large job quite a saving can be effected in this way. The owner's inspection is concentrated at the batching and mixing plant, instead of at the quarries, screens, and bins. Further, it is to the contractor's interest to procure the best graded stone possible because the better it is, the larger quantity he can use, with consequent saving of the more expensive material, cement.

#### THE SIZE OF THE JOB

In considering the best method of measurement for any particular piece of work, the size of the job is important. It is not always economical to go to the expense of providing accurate measuring devices, for on a small job it may cost less to allow for variability in the materials by using more cement, and by taking greater care, especially in the quantity of water used, even with crude devices. The larger the work, however, the greater will be the saving in labor, time, and the total cost of materials secured by using the most efficient and accurate devices, while the cost of installing the necessary equipment becomes proportionately less. Every project presents its own problems, the use of equipment already on hand or available being one of the factors to be considered. It is believed, however, that the point of view here presented for the very practical problem of measuring materials for batch mixtures will be helpful even in many cases where, for good reasons, it is not deemed wise to resort to the most accurate methods.

Paper No. 1752

### SILT TRANSPORTATION BY SACRAMENTO AND COLORADO RIVERS AND BY THE IMPERIAL CANAL\*

By C. E. GRUNSKY,† PAST-PRESIDENT, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. C. S. HOWARD, HARRY F. BLANEY, E. S. LINDLEY,  
THADDEUS MERRIMAN, IVAN E. HOUK, AND C. E. GRUNSKY.

#### SYNOPSIS

Data relating to the transportation of silt or fine sand and other detrital material by the Sacramento and Colorado Rivers and by the Imperial Canal, with inclusion of the results of personal observations, are presented in this paper.

Repeated surveys to determine the frequent changes in the elevation of the bed of the Imperial Canal in its upper reaches, and the removal of large quantities of silt from the head reaches, have furnished an exceptional opportunity for estimating the volume of silt transported by the canal, including its bed load. Over a period of  $2\frac{1}{2}$  years the available data indicate deposit followed by erosion to have averaged in excess of 500 000 cu. yd. per month, with a canal flow of about 2 000 000 acre-ft. per year.

The suspended load of silt in the Colorado River has been determined with unusual care at Yuma, Ariz., by the U. S. Bureau of Reclamation, and an analysis of the observations does much to explain the distribution of silt throughout the cross-section of the river, the varying quantities of silt at different stages of the river and at different times of the year, and the total volume transported during the period of observation, since 1909.‡

#### OBSERVATIONS ON SACRAMENTO RIVER, CALIFORNIA

*Early Gauging.*—In 1879, one of the gauging stations on the Sacramento River was located at Freeport, Calif., about 14 miles below Sacramento. For

\* Published in August, 1929, *Proceedings*.

† Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

‡ The writer was on the Engineering Staff of the State Engineer of California from 1878 to 1888. He was a Consulting Engineer to the Imperial Irrigation District from 1916 to 1920.

this station a program was arranged by the State Engineer, for a comprehensive observation of phenomena throughout a fairly long stretch of river, to develop a dependable rating curve and to facilitate computation of discharge for any known river stage.

The instructions covered a careful determination of the river cross-section in order that the necessity for sounding might be avoided when gaugings were repeated. Additional cross-sections, 100 ft. above and 100 ft. below the section selected for gauging with current meters, were to aid in establishing the average river dimensions over a 200-ft. float course. The gaugings were made at a fairly high stage (15 to 20 ft. above low water) and velocities were measured both with current meters and with floats.

The equipment included a catamaran, constructed of two rowboats about 2 ft. apart, united by a light platform. On this deck there was a simple structure that supported a drum of small diameter which was turned with a hand-crank and was used for lowering and raising a weighted frame that carried the current meter. With this outfit there was no trouble in lowering the meter to any desired depth and holding it there. A stay-rope from a boat 100 ft. up stream held the meter frame vertically beneath the catamaran. In taking soundings the depth was read accurately on one of the two light cables by which the frame was raised and lowered.\*

The work brought its disappointments, however. There was no agreement between the original and later soundings. Evidently, something was happening to the bed of the river, and, therefore, a systematic study was undertaken to determine the extent of the changes. From day to day soundings were taken in longitudinal lines about 50 ft. apart, each carefully located. At the upper end of each line the control boat was secured by two anchors, and its position was definitely determined by triangulation from shore. A second boat was then dropped down stream and carefully held to line by a helmsman, in order to take soundings every 25 ft. The stretch of river thus covered extended 400 ft. up stream and 100 ft. down stream from the gauging section.

*Hydraulic Gradients.*—The cross-sections in Fig. 1 show that the configuration of the river bottom, which is a straight reach at this point, was uneven and constantly changing. The material in the river bed was clean sand, most of which was fine enough to pass a 40-mesh screen.†

The gauging work was intended not only to measure discharge, but to establish a dependable value of  $n$  in Kutter's formula. Consequently, a careful observation of the river slope was to be made. Gauge rods were set at the gauging station and at points about 4 000 ft. up stream and a like distance down stream and, for days, readings of the water-surface elevations at these three points were taken at 10-min. intervals.

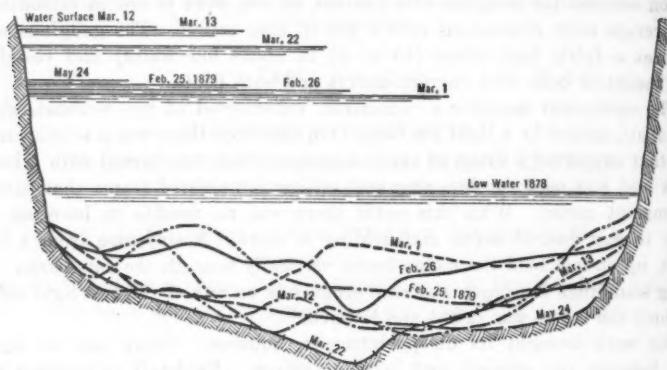

When the observations were plotted on a time scale it was seen at once that the water surface gradient was constantly changing. There was a rather long rhythmic pulsation as if elongated waves were following each other down the river. It was found, in other words, that simultaneous observations would not correctly represent the river gradient, but that this gradient would have

\* See Report of Commr. of Public Works, California, 1895. Contribution by the writer.

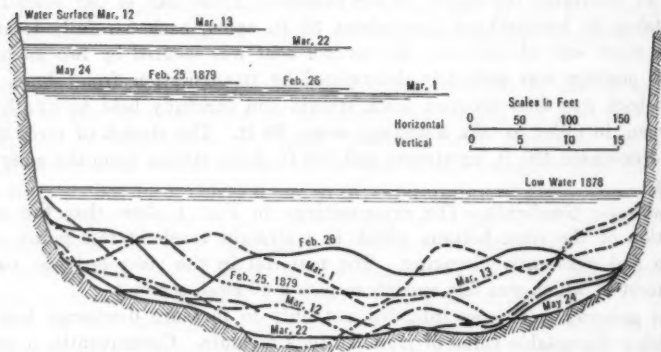

† This is the writer's estimate; no actual determination was made.

to be determined from a long series of observations. The cause of the pulsation was not discovered. In part at least it may have been the result of sudden changes in the river bed.

*River Eccentricities.*—An anchored rowboat, unattended, was swamped by an accumulation of reeds and other drift on its anchor ropes. Strenuous efforts of the whole available crew, assisted by a launch, could not free it from its sand grave in the bed of the river. It was never recovered.

(a) CROSS-SECTION 200 FEET ABOVE GAUGING SECTION

(b) CROSS-SECTION 100 FEET ABOVE GAUGING SECTION

FIG. 1.—CROSS-SECTIONS IN THE SACRAMENTO RIVER AT FREEPORT, CALIF., IN 1879.

The current meters (of the Henry type), reporting every revolution by a clicking sound, indicated a decided pulsation of the current which was attributed to the effect of the whirls in the water. The whirls were quite apparent.

"Boils" were frequent at the river's highest stages. Under the influence of an upward current, the water would rise over a circular area generally 10 to 20 ft. in diameter with a maximum superelevation of about 10 in. at the center. While no cause was ascribed to these boils at the time, the writer

concluded in later years that they must have been the result of a sudden yielding of a considerable area of river bottom.\* This action leaves a cavity in the river bed into which the water plunges, is deflected upward, and becomes manifest at the surface as a "boil". On the Sacramento River the boils observed by the writer occurred at points where the depths were 20 to 30 ft. and at velocities in mid-stream of 5 to 7 ft. per sec.

In 1879, during a high-water stage, the piles of a dolphin above the Southern Pacific Railroad Bridge, at Sacramento, Calif., were floating away as if they had been inadequately driven. Soundings by the writer confirmed this view. They showed that in mid-stream the bed was then 25 ft. lower than it had been at a low-river stage a few months before.

In December, 1890, the Paine Crevasse occurred below Sacramento on the opposite side of the river. Soundings above this point revealed a tremendous scour due to accelerated current. More than 2 000 000 cu. yd. of sand had been scoured out of a 2-mile stretch of river within one day. In mid-stream, about opposite the down-stream edge of the crevasse, where there had been 20 ft. or more of water before the breach in the levee, the oars touched bottom in rowing; and a few days later there was again deep water at the same spot.

During the fall of 1878, in the mouth of the American River just above Sacramento, at the low stage of the river, a sand-bar was found along the north bank of the channel. During the winter freshet this sand-bar was swept out, and in the spring of 1879, during a protracted over-bank stage of the river, a new deposit was made, level from bank to bank, completely obliterating the old low-water channel. Through this new deposit the falling river cut a channel along the north bank a little later, and no trace of the low-water channel of 1878 along the south bank was left. It was estimated, at the time, that these river-bed changes represented a delivery of more than 340 000 cu. yd. of sand from the American into the Sacramento River, not including that delivered as an ordinary bed load.

Thus, under certain conditions, the configuration of fairly large sections of river bottom may be quickly changed. Every such change, moreover, evidences a rapid down-stream movement of sand in the river bed, probably by saltation of the material which, at low and ordinary water stages, travels in small sand waves.†

*Mining Detritus.*—The bed of the Sacramento River in its lower valley reaches has a sandy bottom. This section received large quantities of detrital matter from the hydraulic mines that were operated extensively along its tributary streams until about 1880. The accumulation below the mouth of the Feather River was large. This sand is clean and of a medium fineness. Originally, the water was fairly clear at low stages and never very heavily charged with sediment. Observations in 1879 indicated that the maximum quantity of material in suspension at mid-depth (still far in excess of that under original conditions) was about 0.1% by weight. The river, undoubtedly, carried much more material in suspension some years before, during the greatest activity of the hydraulic miners.

\* Report of Examining Commission on Rivers and Harbors for California, 1890, p. 35.

† Described by G. K. Gilbert, in *Professional Paper No. 86*, U. S. Geological Survey.

For many years the two principal tributaries of Feather River—the Yuba and Bear Rivers—were heavily charged with mining detritus. They originally entered the Great Central Valley of California in secondary valleys flanked by the higher (so-called “valley”) plains. Their well-defined channels meandered through fertile bottom-lands; but the large volumes of sand dumped into the mountain reaches greatly overtaxed the transporting power of these streams. The natural channels in the secondary valleys were filled and the bottom-lands, too, were covered with a layer of clean sand. For example, in 1880 the Yuba River where it entered the main valley had obliterated its bed and had covered its bottom-lands with coarse sand 2 to 3 miles in width. It ran wild over the surface, behaving like all rivers when the supply of sand exceeds their transporting power and spreads over broad areas in shallow, unstable channels.

Why, was the first thought, had not these rivers cut deep channels and, with concentrated energy, swept the sand along instead of covering fields with it and filling houses almost to the tops of the windows? The answer is simple. The bottoms of overloaded streams are invariably flat, almost level, from bank to bank. On the other hand, streams carrying but little sand are in deep narrow channels. Whenever there is more material presented to a stream for transportation than there is capacity to transport, the stream will flatten out, increasing its width and reducing its depth. Thereby it increases the area of bottom subjected to sand traction and to scouring and correspondingly increases the volume of material pushed along as a bed load.\* Many of the small streams which enter the San Joaquin Valley from the Sierra Nevada have channels of the surcharged sand type.

*Progressive Bed Changes.*—By the accession of sand from its principal tributaries (the Feather and the American Rivers), during the period of hydraulic mining activity, the bottom of the Sacramento River was raised progressively until about 1880. For some years thereafter the river bed near Sacramento was at a higher elevation than the water surface at low-river stages had been under natural conditions. In Fig. 2,† which shows this condition, the zero point on the gauge is 3.85 ft. above low tide in Suisun Bay, or 4.35 ft. above low tide in San Francisco Bay. From 1849 to about 1860 there was a rise and fall of the river at Sacramento due to tidal action (during the river's annual low-water period) of more than 2 ft. By 1871 the tidal range had been reduced to about 9 in., and about twenty years later had disappeared. The low-water stage at Sacramento was zero on the river gauge as late as 1856; 5.5 ft. in 1878; 7 ft. in 1880; and 8 ft. in 1889. It reached 10.5 ft. in 1890. Then bed erosion began; the material transported exceeded the supply. The low-water stage of 1894 was at 7.5 ft. on the river gauge and, by 1920, it was again at zero as in the days before hydraulic mining.

Although in the Sacramento River the low stages of recent years are due, in some measure, to the reduction of the low-water discharge by diversions

\* For discussion of detrital material delivered into the rivers of the Sierra Nevada Mountains, California, by hydraulic mines from about 1853 to 1881, see “Hydraulic Mining Debris in the Sierra Nevada,” by Dr. G. K. Gilbert, *Professional Paper No. 105*, U. S. Geological Survey.

† Reproduced from Report of Examining Commission on Rivers and Harbors of California, 1890, pp. 32–33.

for irrigation, and also to channel enlargement by dredging at down-river points for levee material, nevertheless these data indicate the passage of a great wave of debris (sand) down the river. The crest passed Sacramento about 1890 and reached the river's outfall point about 60 miles farther down stream, about 1917.

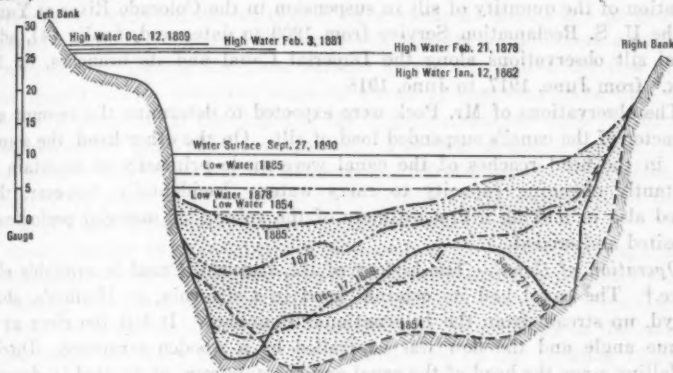

FIG. 2.—CROSS-SECTION OF THE SACRAMENTO RIVER, AT THE FOOT OF K STREET, SACRAMENTO, CALIF.

#### FINE SAND IN THE COLORADO

*Physical Characteristics.*—The rivers of the southwestern part of the United States are in a class by themselves. Of these, the Colorado is typical. At Temple Bar in 1896, about 12 miles up stream from the mouth of the Virgin River, the water looked like chocolate as it is ordinarily served. In a glass of water dipped from the surface,  $\frac{1}{2}$  to  $\frac{1}{4}$  in. of sediment would settle in a few minutes. A sample from the most promising mud-bar was analyzed to determine its suitability for making brick. The report showed no clay. The material was practically all silica in very fine particles.

In this part of the river there are alternate gravel-bars and deeps. In the Iceberg Canyon, a few miles farther up stream, where the bottom is a coarse gritty sand, the river is less than 250 ft. wide at its low stages and 30 to 60 ft. deep. Here and there in broad bars fine river silt is found. Some is mud and clay-like in character, shrinking and cracking as it loses moisture; some is fine sand most of which will pass through a 100-mesh sieve.

Where the river formed its great eddies the bottom was covered with this fine sediment. A loose log-boom circulated for hours in such an eddy, several hundred feet in diameter. While recapturing this boom an attempt was also made to recover a  $\frac{5}{8}$ -in. wire cable. Although a small scow was available and a strong pull, practically vertical, could be exerted, the cable could not be broken out of the quicksand bottom. Under water this material had a firm surface until its cohesion was broken by vibration, whereupon its behavior was momentarily that of a liquid. Over considerable areas of the bottom there were constantly occurring sudden changes of bed elevations as blocks of sand would rise and float away.

*Silt Load of the Colorado River and the Imperial Canal.*—The material now available for study consists of (1) determinations of the quantity of silt in suspension in Imperial Canal (which carries Colorado River water) during 1914 and 1915, by Mr. J. E. Peck; (2) determinations of bed elevation in the upper reaches of the canal, particularly from 1914 to 1920; (3) a determination of the quantity of silt in suspension in the Colorado River at Yuma, by the U. S. Reclamation Service from 1909 to date; and, finally (4), additional silt observations along the Imperial Canal and its branches, by Mr. Peck,\* from June, 1917, to June, 1918.

The observations of Mr. Peck were expected to determine the amount and character of the canal's suspended load of silt. On the other hand, the soundings in the head reaches of the canal were made primarily to ascertain its constantly changing capacity to carry water. Incidentally, however, they served also in making a first estimate of the volume of material periodically deposited and eroded.

*Operation of Canal.*—The history of the Imperial Canal is available elsewhere.† The canal had its original head in California, at Hanlon's, about 100 yd. up stream from the International Boundary. It left the river at an oblique angle and the flow was controlled by a wooden structure. During the falling stage the head of the canal and the gate were obstructed by deposits of silt which interfered with the successful operation of the canal.

The resulting water shortage followed by failure to secure sympathetic action by Congress prompted an application to Mexico in 1904 for a permit to divert water on Mexican territory. When this privilege was granted a new connection with the river was made just below and paralleling the boundary line; but this too, was choked by silt deposits. As a further relief measure another connection was opened about 4 miles south of the International Boundary at a point where the river and canal were only about  $\frac{1}{2}$  mile apart. The diverted water was allowed to flow in this cut without regulating works. The result was disastrous. Erosion at an increasing rate, and, later, failure to check the increasing flow, resulted (November, 1905) in a complete deflection of the Colorado River from its original course, and the formation of the Salton Sea.‡

In the light of these facts and because silt conditions in the laterals and distributing ditches of the Imperial Canal System were giving increasing trouble, it was found desirable (1916) to provide means for silt removal from the head of the canal. Conditions both physical and political made it impracticable to construct and maintain a permanent dam in the river with a settling basin at the canal head. Therefore, suction dredges operating in the head reach of the canal were provided, one in 1918 and another in 1919. A third suction dredge was later put to work in the canal just below the Hanlon Gate. When all convenient dumping space was filled, the dredged material was

returned to the river channel below the head-works. It was quickly swept away at the stream's next high stage.

*Conditions in the Canal.*—From these dredging operations in the head reach of this large canal the magnitude of the changes which must take place in the unstable bed of the Colorado River, can be inferred. Periodic surveys of the canal bed showed that at certain seasons there was a pronounced tendency to build up the canal bottom by silt deposits and at others a tendency to cut channel. During the years covered by the silt studies the flow of the canal ranged from a low-water stage in winter of somewhat more than 2 000 sec.-ft. to a maximum at the height of the irrigation season—June to August—of between 5 000 and 6 000 cu. ft. per sec. The total annual diversion ranged from about 2 000 000 acre-ft. to more than 2 500 000 acre-ft. The sides and bottom of the canal to an unknown depth consist of the same fine silt that is carried as a bed and suspended load by the Colorado River.

Studies during 1917 and 1918, in co-operation with the U. S. Department of Agriculture disclosed that the material deposited in the canal and found in its bed and in the beds of its various branch canals, is fine sand. This is shown in Table 1. Attention is directed to the fact that the sampling of the material in the bed of the Main Canal at the Hanlon Gate on one occasion (July 15, 1917) showed, in relatively coarse sand, 33% caught on a No. 40 sieve.

*Alignment and Structures.*—At that time the Imperial Canal partook in large measure of the character of a natural stream.\* The water diverted from the Colorado River was carried for 4 or 5 miles in a dredger cut and was delivered into a channel having an irregular alignment, resulting from the enlargement by erosion of an old natural overflow channel. For miles, the canal follows this "Alamo River" and has its deeps and shoals just like a natural stream. Throughout the period covered by Mr. Peck's sampling, the water entered the canal through a cut which functioned as an arm of the river. At high-water stages, generally from March to July, partition of the water from the river to the canal intake took place just as at a point of separation of a narrow from a broad delta channel. At low-water stages the flow in the river channel was checked by a temporary weir of rock or brush. Then the canal took the major portion, and occasionally all, of the river flow.

Until 1918 this water flowed in an open cut or reach about 1 700 ft. long to the Hanlon Regulating Gate, a concrete structure with eleven openings controlled by Taintor gates. In 1918, the Rockwood Head-Gate,† about 1½ miles above the Hanlon Gate, was completed. It is a structure of concrete with seventy-five openings controlled with flash-boards. The Rockwood Gate replaces about 600 ft. of river bank, its up-stream face being set back only a few feet from the original bank alignment.

The natural turbidity of the river at the head of the Imperial Canal, it should be noted, may have been disturbed, in some measure, by the flow and sluicing control operations at the head-works of the canal of the Yuma Reclamation Project, which are at the Laguna Dam about 20 miles up stream. Before the diverted water enters the Yuma Canal, it flows through a settling

basin so arranged that the deposited silt can be sluiced into the river below the dam. The sluice-gates are opened one day a week, when for the first few hours the river below is muddier than at other times. No correction due to this condition has been applied to any of the determinations of suspended silt in the canal by Mr. Peck, or in the river by the U. S. Reclamation Service.

*Silt Loads.*—The results of the observations on the canal are chiefly valuable in showing that the water supports and carries its suspended load throughout the entire length of the canal. Sometimes there is less, sometimes a little more, sediment in suspension at the head of the canal than at points 20 to 40 miles below; but, generally, when the water is very muddy at the head this condition persists through the entire length of the canal.

In 1914, the samples at the head of the canal were taken daily from the turbulent water just below the Hanlon Regulating Gate. The purpose was to get fair average samples from a single station in the head of the canal. The specific gravity of the silt in the canal averaged 2.64 and the voids in the material, as deposited in the bed, about 40 per cent.

A phenomenon illustrative of occasional conditions favoring the temporary conversion of the bed load of a river into a suspended load is the formation of a standing wave. This is noticed in streams of moderate depth, flowing in beds with fine sand bottom. It differs somewhat from the "boils" noted on the Sacramento River. It is a common phenomenon on the Lower Colorado. It represents a violent, sometimes fairly long-sustained attack on the river bed. "Sand is running", or "a sand wave is moving down stream", are phrases locally applied to this phenomenon. A standing wave is noted at the up-stream end of a disturbed area similar to that caused by a broad submerged snag in the river. Down stream the waves decrease in height, but extend over a gradually widening area and usually run out within 100 or 200 yd. Such a disturbance appears to the eye to be traveling slowly up stream, but is, in fact, fairly stationary. Undoubtedly, it is due to the yielding of a considerable stretch of the river bottom and the formation of a temporary depression which disturbs the steady flow of the stream. The waves gradually lose height and finally disappear when the depression is refilled to the original level by the river's bed load. The phenomenon is undoubtedly the result of the "anti-dune" movement of the stream's bed load which has been described by Dr. Gilbert.\*

#### THE BED LOAD IN THE IMPERIAL CANAL

*A Special Study.*—A river's suspended load of silt can readily be determined by taking samples of the water at a sufficient number of points in any cross-section. The problem of ascertaining the bed load, however, is a difficult one to solve, and the engineer must usually be content with some random estimate.

It will not do to assume that, because somewhere else the bed load of a river was one-fifth, or some other fraction, of its suspended load, this ratio will hold in other streams. Such comparison is only permissible when all conditions are similar. There is no limit to the range of this relation. Near

\* Professional Paper No. 86, U. S. Geological Survey.

one extreme there are comparatively clear rivers that transport a bed load of cobbles and gravels; and at the other extreme are the streams of the Colorado type, heavily charged with fine silt flowing in beds of material differing but little from that carried in suspension. Realizing this fact, and requiring information regarding the bed load of the Imperial Canal, a special study of new and of earlier observations was made by the writer to ascertain whether changes in the elevation of the canal bottom during a number of years would "throw some light" on this subject. The stretch of canal selected extends down stream 18 000 ft. from the Hanlon Regulating Gate which, as explained, is about  $1\frac{1}{4}$  miles below the Rockwood Gate in the head of the canal.

For some months after the completion of the Rockwood Gate the canal water flowed from the river through this upper gate uncontrolled, but in the summer of 1918, stop-planks were put into use and thereafter the water from the river dropped over them.

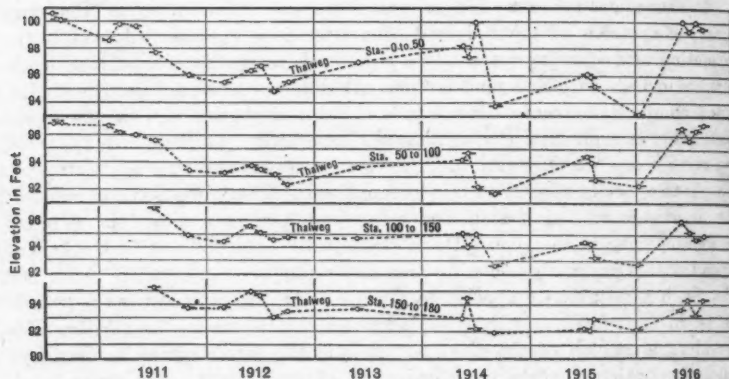

FIG. 3.—AVERAGE ELEVATION OF LINE AT GREATEST DEPTH, IMPERIAL CANAL.

*Seasonal Changes.*—It was found that in the spring while the river was rising from its low (winter) to a high (spring and summer) stage, more silt was deposited in the canal than its water could transport. The canal bed, at least in its upper stretches, rose to a highest position in June and was lowest in mid-winter. Considering only the selected 3.5 miles of canal, this rise, due to the deposit in the first four or five months of the year, ranged from a minimum of 1 ft. in 1912, to a maximum of 4.4 ft. in 1916. Thereupon, generally beginning in June or July, the same stretch of canal was deepened by erosion; the amount of this deepening was about 3.5 ft. in 1911, about 2.1 ft. in 1912, and about 2.7 ft. in 1915. These changes in the average elevations of the canal bed are shown diagrammatically in Figs. 3 and 4. On these diagrams each point represents the average elevation of the thalweg or of three parallel lines representing the canal bottom for the particular stretch of canal as marked. These curves bring the information

relating to bottom elevation forward to the time when dredging operations in the head of the canal modified the earlier conditions.

As was expected, these studies have thrown some light on the rate of the bed-load movement of the water. It appeared obvious that an increase of deposit represented accession of silt from up stream, arriving as bed load or as material dropped from suspension, and that erosion represented depletion in excess of the material arriving from up stream and temporarily coming to rest.

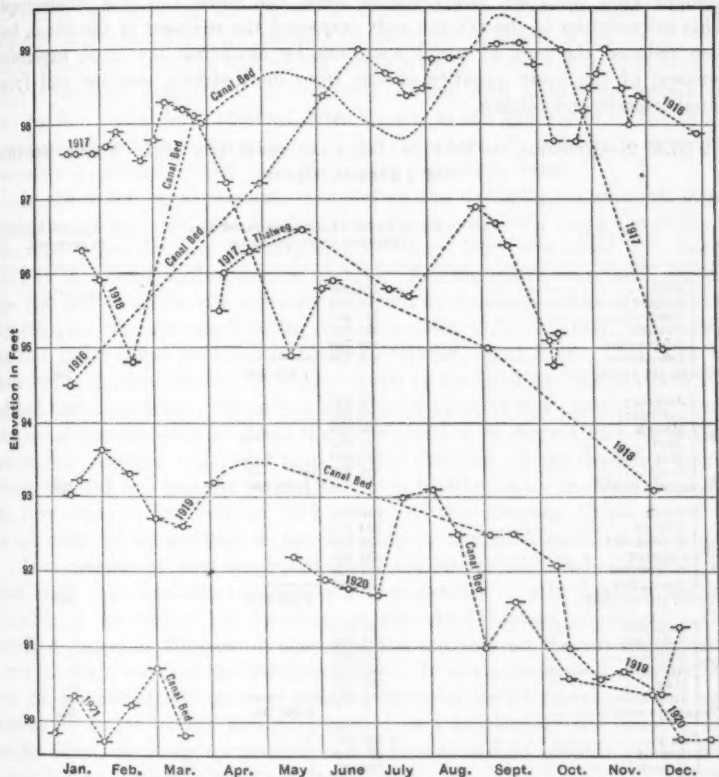

FIG. 4.—AVERAGE ELEVATION OF CANAL BED, IMPERIAL CANAL.

These studies show that during late winter and spring at least 280 000 cu. yd. of silt per month were being deposited, temporarily, in the canal stretch under observation and that a like volume was removed later in the year. How much more silt was traveling along the bed in continuous movement in sand waves could not be ascertained, but the quantity was suspected to be large. Inspection disclosed that the canal bed, at least near shore, was covered with small sand waves about  $\frac{1}{4}$  in. high and traveling slowly like sand dunes. The

individual sand particles roll up and over the crests into the troughs.\* Occasionally, the water would take on a disturbed appearance for a time probably denoting temporary instability of "anti-dune" sand traction.

The annual water delivery of the canal at the time of these studies was about 2 000 000 acre-ft. The water slope was about 1.5 ft. per mile, and the mean velocity about 3 to 4 ft. per sec. The silt in suspension ranged from about 0.33% to more than 1% by weight, and averaged about 0.8 per cent.

*Dredging Operations.*—In 1918, the canal head-works were modified, suction dredges were installed, and dredging from the canal bed was commenced. This intercepting of the silt not only improved the regimen of the canal, but also reduced the cost of canal operation by obviating the more expensive removal of the same quantity of silt from down-stream sections and from canal laterals and ditches.

The silt thus removed is noted in Table 2. The estimates of volume dredged were made from samples of the discharge, except during the early

\* Professional Paper No. 86, U. S. Geological Survey.

months of dredging when the spoil was used in filling low ground at the head of the canal to canal-bank level. On the plea of economy the amount of dredging in the head reach of the canal was reduced by the Irrigation District authorities in 1920 and was stopped with the close of that year.

Despite the large aggregate volume of dredging involved (nearly 15 000 000 cu. yd. in 30 months), the effect on the regimen of the canal considered in its entirety was hardly noticeable. General conditions remained apparently unchanged; but there was some deepening of the canal bed below Hanlon's. Certainly, the dredging was beneficial and should not have stopped. It has since been resumed for a few months in the year. While it is not quite clear what effect this dredging had on the lower reaches of the canal, it is certain that if the large quantity of the removed silt had been allowed to remain in the canal it would have traveled down stream to the annoyance of the canal management and the inconvenience of the farmer who is constantly receiving excessive quantities of silt with his muddy irrigation water.

In the upper canal reaches, even before the dredging commenced, some deepening of the canal was noted. Thus, for example, the mean elevation of the canal bottom during January and February, 1918, was about 2 ft. lower than in the corresponding months of 1917. For the entire year, 1918, during the last half of which silt was removed from up-stream portions of the canal by dredging, the average lowering was also about 2 ft. In 1919, the bottom of this upper canal stretch was further deepened about 2 ft. This is to be ascribed to the depletion of the supply of silt by dredging and the continuation of bed-load movement. There was some restoration of bed elevation in 1920, the canal bottom being at about the same position in August and September as in the preceding year; and then, despite cessation of the dredging operations, the bed was lowered several feet to a position early in 1921 about 7.5 ft. lower than it had been in 1917. Some of this lowering (Figs. 3 and 4) is no doubt to be ascribed to the dredging in the head reach of the canal.

It is noteworthy that the dredging did not relieve the canal entirely of its bed load. The periodical accretion and depletions of silt deposits, as evidenced by the rising and lowering of the canal bottom, continued. The dredged sumps in the head of the canal did not trap all the silt which came over the flash-boards of the Rockwood Gate. It now appears that even 500 000 cu. yd. per month (the average quantity removed for  $2\frac{1}{2}$  years) does not represent the entire load of fine sand carried as a bed load by the canal. How much more was being transported is not known, and no entirely satisfactory basis for estimating it has been found.

Dredging, as Table 2 shows, removed on an average about 310 acre-ft. of silt per month from the bed of the canal for  $2\frac{1}{2}$  years, and more than 400 acre-ft. per month for certain periods of 12 months. Had there been no removal by dredging, it is reasonable to assume that this material would have been carried down the canal mainly as a bed load.

*The Bed Load of River by Comparison with That of the Canal.*—It appears from the foregoing that the canal, with an annual discharge of from 2 000 000 to 2 500 000 acre-ft., transported about 4 000 acre-ft. of silt (at 100

lb. per cu. ft.) by traction, as its annual bed load. There must have been, of course, some pick-up and temporary transport in suspension. Because of this fact the estimate of canal-bed load may be accepted as a minimum.

If this determination be accepted it affords means for estimating, approximately at least, the bed load of the Colorado River itself. The traction exerted by the river on its bed may be regarded as independent of the suspended load. The sand on the bottom travels by rolling or by saltation regardless of whether the water is clear or muddy. In view of general similarity of canal and river beds, the annual bed loads of the canal and of the river may be assumed to be proportional to the annual discharge. This assumption ignores the fact that the river departs most widely from the characteristics of the canal when its discharge is greatest and the attack on its bed is most vigorous. The resulting estimate, therefore, is again more likely to be too small than too large.

On this assumption the bed load of the Colorado River, with its annual discharge of about 15 000 000 acre-ft. of water at Yuma, should be about six or seven times as great as that of the canal, or 25 000 to 30 000 acre-ft. per year. The assumption as to corresponding fineness of material applies to the material in the beds of river and canal, as well as to that in suspension. The larger velocities in the river at its high stages, if taken into account, would probably increase somewhat its relative, and therefore, also, its total, bed load.

*Silt in Suspension in Imperial (Alamo) Canal.*—The sampling of the water of the Imperial Canal, in 1914, was done in such a way that the results indicate the canal's full load of silt (Table 3). The samples were taken from the turbulent waters just below the gates of the Hanlon Regulator, where, by the flow under the gates, the bed load was converted temporarily into a

suspended load. During that year the river carried 0.93% of its weight in suspended silt. The total silt load of the canal was 0.86 per cent. These figures indicate a smaller proportion in the canal than in the river. The difference may have been considerably more, because in addition to the 0.93% in suspension, the river must have rolled considerable material along its bed.

From July, 1918, to December, 1920, while material was being removed from the canal by dredging (Table 2), the river carried in suspension 0.87% of silt. Unfortunately, there is no corresponding determination of silt in the canal. However, that which must have entered as a suspended load, computed from the volume of water and the silt content near the surface (about 0.83%), amounted to about 1 300 acre-ft. per month at 100 lb. per cu. ft. in place. Of this, 310 acre-ft. per month were removed by dredging (Table 2). The remainder was carried down the canal in part as suspended, and in part as bed, load.

\* 2 000 lb.

The samplings of the canal water from June, 1917, to May, 1918 (Table 4) may be cited to show that part of what was suspended load in the river became bed load in the canal. These samples were taken below the zone of influence of the Taintor gates, below the Hanlon Regulator, where possibly some, if not all, separation of bed load from suspended load already had taken place. They showed 0.28% of silt in suspension, while in the same period the river water carried 0.54 per cent. Based on the mean flow of the

canal (3 470 sec.-ft.) and the assumption that the water which flowed unobstructed from the river into the canal was charged with the same quantity of silt as at Yuma, the total volume of silt which entered the canal was about 700 cu. yd. per month, of which 340 cu. yd. became a bed load or temporarily came to rest in the canal bed.

It should be noted, however, that at 0.54% the river water was materially short of the silt contents determined at Yuma, 0.93% for the longer period of 30 months, of which only the first 6 months are covered by simultaneous sampling.

The sampling of the disturbed or turbulent water of the canal just below the Taintor gates at Hanlon's in 1914, indicated a transport of silt by the canal water as shown in Table 3. The volume of wet silt "after 24 hours" (Column (4)), shows the variable rate at which the silt in suspension settles to the bottom of a container. The data are not intended, however, to indicate the space it will occupy when finally incorporated in the geologic structure of the river's delta region. This volume can be computed from the unit weight of the deposited material. For convenience a weight of 100 lb. per cu. ft., about the weight of the material in the beds of the main canals, has been assumed (see Table 1). As small a value as 85 lb. per cu. ft. is sometimes assumed in converting weight to volume, particularly in estimating the space that the silt which is deposited under water will occupy in a reservoir. The studies made on the Imperial Canal and its branches indicate that the larger weight is more nearly correct for this locality.

The observations in the canal, listed in Table 4, were made some distance below the Hanlon Gate and results were reported by Messrs. C. E. Tait and J. E. Peck, the sampling having been done by Mr. Peck. The observations in the Colorado River are those of the U. S. Reclamation Service. Where figures do not agree with original records it is due to the fact that it was necessary to correct averages of incomplete records by approximating missing observations. Furthermore, the values noted in this table are weighted means and not averages. The figures presented in Table 3 depart in some instances widely from those computed by the U. S. Bureau of Reclamation. This is due to the fact that the Bureau has determined monthly values as straight averages of the daily percentage determinations, while, in preparing the tables in this paper, except as otherwise noted, each daily observation was duly weighted according to the discharge to which it applies.

*Variation in Silt Content.*—Comparison of values in Table 3 shows that during the months of May and June, 1914, the volume of silt in suspension expressed in weight (Column (3)) was only one-half as great as the volume that settled in the bottom of a tube in 24 hours (Column (4)). In other months, February, March, September, and October, 1914, the percentage by volume exceeded that by weight sixfold. These large variations suggest lack of uniformity in the character and condition of the river's suspended load, at first attributed to the occasional large admixture of Gila River water, just above Yuma. This seemed to be borne out by the relative river stages in 1914; but, later, daily observations (June, 1917, to June, 1918, inclusive) failed to substantiate this conclusion. However, when the water was heavily

† Approximations from incomplete records.

charged with silt, the settling nearly always was slower than when its load was light.

The canal does not hold quite as much silt in suspension as the river. This is ascribed to the fact that it is less turbulent than the river and, in consequence, the heavier grains of silt drop to its bed, thus becoming a part of its bed load. The difference in the suspended loads of the canal and the river was most striking in 1917 and 1918 (see Table 4), the figures being: For the canal, 0.28% and, for the river, 0.54 per cent.

Sampling of canal water was carried on systematically throughout the canal system from June, 1917, to May, 1918, the water being followed through the main canal into its many branches. The records are too voluminous to be reproduced herein in detail. The monthly summaries, however, have been assembled in Table 5.

It is to be regretted that during this period the Colorado River was never very muddy for longer than a few days. Nevertheless, Table 5 shows but slight change in the canal's suspended load of silt with distance from the intake. The suspended silt remains in suspension; the only exceptions are in the West Side laterals in which the smaller silt burden is explained by the opportunity afforded in its feeder, the Solfatara Canal, to drop a part of its load in a basin, provided for the purpose, along the northern base of Volcano Lake Levee.

#### SILT IN SUSPENSION IN COLORADO RIVER AT YUMA, ARIZONA

*Sampling of River Water at Yuma.*—Since 1909 the U. S. Reclamation Service and its successor, the U. S. Bureau of Reclamation, have made observations on the Colorado River at Yuma to determine the volume of silt transported. Twice a week samples have been taken in three verticals of a cross-section (one at mid-stream and the others at about the quarter-points). They were taken at the water surface, at mid-depth, and near the bottom of each vertical.

The results from 1909 to 1918 are presented in Table 6. The average percentage of silt carried as a suspended load during the entire ten years (0.89%) was found by comparing the total discharge with the aggregate weight of the material carried in suspension, as determined month by month. The percentages reported by the U. S. Reclamation Service for each month were accepted (for this period only) in making the calculations, although it is understood that they represent straight monthly averages instead of weighted averages. The error thus introduced for this particular period, although it is worth considering for individual months, is not material for present purposes. In Table 6, the volume of silt is computed at 100 lb. per cu. ft. The percentage of silt is as reported by the U. S. Reclamation Service. The individual determinations (8 or 9 months) appear to have been averaged—not weighted—and the monthly averages are, therefore, occasionally subject to material correction.

*Distribution Throughout Year.*—The large volume of silt considered in relation to discharge in January, February, and March (Table 6), is not

fairly representative of ordinary winter conditions for the reason that in one year of the period (1916) the winter discharge of the river at Yuma was multiplied five or six times by high stages of the Gila and other lower tributaries. The admixture of these unusual freshet waters increased the average volume of silt in suspension in January, 1916, to 3% by weight, whereas ordinarily it is between 0.2% and 1.0 per cent. The discharges in February and March, to a lesser degree, were also affected. In February, 1915, the Colorado, with more than twice its ordinary discharge, had very muddy water, the silt averaging 2.48 per cent. The data for the winter months of this particular group of years, because of such extreme conditions, do not properly indicate the probable or normal relation between discharge and silt in suspension.

In the nine years, 1919 to 1927 (Table 7), all original semi-weekly observations were given weight according to river discharge in the computation of monthly mean percentages. Consequently, these are to be regarded as more nearly in accord with actual fact than those preceding 1919, particularly for the individual months.

The total quantity of silt annually transported in suspension past Yuma, estimated from these dependable figures, is shown in Table 7; also, the average volume and the probable volume of silt per calendar month for the 9-year period.

For convenience of reference the amount of silt in suspension in the Colorado River at Yuma is given in Table 8 by years. A summary of data given in Tables 6 and 7 is listed in Table 8, together with data concerning the columns of silt in suspension. The percentages from 1911 to 1918 are based on observations which were not weighted to get monthly means. The figures for these years are, therefore, subject to some correction. The percentages from 1919 to 1927 are true means and are, therefore, to be accepted as thoroughly dependable.

#### COMPARATIVE AMOUNT OF SILT—SURFACE TO BOTTOM

*Conditions Affecting Data.*—The long-continued observations at Yuma are particularly valuable, not only because they furnish a dependable basis for estimating the quantity of silt in suspension, but also because they throw light on the distribution of the silt throughout a body of flowing water. The width of the Colorado River at the sampling station is about 650 ft. The verticals in which samples were taken were generally 130, 325, and 520 ft from the left bank.

Occasionally, samples from near the bottom show excessive quantities of silt when compared with the corresponding samples at mid-depth and near the surface. These no doubt reflect a momentary condition of bed-load salutation and should be connected with the river's bed load rather than with its suspended load. In the following deductions such clearly discordant determinations of silt in suspension have been disregarded.

The Yuma Reclamation Project Canal taps the river at Laguna Dam about 12 miles up stream from Yuma. The head-works of the canal at this point include a desilting arrangement already described. When the tem-

porary discharge through the Laguna Dam sluice-gates is large in relation to the entire flow—as at low stages—the picture of silt conditions may not be dependable. At high stages this disturbing cause is negligible.

*Classification of Findings.*—In 1916, after seven years of observations in more than 1 100 verticals (three samples each), studies of the results of these observations were made by the writer to confirm the conclusion that the admission of river water to the Imperial Canal over flash-boards, at a proposed new head-gate, would reduce the entrained bed load of silt, and, perhaps, in some measure, also, the suspended load, when compared with flow under gates of the ordinary type. The sampling at Yuma has been continued to the present by the U. S. Bureau of Reclamation and, therefore, it has been possible to supplement and extend the studies of 1916.

The observations from 1909 to 1916 were first separated into groups, according as the silt content (by weight) was: (1), Less than 1%; (2) between 1% and 2%; and (3) exceeded 2 per cent. There were 769 verticals in Group (1); 315 in Group (2); and 81 in Group (3).

A combination of the results in all verticals (1 165 in number), with sole regard to the relative quantity of material in suspension near the water surface, at mid-depth, and near the bottom, was then made. Similar combinations were made, too, for each calendar year.

The results of the studies undertaken in 1916 are shown in Table 9. The results of the more recent studies covering the period from 1919 to 1927, are given in Table 10. These data show that a little more material in suspension is to be expected at mid-depth than at the surface and still more near the bottom. In preparing Table 10, the observations were grouped roughly by periods during which the river's silt load remained fairly uniform.

TABLE 9.—DISTRIBUTION OF THE SILT IN SUSPENSION FROM WATER SURFACE TO BOTTOM IN COLORADO RIVER AT YUMA, ARIZONA.

(From observations by U. S. Reclamation Service, 1909 to 1916.)

Year.	Number of verticals.	SILT IN PERCENTAGE BY WEIGHT.		
		At surface.	At mid-depth.	At bottom.
1909.....	24	0.486	0.594	0.794
1910.....	66	0.452	0.526	0.571
1911.....	156	1.040	1.063	1.095
1912.....	201	0.652	0.660	0.682
1913.....	195	0.835	0.845	0.889
1914.....	272	0.974	1.011	1.126
1915.....	196	0.901	0.922	0.998
1916.....	55	1.280	1.441	1.485
Weighted average.....	1 165	0.86	0.89	0.96
Light load.....	769	0.49	0.51	0.59
Moderate load.....	315	1.29	1.33	1.40
Heavy load.....	81	2.67	2.74	2.78

*Turbidity Varies with Depth.*—It is to be noted that in the Colorado River, which is a very muddy stream, the increase of the suspended load downward from the surface bears no fixed relation to the loads at the surface or at mid-depth. The increase with depth is very nearly constant in the sense of being independent of the total suspended load. Thus, for example, the 769 separate determinations from 1909 to 1916, during periods with a load of about 0.5%, show an actual increase from 0.49% at the surface to 0.59% at the bottom, a percentage difference of 0.10. The 315 determinations in the same years, during periods with a load of 1.0 to 1.5%, showed 1.29% at the surface and 1.40% at the bottom, a percentage increase of 0.11; and the 81 determinations, when the load of silt was heavy, showed 2.67% at the surface and 2.78% at the bottom, or an increase in percentage of 0.11 at full depth. The combination of results in all the 1 165 verticals indicates that the percentage of silt at mid-depth is greater than that at the surface by 0.03 of the weight of water; and that at the bottom the percentage of silt exceeds that at the surface by 0.10. Corresponding comparisons for the period, 1919 to 1927, show the following increases from surface to bottom: For a light silt load, 0.12% of the weight of the water; for a moderate load, 0.08%; and for a heavy load, 0.15 per cent. The combination of results in all the 1 841 verticals of this period show 0.73% silt at the surface; 0.77% at mid-depth; and 0.84% at the bottom, the increase of the percentage being 0.04 from surface to mid-depth, and 0.11 from surface to bottom. In other words, if the percentage by weight of the suspended material in the Colorado River at the surface is represented by  $p$ , the percentage of suspended material at mid-depth may be taken at  $p + 0.04$  and that at the bottom at  $p + 0.10$ .

*Quantity of Silt in Relation to River Stage.*—The Colorado River at Yuma flows on a bed of very fine sand. The three-point determinations of silt in suspension, of which use was made in the foregoing comparisons, did not include observations at points where the depth was less than 5 ft. The average depths at the included sampling stations are indicated in Table 10. The mean velocity of the river at low stages is generally 2 to 4 ft. At high stages it may go to 6 or 7 ft. per sec. When the river is in equilibrium, there

is as much sand being picked up from the bed as is dropped from the suspended load. At such times the river bed, underfoot, appears firm, smooth, and comparatively hard, like a felt-covered floor. With a current of about 3 to 4 ft. per sec., attack on the bed quickly begins whenever there is local acceleration of velocity such as may be caused by even small obstructions, for example, the legs and feet of a man standing in the stream.

Expressed in relation to the weight of the water, there is a wide range in the turbidity of the river, as the long-continued observations disclose. The tabulated results show that the Colorado River is not as muddy at low stages as at moderately high stages—stages with a discharge of 15 000 to 50 000 sec.-ft. They also show that the turbidity, expressed in percentages, decreases as the river goes to still higher stages. This does not mean, however, that the river's load of silt decreases with increasing volume. This will become apparent by reference to Fig. 5, which shows the relation of the volume of silt carried in suspension, expressed in acre-feet per month (estimated at 100 lb. per cu. ft.), to the river discharge, this being noted both in acre-feet per month and in second-feet. In plotting Fig. 5, only the mean monthly values as determined for the two periods, 1909 to 1918 and 1919 to 1927 (see Tables 6 and 7), were used. The curve representing volume of silt was first plotted and the percentage curve was deduced therefrom.

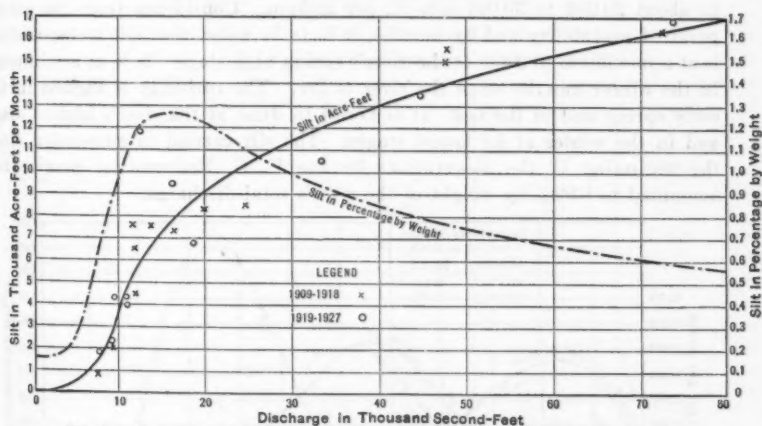

FIG. 5.—RELATION OF AMOUNT OF SILT IN SUSPENSION TO THE DISCHARGE OF THE COLORADO RIVER AT YUMA, ARIZONA.

This study should possibly have been supplemented by a more minute examination of results at the river's lowest stages when the discharge is 6 000 sec.-ft., or less, but in view of the complication resulting from the desilting operations at Laguna Dam where upward of 1 000 sec.-ft. of desilted water are frequently under diversion into the Yuma Canal, this additional study was not attempted.

The curves in Fig. 5 show a moderate increase of load until the river reaches a 6 000 sec.-ft. stage; thereupon the load in suspension, considered in

its entirety, rapidly increases from about 1 000 to 10 000 acre-ft. per month, this quantity being reached when the river is at a 25 000 sec-ft. stage. Thereafter, the increase of load continues as the river rises, but the rate of increase is less rapid. At 80 000 sec-ft. the silt carried in suspension amounts to about 16 500 acre-ft. per month, and, for still higher stages, there is an increase of about 700 acre-ft. for each additional 20 000 sec-ft. of discharge. The curve denoting percentage of silt shows that the Colorado River is muddiest when it is discharging 15 000 to 30 000 sec-ft.

The probable volume of silt carried in suspension by the Colorado River changes not only with the discharge of the river, but also from month to month through the year. This change occurs with some regularity, as is made clear by the curves in Fig. 6. In preparing the curves of probable volume the average values ascertained for calendar months for the two periods, 1909-1918 and 1919-1927, were used. Turbidity has two periods of maxima in the year, but with frequent wide departure from mean values. The probable turbidity at any time of the year appears in Fig. 6.

These curves indicate a total annual load of silt in suspension in the Colorado River of about 94 000 acre-ft., estimated at 100 lb. per cu. ft. (which is equivalent to 111 000 acre-ft. at 85 lb. per cu. ft. of deposited silt). This does not include the river's bed load, which, as shown elsewhere, may amount to about 20 000 to 30 000 acre-ft. per annum. Considered from the standpoint of probability and by months, it is to be noted that silt transportation is at a maximum in June at the river's spring high stage. It is at a minimum in the winter months when the river is low. The turbidity is highest in the early spring and in the fall. It is lowest in June at the river's highest stage and in the winter at its lowest stages. The silt carried in suspension since the beginning of the observations by the U. S. Reclamation Service has amounted to 0.90% by weight of the river's total discharge.

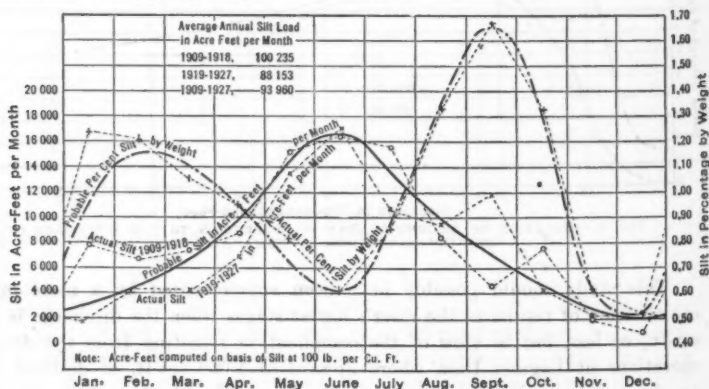

FIG. 6.—SILT IN SUSPENSION IN COLORADO RIVER.

Perhaps there are other causes affecting the degree of muddiness besides the river stage. It is suggested by Mr. J. F. Breazeale that the silt in the

lower river in many ways shows "signs of being dispersed, that is, the colloidal particles seem to be carrying negative charges."\* He believes that the source of the water and its chemical composition affects the degree of dispersion, or of flocculency, as the case may be, and, therefore, causes a greater or smaller volume of silt in suspension. He explains that, when clays are flocculated, the individual particles are fairly large, but when they are dispersed, carrying charges of negative electricity, each flocculated particle splits into many subdivisions, sometimes so small as to be colloidal.

#### VARIATION OF SUSPENDED SILT ALONG THE COLORADO RIVER

Since 1925 the U. S. Geological Survey has made determinations of the quantity of material in suspension in the waters of the Colorado River at a number of points up stream from Yuma. Some of the results are accessible in published form.† These data have enabled a preliminary comparison of the quantities of silt in suspension, expressed in percentage of weight, to be made at Lee's Ferry, Grand Canyon, Topock, and Yuma, as shown in Table 11. These values are based, at least in part, on composite samples.

\*There is a similar sheet for each month, June, 1917, to June, 1918. Figures in parentheses were supplied by the writer. Brackets have been used to show that the reported figures need correction.

tance below the Grand Canyon; in other periods, such as March to May and August, 1926, the suspended load remains fairly constant. In September, 1926, there was even a decrease of suspended load with distance below the Grand Canyon. These results seem to confirm the conclusion that at times the river picks up material from its bed and other times it drops part of its suspended load.

In the Grand Canyon and in the various narrows below, there is coarse sand and gravel in the river bed, and the silt carried by the river is supposed to be in suspension. It was hoped, therefore, that the comparison presented in Fig. 6 might disclose some facts that could be used in estimating the river's bed load, but they give no indication, except possibly that a considerable portion thereof originates below the Grand Canyon.

*The Basic Record of Silt Determinations.*—The records of the determinations of silt in suspension in the Colorado River, at Yuma, are too voluminous to be incorporated in this paper. The same is true of the records of the

sampling results on the Imperial Canal System. Sample sheets illustrate the nature and scope of these records. These are presented as Tables 12 and 13. It is to be noted that the recomputed weighted mean for February, 1920 (Table 13), is 1.70% and the volume of silt carried is 28 000 acre-ft. at 85 lb. per cu. ft., instead of 1.35% and 21 477 acre-ft., as appear in the original record. Similar recomputations for use in this paper were made, where necessary, of all Government records at Yuma since 1919.

## DISCUSSION

C. S. HOWARD,\* Esq. (by letter).†—This paper makes reference to the quantities of suspended matter found by the U. S. Geological Survey in water samples collected from the Colorado River and reported in *Water Supply Paper No. 596*. The data in that report were from samples collected for analysis of the dissolved mineral matter and are not satisfactory for making comparisons of the loads of suspended matter carried at specific times of the year.

TABLE 14.—TONS OF SUSPENDED MATTER CARRIED BY THE COLORADO RIVER  
(Based on weighted averages).

Period.	Grand Canyon.	Topock.
October 1, 1925, to September 30, 1926.....	225 000 000	140 000 000
October 1, 1926, to September 30, 1927.....	443 000 000	345 000 000
October 1, 1927, to September 30, 1928.....	189 000 000	209 000 000

The following summary is based on silt samples collected during the past three years (1925-1928), as described in *Water Supply Paper No. 636-B* which gives the complete data. Some of the data are from samples taken at the top, at the bottom, and an "average" sample. Some are from "average" samples alone, which were obtained by opening a bottle near the bottom and drawing it up at such a rate that it was full on reaching the surface. Some data for

TABLE 15.—MEAN PERCENTAGES OF SUSPENDED MATTER IN SILT SAMPLES  
COLLECTED FROM THE COLORADO RIVER DURING THE MONTHS  
OF JANUARY, APRIL, AND JUNE.

Month and year.	GRAND CANYON.		TOPOCK.	
	Percentage.	Mean discharge, in second-feet.	Percentage.	Mean discharge, in second-feet.
January, 1926.....	0.07	6 240	0.25	6 330
April, 1926.....	2.29	27 900	0.99	27 100
June, 1926.....	0.74	57 900	0.54	59 400
January, 1927.....	0.12	6 200	0.17	6 730
April, 1927.....	1.18	24 100	1.07	22 300
June, 1927.....	0.77	59 000	0.84	59 100
January, 1928.....	0.08	7 860	0.51	7 740
April, 1928.....	0.61	15 200	0.94	16 200
June, 1928.....	0.65	64 300	1.28	64 500

single days are means of results obtained in several verticals. Others are from only one vertical. Silt samples were collected at least three times a week at each station and more frequently in times of high water. All the results given in Tables 14 to 18, inclusive, are based on samples collected for the determination of suspended matter. A valuable check on the range in

\* Assoc. Chemist, U. S. Geological Survey, Washington, D. C.

† Pub. by permission of the Director, U. S. Geological Survey, Washington, D. C.

quantities of suspended matter and the sudden variations was furnished by determinations of the suspended matter in samples collected daily for analysis of the dissolved mineral matter.

TABLE 16.—MEAN DAILY LOADS OF SUSPENDED MATTER CARRIED BY THE COLORADO RIVER DURING CERTAIN PERIODS FROM NOVEMBER 1, 1925, TO SEPTEMBER 30, 1928.

(Tons, based on the computed quantities for days on which samples were collected during the designated periods.)

Period.	Grand Canyon.	Topock.
November 1, 1925, to February 28, 1926.....	38 300	70 000
March 1, 1926, to September 30, 1926.....	971 000	468 000
October 1, 1926, to February 28, 1927.....	98 100	141 000
March 1, 1927, to September 30, 1927.....	1 930 000	1 490 000
October 1, 1927, to February 29, 1928.....	73 500	196 000
March 1, 1928, to September 30, 1928.....	746 000	843 000

The results in Table 14 indicate that the suspended load carried past the Grand Canyon Station in the period, 1925 to 1927, was greater than the suspended load carried past the Topock Station; but in the period, 1927-1928, the load at Topock was greater. The differences in the loads may be explained by assuming that some of the material is deposited between the two stations and, later, under certain conditions, is scoured out and carried down the river. Since material is transported along the bottom of the river by stream traction, it seems possible that some of the material carried past the Grand Canyon Station as suspended load is carried past the Topock Station as bed load.

TABLE 17.—MINIMUM AND MAXIMUM QUANTITIES OF SUSPENDED MATTER IN THE COLORADO RIVER BETWEEN OCTOBER 1, 1925, AND SEPTEMBER 30, 1928.

Quantity.	GRAND CANYON.			TOPOCK.		
	Percentage.	Date.	Suspended matter, in tons per day.	Percentage.	Date.	Suspended matter, in tons per day.
Minimum.....	0.03	Dec. 24, 1927	3 720	0.12	Feb. 7, 1927	20 700
Maximum.....	13.8	Sept. 13, 1927	27 600 000	7.9	Sept. 16, 1927	20 600 000

The variation in the quantities of suspended matter carried past the Grand Canyon and Topock Stations during the year is shown in Tables 15 and 16. Table 15 gives the mean monthly percentage of suspended matter for January, April, and June for each of the two stations. Table 16 gives the mean daily load of suspended matter for certain periods of each year at each station.

The minimum and maximum percentages of suspended matter in the silt samples collected at the Grand Canyon and Topock Stations and the daily loads computed from these percentages are given in Table 17.

These data indicate that for the three-year period the extreme loads (both the largest and smallest) were carried past the Grand Canyon Station. The smaller loads at Grand Canyon, shown in Tables 16 and 17 for the period, October to February, are perhaps due to lack of material to be transported rather than to a deposition above the Grand Canyon Station. This suggestion

TABLE 18.—SUSPENDED MATTER CARRIED BY THE COLORADO RIVER AT GRAND CANYON AT DIFFERENT STAGES.

Date.	Discharge, in second-feet.	SUSPENDED MATTER.	
		Percentage.	Tons per day.
February 9, 1927.....	6 210	0.08	13 400
October 26, 1926.....	6 600	0.20	35 600
August 28, 1926.....	6 280	0.55	98 200
October 4, 1926.....	6 320	1.36	232 000
December 12, 1927.....	8 380	0.08	18 100
August 21, 1928.....	8 840	0.32	76 300
August 19, 1928.....	8 670	0.57	133 000
October 9, 1926.....	8 800	0.87	206 000
October 12, 1926.....	8 630	1.17	272 000

is based on the fact that for similar discharges during that period, larger quantities are carried past the Topock Station than past the Grand Canyon Station. It has been found that the range in the percentage of suspended matter carried at a given discharge is very large, as shown in Table 18.

HARRY F. BLANEY,\* ASSOC. M. AM. SOC. C. E. (by letter).—This paper is of vital interest now (1929) since it is probable that large sums of money will be spent during the next ten years building structures to control and utilize the waters of the Colorado River. The life of storage reservoirs built will depend upon the quantity of silt transported by the Colorado River.

At various times since 1917 the writer has conducted silt investigations on the Colorado River and in Imperial Valley for the U. S. Department of Agriculture under the general supervision of Samuel Fortier, M. Am. Soc. C. E., and Mr. W. W. McLaughlin.

Under the immediate direction of the late C. E. Tait, M. Am. Soc. C. E., the writer assisted Mr. J. E. Peck in collecting a large percentage of the data shown in Tables 1 and 5. A detailed description of the field and laboratory methods and equipment used is given in a report† published by the U. S. Department of Agriculture.

The results of the mechanical analyses shown in Table 1, indicate that the character of the bed silt as regards size of particles, in the bed of the main canal, varies with the discharge of the Colorado River. Thus, during March, 1917, the mean flow of the river was 9 800 sec.-ft., and the sieve analysis for March 14 of that year showed only 0.05% of the recently deposited silt in the bed of the Alamo Canal coarse enough to be retained on a No. 40 sieve. On July 15, 1917, eleven days after the passing of the peak of the spring flood

\* Irrig. Engr., U. S. Dept. of Agriculture, Los Angeles, Calif.

† Technical Bulletin No. 67, "Silt in the Colorado River and Its Relation to Irrigation", by Samuel Fortier and Harry F. Blaney, 1928, pp. 13, 36, 37, 38, and 41.

carrying 143 000 sec.-ft., the recent deposits in the bed of the Alamo Canal were much coarser in grain. At that time 12.09% was retained on a No. 20 sieve, 20.88% passed the No. 20, but was retained on the No. 40 sieve; 33.4% passed the No. 40 and was retained on the No. 60 sieve; while 7.28% passed a No. 80 sieve. These results indicate that bed silt is transported and that the high waters bring in most of the heavier silt.

Some appreciable time would be necessary, of course, for the heavier silt to travel down to the lower reaches of the canal system. If this fact is kept in mind and the July 15 analysis of the Hanlon Heading samples is disregarded, no great difference will be apparent between the character of the bed silt near the intake and that in the lower parts of the system.

In computing the volume of suspended silt carried by the Colorado River (see Tables 6, 7, and 8), Mr. Grunsky assumed the dry weight of suspended silt as 100 lb. per cu. ft. Presumably, this is based on the data given in Table 1. The writer\* is of the opinion that this value is too high for "suspended silt," because the material in the samples analyzed in Table 1 was mostly sand or "bed silt" and included very little of the finer "suspended silt." Usually, the canal bottom was hard and compact and, at such times, difficult to sample. Published estimates indicate that the weight of 1 cu. ft. of suspended silt ranges from 33 to 93 lb. according to Mr. C. S. Howard.†

That very little of the "suspended silt" was deposited in the beds of the larger Imperial Canals, is indicated by the data shown in Table 5. Mr. Tait, in referring to these data, stated:‡

"The percentages obtained from the seventeen other stations located on the system below the Hanlon Station show no appreciable reduction, thereby indicating that while great volumes of silt are removed from the canals by mechanical means each year, the amount deposited in the canals is a very small proportion of the total amount at the intake and that most of the silt entering the canals passes on to the lands irrigated."

The results of the mechanical analysis of "suspended silt" samples taken in the Colorado River at Yuma, Ariz., and the Main Imperial Canal at Hanlon Heading, Calif., by Mr. Tait and the writer, indicate that most of the suspended silt was too fine to be retained on a No. 300 sieve. Table 19 gives the results of some typical analyses of suspended silt. At the Yuma Station the total depth was 11 ft., the discharge was 23 500 sec.-ft., and the mean river velocity was 4.82 ft. per sec. At Hanlon, the depth to the bottom was 10 ft., the discharge was 5 749 sec.-ft., and the mean river velocity was 4.1 ft. per sec.

It will be noted from Table 19 that 73 to 94% of the silt carried in suspension by the Colorado River at Yuma and 77 to 95% in the Main Imperial Canal was fine enough to pass a No. 200 sieve. The difference between the two is small.

A comparison of the data shown in Table 19 with the results in Table 1, indicates that the silt found in the beds of the Imperial Canals is consid-

Perhaps the best indication of the weight of 1 cu. ft. of suspended silt (after drying), as carried by the Lower Colorado River, is shown by the data\* collected by Mr. C. A. Engle, of the U. S. Indian Irrigation Service, at Parker, Ariz. Water is supplied to the Parker Project by pumping direct from the river into a settling basin. The weight of dry silt contained in 1 cu. ft. of wet deposit taken from the settling basin varied from 42 to 77.7 lb. and averaged 57.5 lb.

Several of the domestic water-works systems of Imperial Valley have settling basins which afford an opportunity to determine the weight and volume of "suspended silt" deposits.† Samples of these deposits taken by Mr. Peck show dry weights of silt per cubic foot of sediment ranging from 32.3 lb. for the softest material to 52.4 lb. for the most compact material, with an average of about 40 lb.

After a recent investigation of the quantity of suspended matter carried by the Colorado River, Mr. Howard stated‡ that suspended matter from daily samples collected for the U. S. Geological Survey, which were allowed to settle in tubes for a period of more than six months, showed a weight equivalent to about 34 lb. per cu. ft. of the deposited material. These samples did not contain the larger particles in their proper proportions, as the daily samples were taken from the bank. Samples of material from the bottom of the river collected in the experiments on the bed load showed a weight equivalent to 98 lb. per cu. ft. of the material after settling for four months.

\* Technical Bulletin No. 67, U. S. Dept. of Agriculture, p. 71.

† Loc. cit., p. 70.

‡ Water Supply Paper 636-B, U. S. Geological Survey, "Suspended Matter in the Colorado River in 1925-1928", pp. 26-27.

Samples of river deposits\* taken by Mr. McLaughlin and the writer along the Colorado River at Laguna Dam, Yuma, and Imperial Valley Heading, indicated that the unit weight of dry silt in 1 cu. ft. of river deposits ranged from 73.2 lb. for the finer material to 90.7 lb. for the coarser, with an average of 81.6 lb. The material was a mixture of bed silt and sediment formerly carried in suspension, taken from the river's edge where it had been deposited at a low stage. Samples of bed silt taken from canals of the Imperial Valley, about the same time, averaged approximately 100 lb. per cu. ft.

Determinations of the silt content of the river water are usually made on a weight basis. A "percentage of silt by weight" is equivalent to the grammes of dry silt contained in 100 grammes of water, and is derived by weighing the water and then the dry silt, and taking the proportion of the latter to the former. The engineer, from a practical standpoint, is more interested in the volume of silt than in its weight. In order to convert the results of silt samplings on a weight basis to volume, it is necessary to assume the weight of dry sediment in 1 cu. ft. of suspended silt.

After giving careful consideration to all available data, the writer and Mr. Fortier came to the conclusion that the average weight of dry silt contained in 1 cu. ft. of suspended silt, as carried by the Lower Colorado River, would be approximately 62½ lb.† The determination of this weight, while only approximate, simplifies the conversion of the silt content of water from a weight to a volume basis in that percentage of silt by weight equals percentage by volume. The writer is of the opinion that this weight will approximate that of suspended silt deposited in the bottom of a reservoir created by a high dam, such as that at Boulder Canyon, provided the deposits are not given an opportunity to dry out and thus destroy their colloidal condition. However, a mixture of suspended and bed silt deposited on the delta of the Colorado River undoubtedly would dry out and compact sufficiently to approach a dry weight of 100 lb. per cu. ft. after a period of years.

Differences in opinion as to the weight of 1 cu. ft. of silt have resulted in estimates of the average volume of suspended silt that would be deposited annually in reservoirs on the Colorado River ranging from 80 000‡ to more than 250 000§ acre-ft. per year.

At the rate indicated by the higher estimate, the proposed Boulder Canyon Reservoir would probably be almost filled with silt in about 100 years, while at the slower rate the deposited silt would occupy about one-third of the reservoir capacity in the same length of time, provided no other dams were built above it during this period.

A report|| published by the U. S. Geological Survey indicates that most of the previous estimates are too low because the annual load of suspended matter computed from samples collected at Grand Canyon was considerably larger than the average annual load computed from samples collected at Yuma.

|| Water Supply Paper 636-B, U. S. Geological Survey, "Suspended Matter in the Colorado River in 1925-1928", by C. S. Howard, p. 28.

This report states that the volume that will be occupied by the suspended matter is unknown, but that it seems probable that estimates based on 33 lb. and 86 lb. per cu. ft. of the deposited material represent fairly well the extreme conditions of deposition. On the basis of 33 lb. per cu. ft., the quantity of suspended matter carried past Grand Canyon in 1925-26 would occupy 313 000 acre-ft.; if deposited in a reservoir; the volume for 1926-27 would be 617 000 acre-ft.; and the volume for 1927-28 would be 263 000 acre-ft. On the basis of 86 lb. per cu. ft., the corresponding figures would be 120 000, 237 000, and 101 000 acre-ft., respectively.

E. S. LINDLEY,\* M. Am. Soc. C. E. (by letter).—The observations described in this paper began with an attempt to fix a permanent cross-section; they soon showed its utter instability. Under somewhat similar conditions, the writer found a special application of ordinary rating curves useful.

The conditions referred to are those of the Indus and its tributaries within the Panjab; gradients range from several feet in the mile to less than a foot, in alluvium without any harder formations. Current meters were introduced only during the writer's incumbency, and the observations then available had been made only with surface floats. Supervision had been difficult; observations of higher river stages had generally been impossible; the only good point was that when observations were possible they had been made daily. No individual observation could be accepted as reliable. As a test, as well as for other purposes, it was eminently desirable to try temporary or gradually changing rating curves. In the result, although some of the observations were shown to be utterly unreliable, the majority were very much better than was anticipated.

A most useful tool was found in plotting the square roots of discharges against gauge-levels; this made each rating curve approximately a straight line, and avoided the difficulty of locating a curve of greatly changing curvature.†

The rating curves of these shifting sandy rivers were found to be much more stable than was expected. Often a curve held good from the cessation of monsoon floods until the winter flood season; there were no data for monsoon flood seasons, but smaller floods affected the curves less than had been expected.

While it was constantly necessary to guard against giving these rating curves undue weight against actual observations, opportunity arose of definitely proving them. About six successive observations at one site were quite consistent among themselves, but disagreed with the curve for the season. They were found to be wrong when discharges passing that site were compared with those above and below. When evaluating losses and gains between successive sites, more consistent results were obtained from daily discharges taken from the curves than from actual daily observations.

This relative stability of rating curves can be understood if it be remembered that an individual silt dune across the river will hardly affect water

\* Superintending Engr., Indian Public Works Dept., Panjab Irrig. Branch, Wotton-under-Edge, Gloucester, England.

† *Minutes of Proceedings*, Inst. C. E., Vol. CCXVII (1923-24), pp. 401-404.

levels above it, although it will produce higher velocities and a steeper gradient in its own area. The gauge at which a given discharge passes depends on the "average" bed level for some distance below the gauge site, that average being reached by weighting divergences from the mean grade according to their nearness to the gauge. (It is not suggested that this average can actually be calculated.) Therefore, a mere shifting of silt banks is likely to have no practical effect on the rating curve, and the relative gauge height at which the curve stands from time to time is some measure of the more extended changes of general bed level.

In the observations described in the paper, an attempt was made to establish a dependable value of Kutter's  $n$  by applying the average gradient of an 8 000-ft. length to the average cross-section of a 200-ft. length; but this shorter reach may be one of a number in which the depth is either small with high velocity and sharp local gradient, or great with low velocity and flat local gradient; or it may be one in which velocity is either decreasing or increasing. To determine the value of  $n$  dependably, it seems necessary to sound a length of channel sufficient to average these conditions. Friction losses and values of  $n$  may depend less on the rugosity as ordinarily estimated from the channel surface than on the spacing of decelerating sections from rapids to pools, which may be considered a large-scale rugosity and is independent of the former.

In a paper describing observations in Egypt the author, Mr. Arthur Burton Buckley, asserted\* a relation between the value of  $n$  and the silt charge carried by the flow. In the discussion a number of possible physical explanations for the existence of such a relation were suggested, none of them really satisfactory. A possible explanation that did not then occur to the writer is that the humps and deeps of large-scale rugosity are likely to be more smoothed out in the floods that carry silt. It would be of interest to know whether the observations described in this paper throw any light on this question.

The author quotes a series of analyses which seem to show that the silt along the entire canal system was similar. In 1915 similar observations were made on the Lower Jhelum Canal in the Panjab, and on some neighboring inundation canals. Samples were collected from just under the surface of silt banks when the canal was not in flow, at a number of points from the head to the tails, outside and inside offtakes. Those of the observations that came under the writer's notice showed fineness increasing regularly with distance from the head. Most offtakes have a tendency to take more than their share of silt, especially the coarser grades; but the pairs of samples at offtakes showed differences insufficient to account for the disappearance of coarser silt; it was not being eliminated by deposition, as there was no steady accumulation of silt anywhere. It was then suggested that even fine silt is subject to attrition, as gravel and shingle are known to be in swifter streams.

The author refers to "boils" on the water surface, and suggests that they are due to the sudden slipping of areas of the river bottom. The writer believes that he has seen them formed over the paved floors above the under-

\* "The Influence of Silt on the Velocity of Water Flowing in Open Channels," *Minutes of Proceedings*, Inst. C. E., Vol. CCXVI (1922-23), p. 183.

sluices of Panjab head-works, where it was improbable that the bed silt had any chance of coming to rest in the course of its flow.

The author's reference to "rhythmic pulsation as if elongated waves were following each other down the river," recalls some points observed by the writer. At the up-stream pier noses of canal bridges there is generally a rhythmic pulsation of water level, up to about 6 in. at some bridges. The pulsations at adjacent piers are of opposite phase, up at one pier when down on the other. The down-stream "wake" of each pier swings from side to side rather sharply, in time with this pulsation. Although the phenomenon did not seem to have any practical importance, the writer once filled some idle minutes by observing it. A pulsation of the same period was observable at the sides of the canal up stream, diminishing with distance, but still noticeable 2 or 3 miles up stream. The water surface showed slight waves; their approximate spacing divided by the approximate mean velocity of flow roughly agreed with the period of pulsation. It had then become too dark to see whether they were moving; they seemed to be on diagonal lines. No observations of the canal bed were made for comparison, but it has been seen to show dunes 6 to 12 in. high in a 5-ft. depth of water, extending across an appreciable part of the width in single lines, and of about the same wave length as the surface waves; but the dunes would only move very slowly, down stream. Rough figures from memory are a 5-sec. period, 15-ft. wave length, and 3-ft. velocity.

THADDEUS MERRIMAN,\* M. Am. Soc. C. E. (by letter).—The author has assembled and referred to much of the available data relating to the suspended load carried by the Colorado, but the important question as to how much material this river transports as bottom load is treated only as an incident. Through the literature the writer has long been familiar with this river, and a recent opportunity of examining it between Black Canyon and Yuma prompts him to submit the following observations and deductions.

As the discharge of the Colorado increases, a substantial part of the increase in wetted cross-section results from a scouring out of its bottom and sides. The high-water marks along the river between Black Canyon and Yuma bear mute yet convincing testimony that this under-deepening, at all points of approximately equal width, where the channel is confined by hard shores, is of practically equal volume.

As the discharge increases in the spring of the year the bed of the stream is lowered and widened and the surface rises until a maximum depth is reached at or about the time of maximum discharge. Gauge heights during the flood season on the Colorado vary much more uniformly than on many other rivers because: (a) The source of the water is largely in the melting snows; and (b) the regulating effect of the long length of river between Glen and Black Canyons tends to iron out the irregularities of flow. By reason of this approximation to uniformity of discharge, long stretches of the river may, at any one time, be said to be at a proportionately equal flood stage. At such a time, therefore, the Colorado channel within any such stretch will have been excavated to sections corresponding to the river discharge. Now if the rate of

\* Chf. Engr., Board of Water Supply, City of New York, New York, N. Y.

discharge be maintained for a period sufficiently long for the water to travel, say, from Black Canyon to Yuma, then all the material excavated between these points will have been carried to and delivered below Yuma. The flow records at the Topock and Yuma gauging stations indicate that this condition frequently occurs.

A flood as it advances picks up material in proportion to the velocity of flow and thus the bottom load is increased, while a receding flood is constantly reducing the burden it carries. The quantity of bed material moved out by any flood is equal to the product of its crest length and the area of the deepening induced within that length. At or near the maximum gauge height the river transports a maximum of bottom load, and as long as the gauge height and the cross-section remain constant the quantity transported is the same for each unit of time.

Every flood coming down the Colorado carries in its bilges sufficient material to refill the space which it excavates. The numerical difference between the volume of material removed from any section of the river bed and the volume later deposited therein is always sensibly equal to zero. Were this not so, the regimen of the river above the delta area would show progressive changes.

Bearing in mind the foregoing considerations, it is possible to predicate, (1) that at low-water stages the bottom load is small; and (2) that, as the flow varies, the bottom load in any unit of river length will vary directly with the scoured-out area of the wetted cross-section and inversely as the average velocity of flow.

It thus follows that the scoured-out area and the average velocity together constitute a direct measure of the bottom load. That is, the bottom load at any instant in any unit length of the river cross-section is equal to the scoured-out volume of that cross-section divided by the average velocity of flow. Did this equation or condition of equilibrium not obtain, the scoured-out area could never be refilled to its original condition. This fundamental, on which the argument presented is based, may also be stated as follows:

The bottom load carried per unit of time is equal to the volume of material scoured out per unit of length.

This expression is a simple statement that the continuity of the equilibrium always remains unchanged.

By way of example, if the low-water section area is 3 000 sq. ft. and if this be scoured out by 8 000 additional sq. ft., while the surface rise adds 6 000 sq. ft., then the total section area is 17 000 sq. ft., and the bottom load in any section of unit length is 8 000 cu. ft. divided by the mean velocity, say, 6 ft. per sec. The bottom load thus is 1 333 cu. ft. per unit of channel length, and thus 7.8% of the water volume is solid material in motion. As the flow falls off, the condition of equilibrium being maintained, the bottom load is immediately reduced and the bed is partly refilled. Thus if, with a total section area of 8 000 sq. ft., the scoured-out area is 1 000 sq. ft. and the mean velocity is 5 ft. per sec., then 2.5% of the water volume will be bottom load.

The principles advanced should be of ready application, although the writer is aware that certain practical difficulties will arise. In the first place, the Colorado, even at its lowest stages, carries an appreciable bed load and so the zero datum of the scoured-out area may be determined only through a series of approximations; and, secondly, it may develop, on further analysis, that what the writer has designated as bed load may, in fact, be the total load.

The equation of river equilibrium, herein stated, should also find application to a case such as that which the Colorado below Black Canyon will present after the completion of the reservoir at that place. Here, the existing equilibrium will be destroyed, and the river will immediately set itself to the task of establishing new conditions of stability. The effects produced as this process proceeds may be forecast by means of the principle of the continuity of the equilibrium.

Accurate knowledge of the total silt load carried by the Colorado is of vital importance in connection with the many developments which center about its waters. The volume of suspended load reported by the observations of the various Governmental departments seems too small to account reasonably for the actual erosion from the 155 000 000 horizontal acres of the Colorado water-shed above Yuma. The conditions on this water-shed are such as to facilitate erosion and the forces at work are great and ever-acting, even under the prevailing small rainfall. It is even conceivable that, in times past, under a greater precipitation, the total erosion may not have been markedly greater than it is under the conditions of to-day. A low rainfall in a barren country may easily be the cause of more erosion than several times that rainfall on an area closely covered with vegetation.

The principles presented, when applied to the records of flow and change in cross-section areas at the Yuma, Topock, Bright Angel Creek, and Lee's Ferry gauging stations, will, it is believed, shed much light on the problem of the bed load which the Colorado yearly delivers to its delta. In any event, the indications are that the volume of this load, when determined, will prove to be substantially greater than the suspended load which is now known within reasonable limits.

IVAN E. HOUK,\* M. A. M. Soc. C. E. (by letter).—The author has contributed much of value to the subject of silt transportation. He has also presented some interesting discussions of miscellaneous river phenomena, such as boils, pulsations, sand waves, etc. The conditions which cause the formation and occurrence of sand waves are fairly well understood, but those resulting in boils and pulsations are more or less uncertain, despite the fact that such phenomena occur in practically all conditions of flowing water.

Sand waves are known to result from the movement of material on the stream bed. Their action can be studied intensively in the larger sluicing works at canal intakes such as have been built on many irrigation and power projects of Western United States. In the settling basin at the Fort Laramie Canal intake, North Platte Irrigation Project, in Wyoming, sand waves fre-

\* Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

quently form during sluicing operations.\* Sometimes they form at the outlet end of the basin and move up stream as fast as a man can walk. (See Figs. 7 and 8.)

In 1914 the writer made some investigations of boils and pulsations in the flow of the Miami and Erie Canal at Dayton, Ohio. The section of the canal investigated was about 50 ft. wide and about 3 ft. deep; it had a slope of approximately  $\frac{1}{4}$  ft. per mile, and usually carried from 100 to 150 sec-ft. of slightly turbid flow at average velocities of less than 1 ft. per sec. No measurable proportions of sand or silt were transported and no movement of material occurred on the stream bed. The investigations were made in connection with the roughness factor experiments described in the Miami Conservancy District Technical Reports and a detailed description of the location was included in that publication.† However, the results of the investigations of boils and pulsations were not published.

Although the quantities of water flowing in the canal were relatively small, and the velocities relatively low, the conditions of flow were quite irregular. At times, the water surface would be covered with boils of varying magnitude; at other times, it would appear to be perfectly smooth and uniform. Sometimes, the surface would be so smooth that the entire body of water would appear to stop and remain stationary for a few seconds, and then to move on down stream in a solid mass with only minor surface disturbances. On other occasions the current would shift from one side to the other in a very noticeable manner. Although in a few cases the water would seem to boil up from the bottom and spread out on one side, or on all sides, without any apparent regularity, in the majority of cases there was a definite rotary movement. The direction of rotation was practically always contra-clockwise on the left side of the channel, and contra-clockwise in the majority of cases on the right. Although theoretically, this direction of rotation would be caused by the rotation of the earth, it is much more likely that the conditions that caused the formation of the boils also caused the direction of rotation, except for such effects as would be produced by the velocity distribution in the canal. Since the velocities increased from the sides of the channel toward the center, the velocity distribution would tend to cause a contra-clockwise rotation on the left side of the canal.

The investigations of boils and pulsations were made for the purpose of determining what, if any, relation existed between these two phenomena; whether they had any effect on the accuracy of current meter gaugings of discharge; and whether their formation and occurrence were in any way related to the growth of moss on the bed and sides of the channel. Observations consisted of careful, prolonged, current meter measurements of velocity, at two-tenths and eight-tenths of the depths, at certain stations in the cross-section, for the purpose of determining velocity pulsations. Notes were taken regarding size, frequency, location, direction of rotation, and general characteristics of boils. Readings were taken on September 15, October 6 and 9,

\* "Sand Control Works at Fort Laramie Canal Intake," by Ivan E. Houk, M. Am. Soc. C. E., *Engineering News-Record*, June 14, 1928, p. 922.

† "Calculation of Flow in Open Channels," by Ivan E. Houk, M. Am. Soc. C. E., Miami Conservancy Dist. Technical Repts., Pt. IV, Dayton, Ohio, 1918, p. 111.

and November 6, 1914. On the first date, the channel was in ordinary mid-summer condition, weeds and grass lining the banks and moss covering the bottom in many places. On the second and third dates, the sides and bottom of the channel had been thoroughly cleaned of weeds, grass, moss, and debris through a distance of about 50 ft. extending up stream from the gauging station; and both banks had been cleaned to some extent for several blocks in both directions. On the last date mentioned, the sides and bottom had been very carefully cleaned of all obstructions for about  $\frac{1}{4}$  mile in each direction.

No connection whatever could be observed between the boils noticeable on the surface and the velocity pulsations indicated by the current meter; the variations in velocity at times were greatest when the surface appeared to be entirely free from disturbances, and at other times they were greatest when the surface was covered with boils. The cleaning of the 50-ft. section just above the gauging station seemed to make conditions definitely worse than they were before, especially in regard to pulsations. Cleaning the entire canal for some distance in both directions resulted in better conditions of flow than were observed on the second and third dates. However, the flow was still more irregular than it had been before any cleaning was done. Apparently, the weeds and moss acted somewhat like baffles in a settling basin, breaking up the pulsations instead of creating them as had been thought possible. The cause of the formation and occurrence of the boils and pulsations was not learned. It is quite likely that the pulsations were related in some way to flow conditions at points up stream, such as the discharge from water wheels at plants along the canal which used the flow for power purposes. The boils probably were related in some way to irregularities in the bed of the channel although there was no shifting of materials on the canal bed. Pulsations in velocity were definitely more pronounced at eight-tenths of the depth than at two-tenths, as would naturally be expected. It was concluded that current meter gaugings by the usual two-point method might be in error as much as 4% due to the effect of pulsations.

The author's estimates of quantities carried as bed loads in Imperial Canal and Colorado River, although naturally approximate, are well worth consideration. The estimate of from 25 000 to 30 000 acre-ft. as the annual bed load of the Colorado River at Yuma, Ariz., does not seem unreasonable when studied in connection with the long and careful record of silt samples taken from the river flow at that location. Such an estimate is approximately 25 to 30% of the total average annual silt load indicated by the samples.

The writer does not feel sure that the bed-load problem is as much of a bugaboo as it is usually made out to be; or that a large part, if not all, of the bed load is not properly considered in a carefully designed and regulated system of silt sampling. It is generally assumed that silt sampling determines the suspended load only. However, the writer is inclined to believe that samples taken at, or just above, the river bottom, as approximately one-third of the samples were at Yuma, include a large proportion of bed-load material. Consequently, estimates of annual silt load based on such a record would tend to include a large part of the so-called bed load.

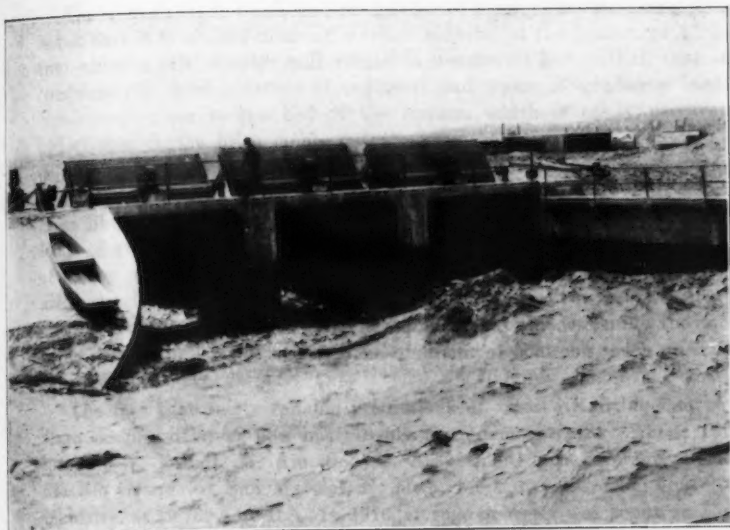

FIG. 7.—VIEW OF TYPICAL SAND WAVES, FORT LARAMIE BASIN, DURING SLUICING PERIOD WITH VELOCITIES VARYING FROM 10 TO 15 FEET PER SECOND.

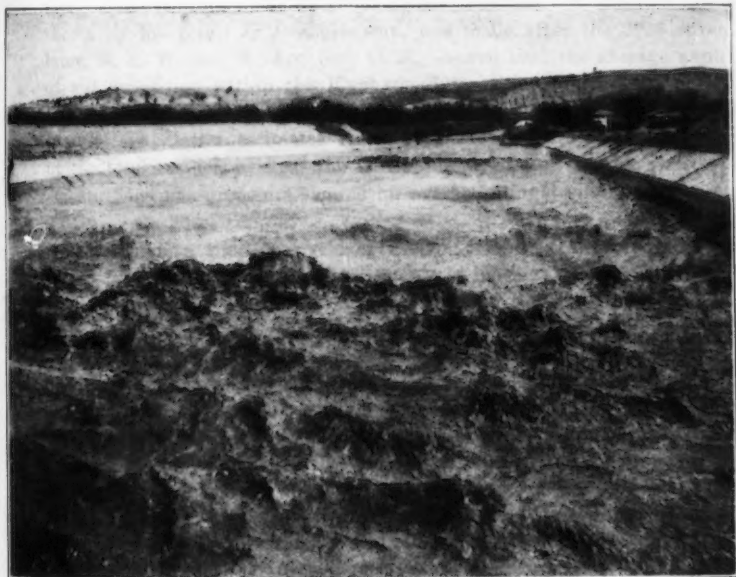

FIG. 8.—SAND WAVES IN SETTLING BASIN AT FORT LARAMIE CANAL INTAKE, DURING SLUICING OPERATIONS.

The writer's idea of bed load in the case of a river like the Lower Colorado is not that it is a solid mass of moving material at the bottom of a channel, into which a silt sampler will refuse to penetrate; but, rather, that it is a comparatively thick mixture of sediment and water of gradually increasing consistency, close to the bed of the stream, which is easily penetrated to appreciable depths by a comparatively heavy sampler and, consequently, is capable of being sampled. Of course, accurate samples of flow at the bottom of the channel could not be expected in the case of extremely large floods in a river like the Colorado; or in the case of large streams transporting heavy loads of gravel, cobbles, or boulders by saltation, unless unusually large sums of money were available for such investigations. However, there undoubtedly are many silt-bearing streams of characteristics such that a carefully regulated and relatively inexpensive system of sampling would determine the total silt load. This would be especially true of artificial channels, such as irrigation canals.

The fact that fairly reliable predictions of reservoir silting can be made from samples of river flow has already been demonstrated. About 1913, the late W. W. Follett, M. Am. Soc. C. E., estimated the average silt load of the Rio Grande at San Marcial, N. Mex., for the period from 1897 to 1912, inclusive, at 19 739 acre-ft.\* In 1916, storage of water was begun in Elephant Butte Reservoir, just below San Marcial; and since that time rates of silt deposition within the reservoir have been determined by hydrographic and topographic surveys made at about 5-year intervals. A study of the results shown by the reservoir measurements was made after the 1925 survey and, later, R. F. Walter, M. Am. Soc. C. E., showed that the average annual rate of silt deposition within the Elephant Butte Reservoir, for the period from 1916 to 1925, was 20 508 acre-ft., or only 4% greater than Mr. Follett's estimate.† The latter estimates showed an average silt load equal to 1.66% of the total run-off, whereas the U. S. Bureau of Reclamation's reservoir and stream flow measurements showed an average annual silt deposition equal to 1.64% of the total run-off.

Silt entering the upper end of Elephant Butte Reservoir, although relatively fine, is coarser and heavier than silt in the Colorado River at Yuma. Consequently, the proportion of total silt load carried as bed load probably is greater in the Rio Grande than in the Colorado. The total annual flow in the Rio Grande is much less than in Colorado, floods are much smaller, and bed-cutting during flood periods is much less pronounced.

Mr. Follett's estimate of average annual silt load at San Marcial was based on a 16-year record of stream flow and silt sampling, the first half of which was computed from observations at El Paso, Tex., proper corrections being applied to allow for differences in discharge at the two locations. Only a limited number of samples were available for determining the silt content of the river during the first 8-year period; but a total of 824 was available for the second, which was an average of 103 samples per year for the last 8 years

\* "Silt in the Rio Grande," by W. W. Follett, *Bulletin*, U. S. Dept. of State.

† *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1727.

of the 16-year period. Mr. Follett's estimates may have contained compensating errors which would not necessarily exist in other cases. He assumed the average unit weight of dry Rio Grande sediment to be 53 lb. per cu. ft., a figure obtained by securing one 3-in. cube of silt and determining its dry weight. The cube was carefully cut from a sediment bar just above the Mexican Dam, at El Paso, on June 29, 1904, after the spring flood had subsided and after considerable shrinkage had taken place in the silt deposit. The Bureau of Reclamation's subsequent investigations indicate an average weight of 85 lb. per cu. ft. for dry Rio Grande silt. Moreover, it is understood that after Mr. Follett's *Bulletin* was published an error was found in his original computations, and that the correction of this error would have increased his value of 53 lb. per cu. ft.

If it is assumed that Mr. Follett's estimates of silt load volume should have been based on a unit weight of 85 lb. per cu. ft. instead of 53 lb., his estimate of average annual silt load at San Marcial would have been 12 308 acre-ft. instead of 19 739, or only 60% of the Bureau of Reclamation's measured value. Assuming the value obtained from the reservoir surveys to be correct, the estimate made from the samples of river flow, which, in this case, would be mostly suspended sediment, would leave 8 200 acre-ft., or 40% of the true total, as a possible average annual bed load in the Rio Grande. It thus appears that Mr. Follett's use of a relatively low unit weight of silt may have approximately offset his inability to secure accurate quantitative data on bed-load transportation. However, be that as it may, the interesting fact remains that his estimate of average annual silt load was almost identical with the value obtained by careful reservoir surveys.

C. E. GRUNSKY,\* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—There is little to add to the discussion of this paper. The question is brought up by Mr. Blaney as to whether 100 lb. per cu. ft. is in fact a proper weight to apply in determining the volume of Colorado River silt from the weight of suspended matter. It is well known that investigators of the character of the silt of the Colorado River, as a rule, have adopted a much smaller figure. However, if the material in the delta region of the Colorado River is examined, all of which was deposited in the course of time by the river, it will be found that 100 lb. is not so very far out of the way. This value was used because it facilitates computation of volume on any other basis of weight and because the few samples taken of the deposit in the stream or canal channels had a weight approximating 100 lb. per cu. ft. The suspended material, freshly deposited, occupies more space and is lighter than it will be after some years, particularly if occasional opportunity is given for it to dry out. How much volume any given weight thereof will occupy in a large reservoir after a series of years has not yet been ascertained.

Some fairly definite basis for estimating a lower limit of the Colorado River's bed load is given in the paper. The gauging work at Yuma has disclosed that at high water the bed of the river may be depressed at that point about as much as the river stage rises above normal. It is not likely that such

\* Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

deepening of channel is coincident at all points of the Lower Colorado, as Mr. Merriman assumes, for the purpose of establishing a basis for a silt formula. If this were the case all the eroded material would appear as the river's suspended load during long periods and there would still remain the difficulty of estimating the bed load—the term, bed load, being used to designate the material rolled along the bottom or moving by saltation within an inch or so of the bottom. It was hoped that the discussion of the paper might disclose other facts than those cited, bearing on bed loads, but this has not been the case.

Mr. Houk is inclined to assume that a part of the bed load of the river is usually reported as suspended material. Whatever the sampling of the water for material in suspension discloses is to be classed as material in suspension no matter how near the bottom the sample is taken. The bed load includes only the material which, under the influence of the current rolls along the bottom up the back of a wave of sand and down its face, or up the long upstream slope of a gravel or sand-bar and down its steeper down-stream face. There is no movement throughout the mass of submerged sand or gravel. All movement is of the sand grains or gravel particles at the surface of the sand or gravel mass; but this movement carries the individual particles forward over a crest and brings them to rest in valleys or deeps where they remain until the wave or bar has traveled its full length, whereupon any particle in question again travels, by rolling or in minute saltations, the full length of the wave or bar. A gravel bar in the Sacramento River, for example, near Princeton, was about  $\frac{1}{4}$  mile farther down stream at one low-water period than it had been the year before. The entire movement of this bar, which had a length of possibly  $\frac{1}{2}$  mile, resulted from the travel of gravel particles by rolling from its up-stream edge over its back and crest to its down-stream end where they would fall to the level of the base of the bar. There they would come to rest as explained and would remain so until all other particles composing the bar had made a similar journey. The bed load of the river at this point is represented by the volume of the bar and its longitudinal displacement in the time interval between observations.

The writer desires to again emphasize the fact that the bed load is in no sense dependent upon, or ascertainable from, the load of sediment which a river carries in suspension.

### ANALYTICAL SOLUTION OF MASONRY DOMES: UNBALANCED LOADS\*

By DAVID C. COYLE,† M. Am. Soc. C. E.

With Discussion by MESSRS. A. FLORIS, and DAVID C. COYLE

#### SYNOPSIS

This paper is a continuation of the theory of masonry domes, the elementary formulas of which are given in a paper‡ previously published by the Society. The following discussion deals with the more advanced theory involved in the problems of partial loadings and wind loads.

The assumptions are necessarily in the nature of very rough approximations, but in the investigation of unbalanced loads the aim is not so much to get an exact knowledge of the actual stresses as to obtain a theoretical assurance that in the case of some particular dome these stresses may safely be neglected. The formulas based on roughly approximate assumptions will give results which indicate the order of magnitude of the stresses in question and, in this way, serve as a guide to the judgment in unusual or extreme cases in which previous experience cannot be called upon for guidance.

Following a summary of the notation and the elementary formulas from the previous paper, the discussion deals with four cases: (1) Live load on one-half the dome; (2) live load on the center part only; (3) live load on the haunch only; and (4) wind load.

#### NOTATIONS§

The following is the general notation used:

$A$  = meridional stress, in pounds per foot of horizontal section, for dead or balanced loads.

\* Published in August, 1929, *Proceedings*.

† Cons. Engr. New York, N. Y.

‡ "Analytical Solution of Masonry Domes," by David C. Coyle, M. Am. Soc. C. E., *Transactions, Am. Soc. C. E.*, Vol. 88 (1925), p. 102.

§ *Loc. cit.*, p. 103.

$A_L, A_W, A_T$  = same meridional stress for unbalanced live load, for wind, and for total loads.

$B$  = ring stress, in pounds per foot of profile.

$B_L, B_W$ , and  $B_T$  are analogous to  $A_L$ , etc.

$C$  = tension in the top ring of a vertical support, or compression in the bottom ring of a vertical lantern, in pounds.

$C_L, C_W$ , and  $C_T$  are analogous to  $A_L$ , etc.

$V_L, V_W$ , and  $V_T$  = shear on the horizontal or vertical planes at any point, due to unbalanced live load, wind, and total, respectively.

$W$  = sum of all balanced loads above a given level,  $x$ .

$p$  = balanced load per square foot, at level,  $x$ .

$G$  = sum of all partial live loading above level,  $x$ .

$g$  = partial live load per square foot, at  $x$ .

$P$  = sum of all wind pressures above level,  $x$ .

$f$  = wind load per square foot, at  $x$ .

$x$  = distance of any point above reference plane.

$y$  = abscissa from axis of dome (plus to the right).

$z$  = horizontal ordinate perpendicular to  $y$  (see Fig. 1).

$R$  = radius of curvature of profile at  $x$ .

$r$  = horizontal distance from  $x$  to axis of dome.

$\theta$  = angle between radius,  $R$ , and horizontal.

$H$  = radial bursting force on a circle of radius,  $r$ , for an area of 1 ft. of circumference times 1 ft. of profile, in pounds per square foot.

$e$  = eccentricity of an unbalanced load.

The following notation applies to pyramidal domes:

$R$  = radius of curvature of the profile on a diagonal at  $x$ .

$D$  = semi-diagonal of a horizontal section at  $x$ .

$d$  = semi-diameter of a horizontal section at  $x$ .

$n$  = number of sides of polygonal horizontal section.

$L$  = side of a polygon on a horizontal section at  $x$ .

$\phi$  = angle between diagonal and side of polygon.

$M$  = bending in a horizontal element at level,  $x$ , in foot-pounds per foot of profile.

The following notation applies to spherical domes:

$S_0$  = height from top of dome to level,  $x$ .

$p$  = uniform weight per square foot of shell.

$g$  = uniform live load per square foot on loaded area.

$f$  = uniform wind load per square foot on the entire surface of a dome.

$h$  = height from center of sphere to point,  $x$  ( $h = x$  in Fig. 1).

$V$  = weight of lantern, in pounds.

$w$  = weight of shell per cubic foot.

$t$  = thickness of shell,  $= \frac{p}{w}$ .

The following notation applies to conical domes:

$a$  = vertical height of apex of cone above  $x$ .

$h$  = vertical height of top of masonry above  $x$ .

$s$  = slant height of top of masonry above  $x$ .

$r_0$  = horizontal radius at top of masonry.

$p$  = uniform weight of shell per square foot.

$g$  and  $f$  = uniform live loads and wind loads per square foot.

## ELEMENTARY FORMULAS FOR BALANCED LOADS\*

*Conoids*.—The ring tension at the level,  $x$ , equals

$$B = \frac{W}{2\pi R} \sec^2 \theta - p r \tan \theta \dots \dots \dots (1)^\dagger$$

The meridional compression at the level,  $x$ , in pounds per horizontal foot of circumference, equals:

$$A = \frac{W}{2\pi r} \sec \theta \dots \dots \dots (2)$$

The tension in the top of a cylindrical support, or the bottom of a cylindrical load, applied at the level,  $x$ , equals

$$C = \pm \frac{W}{2\pi} \tan \theta \dots \dots \dots (3)$$

In a closed dome pointed at the top, the stresses near the top are:

$$B = \frac{p r^2}{2 R \sin \theta} \sec^2 \theta - p r \tan \theta \dots \dots \dots (4)$$

$$A = \frac{p r}{2 \sin \theta} \sec \theta \dots \dots \dots (5)$$

In a closed dome rounded at the top, the stresses are:

$$A = B = -p \frac{R}{2} \dots \dots \dots (6)$$

The corresponding equations for pyramids are:

$$B = \frac{W D}{n L R} \sec^2 \theta - p D \tan \theta \dots \dots \dots (7)$$

$$A = -\frac{W}{n} \sec \theta \dots \dots \dots (8)$$

$$C = \pm \frac{W D}{n L} \tan \theta \dots \dots \dots (9)$$

The bending in a horizontal element, 1 ft. high, is,

$$\pm M = \frac{W L D}{12 n R d} \sec^2 \theta - p \frac{L^2 D}{12 d} \tan \theta \dots \dots \dots (10)^\ddagger$$

The equations corresponding to Equations (1), (2), and (3), for spherical domes, are:

$$B = \frac{R^2}{r^2} S_0 p - p h \dots \dots \dots (11)$$

$$A = -\frac{R^2}{r^2} S_0 p \dots \dots \dots (12)$$

$$C = \frac{R}{r} S_0 p h \dots \dots \dots (13)^\S$$

\* Positive sign indicates tension.

† *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 105, Equations (4), (5), and (6).

‡ *Loc. cit.*, p. 107, Equation (11), corresponding to this formula, is incorrect.

§ *Loc. cit.*, Vol. LV (1905), p. 214, Equation (4).

For conical domes the stresses are:

$$B = -\frac{p r^2}{a} \dots \dots \dots (14)$$

$$A = -\frac{p s^2}{2 h} \left( \frac{r + r_0}{r} \right) \dots \dots \dots (15)^*$$

$$C = \frac{s p r}{2 a} (r + r_0) \dots \dots \dots (16)$$

For a cone closed at the top:

$$B = -\frac{p r^2}{a} \dots \dots \dots (17)$$

$$A = -\frac{p s^2}{2 a} \dots \dots \dots (18)$$

$$C = \frac{s p r^2}{2 a} \dots \dots \dots (19)$$

#### CASE 1.—LIVE LOAD ON ONE-HALF OF DOME

*Conoidal Formulas.*—Assume a homogeneous conoidal dome, with the lines of stress in the center of the thickness of the shell, and with a vertical live load over the right half of its surface (see Fig. 1). The total live load above the level,  $x$ , is equal to  $G$ , its center of gravity being distant,  $e$ , from the axis. The intensity of live load ( $= g$  per square foot of surface) is assumed uniform at all points on the same level.

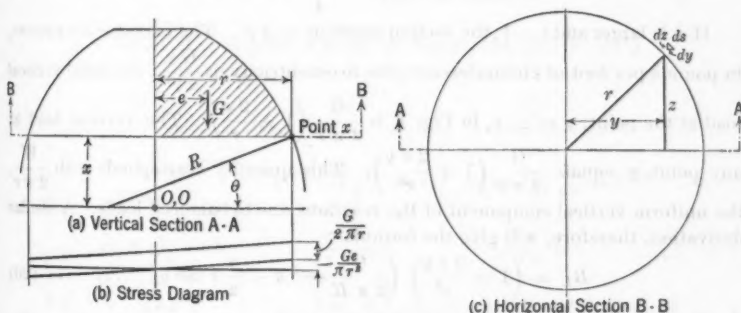

FIG. 1.

On the horizontal section at the level,  $x$ , it is roughly assumed that the vertical components of the reactions resisting the unbalanced live load are distributed over the section in accordance with the common theory of flexure; that is, the vertical stress equals a uniform stress due to the load plus or minus a bending stress due to the eccentricity, varying uniformly in proportion to its distance from the neutral axis. It is apparent that the bulging of the dome under load will affect the accuracy of this assumption, but not so seriously as to render the results valueless as a guide.

\* Transactions, Am. Soc. C. E., Vol. LII (1904), p. 303, Equation (73).

Then, the direct vertical load on the horizontal section is  $\frac{G}{2\pi r}$ ; the moment on the horizontal section is  $G e$ . The section modulus of a cylinder 1 ft. high, about a horizontal axis through the center, is  $\pi r^2$ , derived as follows (see Fig. 2 (a)):

$$\text{Section modulus} = \frac{\pi (d^4 - d_1^4)}{32 d} = \frac{\pi}{32 d} (d^2 + d_1^2) (d + d_1) (d - d_1)$$

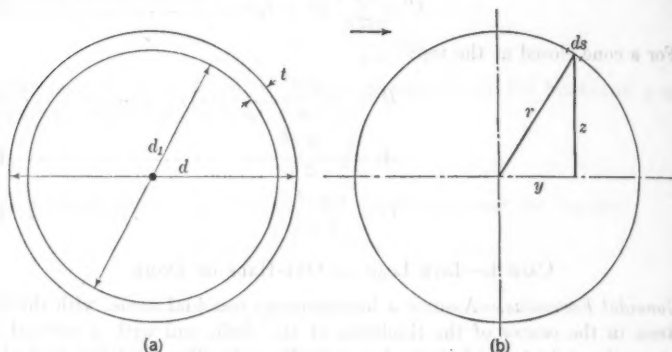

FIG. 2.

Substituting for  $d - d_1$ , its equivalent,  $2 t$ , and if  $t$  is small,  $d = d_1$ , then,

$$\text{Section modulus} = \frac{\pi d^2}{4} t = \pi r^2 t$$

If  $d$  is larger and  $t = 1$ , the section modulus  $= \pi r^2$ . The extreme fiber stress, in pounds per foot of circumference, due to eccentricity, is  $\frac{G e}{\pi r^2}$ . The total vertical load at the point,  $y = \pm r$ , in Fig. 1, is  $\frac{G}{2\pi r} \left(1 \pm \frac{2e}{r}\right)$ . The vertical load at any point,  $y$ , equals  $\frac{G}{2\pi r} \left(1 + \frac{2e y}{r^2}\right)$ . This quantity corresponds with  $\frac{W}{2\pi r}$ , the uniform vertical component of the reactions due to balanced loads. A similar derivation, therefore, will give the formulas:

$$B_L = \left(1 + \frac{2e y}{r^2}\right) \left(\frac{G}{2\pi R} \sec^2 \theta - \frac{g}{2} r \tan \theta\right) \dots \dots \dots (20)$$

(Note that  $\frac{g}{2}$  in Equation (20) corresponds to  $p$  in Equation (1), as  $g$  covers one-half the section.)

$$A_L = - \left(1 + \frac{2e y}{r^2}\right) \frac{G}{2\pi r} \sec \theta \dots \dots \dots (21)$$

$$C_L = \pm \left(1 + \frac{2e y}{r^2}\right) \frac{G}{2\pi} \tan \theta \dots \dots \dots (22)$$

In the case of unbalanced loads there is also a shear on the horizontal and vertical sections at any point; that is, the principal stresses are not horizontal and meridional.

Consider the dome to be cut off at the horizontal section,  $x$ , and to rest on the top of a thin cylinder. In general, a ring will be required at the top of the cylinder, and below this ring all the stresses in the cylinder are vertical and varying in amount analogous to any eccentrically loaded pier. The stress in the ring is given by Equation (22), and is seen to vary with  $y$ , the distance from the neutral axis. Below the ring there is no horizontal shear, as all stresses are vertical. The change in stress in the ring, therefore, must be brought about by tangential shear between ring and dome, which is the same as the horizontal shear in the dome at this section. The dome is assumed to be thin and to carry no radial shear.

The tangential horizontal shear at any point in the level,  $x$ , is then equal to  $\frac{dC}{ds}$ ,  $s$  being the arc (see Fig. 1(c)). Then, since  $\frac{dC}{dy} = \frac{Ge}{\pi r^2} \tan \theta$  and  $\frac{dy}{ds} = \frac{z}{r}$ ,

$$\frac{dC}{ds} = \frac{dC}{dy} \frac{dy}{ds} = V_L = \frac{Ge z}{\pi r^3} \tan \theta \dots \dots \dots (23)$$

Special values of Equations (20) to (23) are given in Table 1.

By comparing the formulas for  $y = +r$  with those for balanced load, it is evident that in general the maximum values of  $B$  and  $A$  will be about the same for half loads as they are for the dome fully loaded, since  $e$  is about equal to  $\frac{r}{2}$ . The shear alone is greater with unbalanced load. The values of  $B_L$  and  $A_L$  are of use in estimating the possible distortion, from which to judge whether the change in curvature is sufficiently great to be dangerous.

TABLE 1.—SPECIAL VALUES OF EQUATIONS (20) TO (23).

$y$ .	$B_L$ .	$A_L$ .	$C_L$ .	$V_L$ .
$-r$	$\left(1 - \frac{2e}{r}\right) \left(\frac{G}{2\pi R} \sec^2 \theta - \frac{gr}{2} \tan \theta\right)$	$-\left(1 - \frac{2e}{r}\right) \frac{G}{2\pi r} \sec \theta$	$\pm \left(1 - \frac{2e}{r}\right) \frac{G}{2\pi} \tan \theta$	0
0	$\frac{G}{2\pi r} \sec^2 \theta - \frac{gr}{2} \tan \theta$	$-\frac{G}{2\pi r} \sec \theta$	$\pm \frac{G}{2\pi} \tan \theta$	$\frac{Ge}{\pi r^2} \tan \theta$
$+r$	$\left(1 + \frac{2e}{r}\right) \left(\frac{G}{2\pi R} \sec^2 \theta - \frac{gr}{2} \tan \theta\right)$	$-\left(1 + \frac{2e}{r}\right) \frac{G}{2\pi r} \sec \theta$	$\pm \left(1 + \frac{2e}{r}\right) \frac{G}{2\pi} \tan \theta$	0

*Pyramidal Formulas.*—The general formulas for a pyramidal dome would involve an expression for the section modulus of the polygon about a horizontal axis, which is impracticable. The method may be illustrated by using the most common form of pyramid—the octagonal; any other form may be solved by a similar process.

Let one-half the dome be loaded, as shown in Fig. 3 (a), the load being  $G$  with an eccentricity,  $e$ . The value of  $e$  may be estimated roughly by eye;

the result will be at least as accurate as the distribution of a chance snow load can ever be. The uniform vertical load on each rib due to  $G$  equals  $\frac{G}{8}$ . The moment equals  $G e$ .

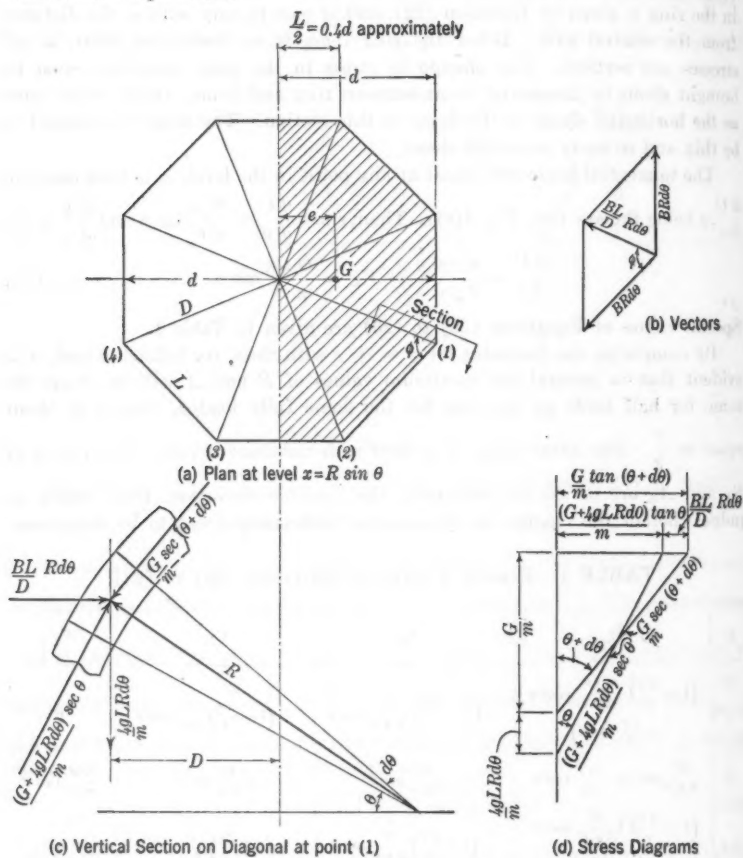

FIG. 3.

Let the vertical loads due to moment be:  $U_1$  and  $U_2$ , at Points (1) and (2), respectively; then,

$$4 \left( U_1 d + \frac{U_2 L}{2} \right) = G e \dots \dots \dots (24)$$

Since  $U_2$  is approximately equal to  $0.4 U_1$  and  $\frac{L}{2} = 0.4 d$ , from Equation (24),

$$U_1 = \frac{G e}{4.6 d} \text{ and } U_2 = \frac{G e}{11.6 d} \dots \dots \dots (25)$$

*Stresses at Point (1).*—The total vertical load above Point (1), (Fig. 3 (a)) is:

$$\frac{G}{8} + \frac{G e}{4.6 d} = \frac{G}{m} \dots \dots \dots (26)$$

in which,

$$\frac{1}{m} = \left( \frac{1}{8} + \frac{e}{4.6 d} \right)$$

The total vertical load on  $R d \theta = 4 g L R d \theta \left( \frac{1}{8} + \frac{e}{4.6 d} \right)$ .

By a derivation similar to that used for the elementary formula\* (see Fig. 3):

$$\frac{B L}{D} R d \theta = \frac{G}{m} \tan (\theta + d \theta) - \frac{(G + 4 g L R d \theta)}{m} \tan \theta \dots \dots (27)$$

With  $d \theta = \tan d \theta$  approaching 0, this reduces to,

$$B_{L1} = \left( \frac{1}{8} + \frac{e}{4.6 d} \right) \left( \frac{G D}{L R} \sec^2 \theta - 4 g D \tan \theta \right) \dots \dots \dots (28)$$

Similarly:

$$A_{L1} = - \left( \frac{1}{8} + \frac{e}{4.6 d} \right) G \sec \theta \dots \dots \dots (29)$$

$$C_{L1} = \pm \left( \frac{1}{8} + \frac{e}{4.6 d} \right) \frac{G D}{L} \tan \theta \dots \dots \dots (30)$$

*Stresses at Point (2).*—By a similar process the formulas for Point (2) are:

$$B_{L2} = \left( \frac{1}{8} + \frac{e}{11.6 d} \right) \left( \frac{G D}{L R} \sec^2 \theta - 4 g D \tan \theta \right) \dots \dots \dots (31)$$

$$A_{L2} = - \left( \frac{1}{8} + \frac{e}{11.6 d} \right) G \sec \theta \dots \dots \dots (32)$$

$$C_{L2} = \pm \left( \frac{1}{8} + \frac{e}{11.6 d} \right) \frac{G D}{L} \tan \theta \dots \dots \dots (33)$$

*Stresses at Point (3).*—At this point the vertical load due to eccentricity is negative:

$$B_{L3} = \left( \frac{1}{8} - \frac{e}{11.6 d} \right) \left( \frac{G D}{L R} \sec^2 \theta - 4 g D \tan \theta \right) \dots \dots \dots (34)$$

$$A_{L3} = - \left( \frac{1}{8} - \frac{e}{11.6 d} \right) G \sec \theta \dots \dots \dots (35)$$

$$C_{L3} = \pm \left( \frac{1}{8} - \frac{e}{11.6 d} \right) \frac{G D}{L} \tan \theta \dots \dots \dots (36)$$

*Stresses at Point (4).*—

$$B_{L4} = \left( \frac{1}{8} - \frac{e}{4.6 d} \right) \left( \frac{G D}{L R} \sec^2 \theta - 4 g D \tan \theta \right) \dots \dots \dots (37)$$

$$A_{L4} = - \left( \frac{1}{8} - \frac{e}{4.6 d} \right) G \sec \theta \dots \dots \dots (38)$$

$$C_{L4} = \pm \left( \frac{1}{8} - \frac{e}{4.6 d} \right) \frac{G D}{L} \tan \theta \dots \dots \dots (39)$$

\* Transactions, Am. Soc. C. E., Vol. 88 (1925), p. 107, Equation (7).

*Shears.*—By a process of reasoning similar to that used in regard to conoidal domes, it follows that the horizontal shear in Face (1) to Face (2) (Fig. 3 (a)) is:

$$C_{L1} - C_{L2} = V_{L12} = \frac{e}{7.6 d} \frac{G D}{L} \tan \theta \dots \dots \dots (40)$$

Similarly,

$$C_{L2} - C_{L3} = V_{L23} = \frac{e}{5.8 d} \frac{G D}{L} \tan \theta \dots \dots \dots (41)$$

and,

$$C_{L3} - C_{L4} = V_{L34} = \frac{e}{7.6 d} \frac{G D}{L} \tan \theta \dots \dots \dots (42)$$

In the end sections,  $V_{L11}$  and  $V_{L44} = 0$ .

The theory herein presented applies only to domes of solid masonry. When the space between the ribs is filled with glass there is no material to carry the shears shown in Equations (40) to (42). The ribs in this case have to be thick enough to distribute the unbalanced loads by bending. The line of stress does not remain in the center of the ribs, and the present theory does not apply. Domes of this type may be treated by computing the bending caused by distributing any unbalanced load uniformly over the entire surface, after which the stresses are found for the uniform load and added to those due to bending in the ribs.

When the ribs are filled in with solid masonry there is a theoretical bending in any horizontal element, representing the action necessary to carry the bursting stresses to the ribs where they are held by the tension ring stress.

As in the case of balanced loads,  $\pm M$  is approximately equal to  $\frac{B L^2}{12 d}$ , in foot-pounds per foot of profile. Substituting the several values of  $B_L$  from Equations (28), (31), (34), and (37), there are found values of  $-M$  at the ribs, those of  $+M$  between ribs being estimated by interpolation.

*Spherical Domes.*—The area of a surface with a depth of  $S_0$  is  $2 \pi R S_0$ . Live load covers one-half this surface at a uniform rate of  $g$  lb. per sq. ft.,

the total  $G = \pi R S_0 g$ ; also,  $\tan \theta = \frac{h}{r}$  and  $\sec \theta = \frac{R}{r}$ .

For a sphere, Equation (20) becomes,

$$B_L = \left( 1 + \frac{2 e y}{r^2} \right) \left( \frac{R^2}{2 r^2} S_0 g - \frac{g}{2} h \right) \dots \dots \dots (43)$$

Equation (21) becomes,

$$A_L = - \left( 1 + \frac{2 e y}{r^2} \right) \frac{R^2}{2 r^2} S_0 g \dots \dots \dots (44)$$

Equation (22) becomes,

$$C_L = \pm \left( 1 + \frac{2 e y}{r^2} \right) \frac{R}{2 r} S_0 g h \dots \dots \dots (45)$$

and Equation (23) becomes,

$$V_L = \frac{R}{r^4} S_0 g e z \dots \dots \dots (46)$$

The value of  $e$  for a complete quarter sphere is  $\frac{r}{2}$ .

*Conical Domes.*—The area of surface is  $s \pi (r + r_0)$ ; the live load on one-half this surface is,

$$G = \frac{s \pi g}{2} (r + r_0); \frac{1}{R} = 0; \tan \theta = \frac{r}{a}; \text{ and } \sec \theta = \frac{s}{h}$$

From Equation (20) reduced:

$$B_L = - \left( 1 + \frac{2 e y}{r^2} \right) \frac{g r^2}{2 a} \dots \dots \dots (47)$$

and,

$$A_L = - \left( 1 + \frac{2 e y}{r^2} \right) \frac{g s^2}{4 h} \left( \frac{r + r_0}{r} \right) \dots \dots \dots (48)$$

$$C_L = \left( 1 + \frac{2 e y}{r^2} \right) \frac{s g r}{4 a} (r + r_0) \dots \dots \dots (49)$$

$$V_L = \frac{s g e z (r + r_0)}{2 r^2 a} \dots \dots \dots (50)$$

If the cone is closed at the top,  $r = r_0$ ,  $a = h$ , and Equations (47) to (50) may be simplified correspondingly.

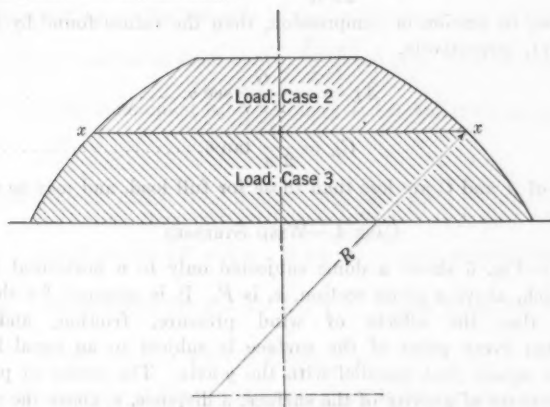

FIG. 4.

CASE 2.—LIVE LOAD IN CENTER OF DOME ONLY

This is shown in Fig. 4, with the load on the area above the level,  $x x$ . Obviously, in the loaded part above  $x x$ , all the stresses are found by the elementary Equations (1) to (25). Below the level,  $x x$ , the formulas are as follows:

$$B_L = \frac{G}{2 \pi R} \sec^2 \theta \dots \dots \dots (51)$$

This value of  $B$  may be greater than that for full load, as the negative term of Equation (1) is missing,  $p$  being zero.

$$A_L = -\frac{G}{2\pi r} \sec \theta \dots \dots \dots (52)$$

This is necessarily less than for full load,  $G$  being less than  $W$ . Therefore, it may be neglected.

$$C_L = \frac{G}{2\pi} \tan \theta \dots \dots \dots (53)$$

This may be neglected for the same reason as  $A$  in Equation (52).

#### CASE 3.—LIVE LOAD ON HAUNCH ONLY

This is shown in Fig. 4, with the load below the line,  $x x$ . Above the level,  $x x$ , the stresses are as determined by the elementary formulas, for dead load only, and all of them are smaller than the stresses for full load, so they may be disregarded. At the top of the loaded area:

$$B_L = -g r \tan \theta \dots \dots \dots (54)$$

This indicates the fact that when  $B$  is compression its maximum value is for a load extending up to the level in question, but not above it. Below the level,  $x x$ ,

$$B_L = \frac{G}{2\pi R} \sec^2 \theta - g r \tan \theta \dots \dots \dots (55)$$

which is less, in tension or compression, than the values found by Equations (51) or (54), respectively.

$$A_L = -\frac{G}{2\pi r} \sec \theta \dots \dots \dots (56)$$

$$C_L = \frac{G}{2\pi} \tan \theta \dots \dots \dots (57)$$

The values of  $A$  and  $C$  are less than those for full load, and may be neglected.

#### CASE 4.—WIND STRESSES

*Conoids.*—Fig. 5 shows a dome subjected only to a horizontal force, the total of which, above a given section,  $x$ , is  $F$ . It is assumed for the sake of simplicity, that the effects of wind pressure, friction, and suction are such that every point of the surface is subject to an equal horizontal force,  $f$ , per square foot, parallel with the  $y$ -axis. The center of pressure is then at the center of gravity of the surface, a distance,  $e$ , above the section,  $x$ . The wind moment is  $F e$ . The section modulus being  $\pi r^2$ , the extreme fiber

stresses are  $\pm \frac{F e}{\pi r^2}$  lb. per ft. of circumference. Similar assumptions are involved as in the case of partial live load.

The vertical component of the stress in the dome at any point in the horizontal section is then  $\frac{F e y}{\pi r^3}$ . The horizontal force,  $f$ , per square foot, parallel to the  $y$ -axis, has components:  $\frac{f y}{r}$ , radial, and  $\frac{f z}{r}$ , tangential.

Consider a voussoir (Fig. 6 (a)), 1 ft. long and  $R d\theta$  high along the meridian, distance,  $y$ , from the neutral axis. The values of  $r$ ,  $y$ , and  $e$  are not the same for  $\theta$  and for  $\theta + d\theta$ , but when  $d\theta$  approaches zero, the differentials of these values disappear without affecting the result. They are omitted, therefore, in the calculations.

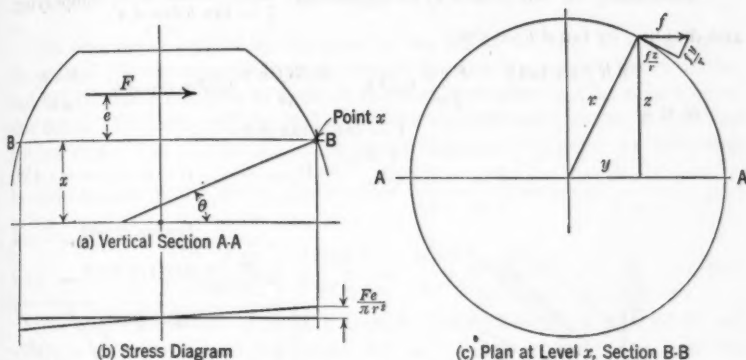

FIG. 5.

The forces acting on the voussoir in the radial plane, are as follows:

- 1.—Meridional thrust from above,  $\frac{F e y}{\pi r^3} \sec (\theta + d\theta)$ , of which the horizontal component is,  $\frac{F e y}{\pi r^3} \tan (\theta + d\theta)$ , and the vertical component is  $\frac{F e y}{\pi r^3}$ .
- 2.—Meridional thrust from below: The total force on the dome down to the bottom level of the voussoir is  $F + 2 \pi r R d\theta f$ . The meridional thrust is  $(F + 2 \pi r R d\theta f) \frac{e y}{\pi r^3} \sec \theta$ , of which the horizontal component is  $(F + 2 \pi r R d\theta f) \frac{e y}{\pi r^3} \tan \theta$ , and the vertical component is  $(F + 2 \pi r R d\theta f) \frac{e y}{\pi r^3}$ .
- 3.—The horizontal local wind force,  $f$  per sq. ft., on the voussoir equals  $f R d\theta$ , and the component in a radial plane is  $f R d\theta \frac{y}{r}$ .
- 4.—The resultant of the vertical components of the ring stress, equal to the difference between the vertical components of Force 1 and of Force 2, or  $\frac{2 R d\theta f e y}{r^2}$ .
- 5.—The resultant of the horizontal components of the ring stress. The value of the ring stress is  $B_W R d\theta$ .

Let Resultant 5 be called  $H R d\theta$ . Then, the sum of all the horizontal forces acting in the radial plane may be set equal to zero, thus:

$$H R d\theta + (F + 2\pi r R d\theta f) \frac{e y}{\pi r^3} \tan \theta - \frac{F e y}{\pi r^3} \tan (\theta + d\theta) - f R d\theta \frac{y}{r} = 0 \dots \dots \dots (58)$$

Substituting for  $\tan (\theta + d\theta)$  its equivalent,  $\frac{\tan \theta + \tan d\theta}{1 - \tan \theta \tan d\theta}$ , simplifying, and dividing by  $\tan d\theta = d\theta$ :

$$H R + \frac{2 R f e y \tan \theta}{r^2} - \frac{F e y}{\pi r^3} \tan^2 \theta - \frac{2 R f e y}{r^2} \tan^2 \theta \tan d\theta - \frac{F e y}{\pi r^3} \frac{1 - \tan \theta \tan d\theta}{\tan d\theta} - \frac{f R y}{r} = 0 \dots \dots \dots (59)$$

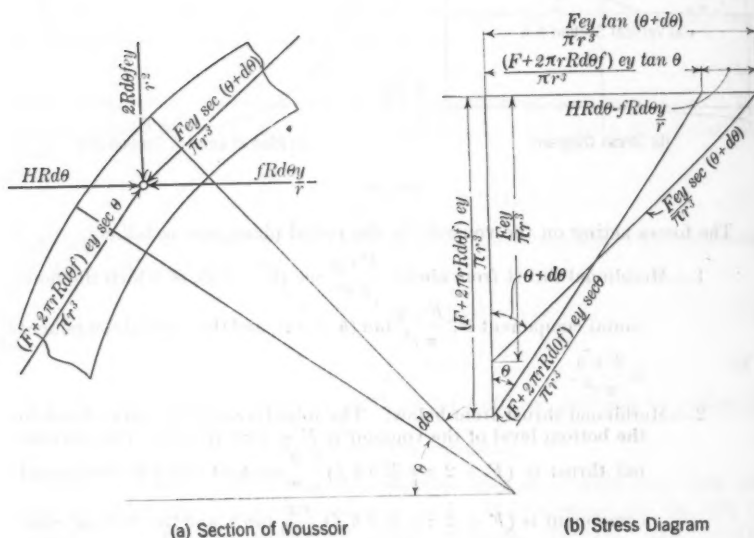

FIG. 6.

Let  $d\theta = \tan d\theta = 0$ ; then:

$$H = \frac{F e y}{\pi R r^3} (1 + \tan^2 \theta) - \frac{2 f e y}{r^2} \tan \theta + \frac{f y}{r} \dots \dots \dots (60)$$

The horizontal ring stress,  $B_w$ , is equal to  $H r$ :

$$B_w = \frac{F e y}{\pi R r^2} (\sec^2 \theta) - \frac{2 f e y}{r} \tan \theta + f y \dots \dots \dots (61)$$

From Fig. 6 it is evident that the meridional thrust is:

$$A_w = - \frac{F e y}{\pi r^3} \sec \theta \dots \dots \dots (62)$$

Consider the dome to be supported on a thin cylinder, not capable of carrying any radial shear. The wind will be resisted by tangential shears in the cylinder. A ring will be required at the top of the cylinder. The tension in this ring is the horizontal component of the meridional stress, multiplied by  $r$ :

$$C_w = \frac{F e y}{\pi r^2} \tan \theta \dots \dots \dots (63)$$

The total shear applied by the dome to the top of the ring at any point is the sum of (1) the tangential shear applied through the ring to the cylinder; and (2) the shear required to produce the change in ring tension occurring at this point. The latter will be analyzed first. Consider an element,  $ds$ , of this tension ring. The change in tension in the elemental distance,  $ds$ , is caused by shear applied by the dome. Then, since  $\frac{dC}{dy} = \frac{F e}{\pi r^2} \tan \theta$  and  $\frac{dy}{ds} = \frac{z}{r}$  (see

Fig. 1):

$$\frac{dC}{ds} = \frac{dC}{dy} \frac{dy}{ds} = \frac{F e z}{\pi r^3} \tan \theta \dots \dots \dots (64)$$

The direct shear due to wind, carried by the cylinder, is a total of  $F$ , and varies in intensity from a maximum at  $y = 0$  to zero at  $y = \pm r$ . Let the maximum at  $y = 0$  be  $\frac{F}{\pi r}$ , which is derived as follows (Fig. 2 (b)): Let the shear be

proportional to  $z$ . At  $ds$  the shear equals  $\frac{a z}{r} ds$ , in which,  $\frac{a}{r}$  is a constant. The component parallel to the  $y$ -axis is  $\frac{a z^2}{r^2} ds$ ; but  $ds = dy \frac{r}{z}$ . Therefore, the component  $= \frac{a z}{r} dy$ , and the total,  $F = \frac{a}{r} \int_{-r}^{+r} z dy$ . Since  $\int_{-r}^{+r} z dy$  = area of the circle  $= \pi r^2$ ;  $F = \pi r a$ , or  $a = \frac{F}{\pi r}$ . Therefore, the shear  $= \frac{F z}{\pi r^2}$  per foot at any point and varies from  $\frac{F}{\pi r}$  at  $z = r$  to 0 at  $z = 0$ . Then,

the shear at any point will be about  $\frac{F}{\pi r} \frac{z}{r} = \frac{F z}{\pi r^2}$ , of which the component parallel to the wind is  $\frac{F z^2}{\pi r^3}$ . The sum of these components is,

$$\int_{-r}^{+r} \frac{F z^2}{\pi r^3} ds = \int_{-r}^{+r} \frac{F z}{\pi r^2} dy$$

Now,  $\int_{-r}^{+r} z dy$  is the area of the circle  $= \pi r^2$ ; so the sum of components parallel to  $F$  is  $\frac{F}{\pi r^2} \times \pi r^2 = F$ , as required.

The ring tension is greatest at the leeward side, so the tendency of the shear between the dome and the ring is, in a sense, to drag the ring toward the left. The tendency of the shear between the dome and the ring due to the

direct wind thrust is, in a sense, to drag the ring toward the right. Therefore, the total horizontal shear at any point is the difference of these two shears, or:

$$V_w = \frac{F e z}{\pi r^3} \tan \theta - \frac{F z}{\pi r^3} \dots \dots \dots (65)$$

At the neutral axis, where  $z = r$ , this shear is a maximum of  $\frac{F e}{\pi r^2} \tan \theta - \frac{F}{\pi r}$ . At the ends of the  $y$ -axis, the shear is zero since  $z$  is 0.

*Pyramids.*—As in the case of unbalanced live load, the method will be illustrated with the octagonal pyramid shown in Fig. 3. Consider it to be acted upon by a uniform horizontal force of  $f$  per sq. ft. over its entire surface, making a total shear,  $F$ , with an eccentricity,  $e$ .

The wind moment is  $F e$ , and the vertical loads due to this moment on the ribs are, as before,

$$U_1 = \pm \frac{F e}{4.6 d}, \text{ and } U_2 = \pm \frac{F e}{11.6 d}$$

*Stresses at Point (1).*—The forces acting on a voussoir of this rib, in the plane of the diagonal, are as follows:

$$(a) \text{ Meridional thrust from above, } \frac{F e}{4.6 d} \sec (\theta + d \theta).$$

$$(b) \text{ Meridional stress from below, } (F + 8 f L R d \theta) \frac{e}{4.6 d} \sec \theta.$$

$$(c) \text{ Horizontal wind on voussoir, component in diagonal plane,}$$

$$f L \sin \phi R d \theta = \frac{d}{D} f L R d \theta.$$

$$(d) \text{ Horizontal resultant of ring stress in diagonal plane, } \frac{B L}{D} R d \theta.$$

Equating the sum of all horizontal components,  $a, b, c, d$ , to 0, and solving in the usual manner:

$$B_{w1} = \frac{e}{4.6 d} \left( \frac{F D}{L R} \sec^2 \theta - 8 f D \tan \theta \right) + f d \dots \dots \dots (66)$$

Similarly,

$$A_{w1} = - \frac{e}{4.6 d} F \sec \theta \dots \dots \dots (67)$$

$$C_{w1} = \frac{1}{2} \frac{F e}{4.6 d} \tan \theta \sec \phi; \sec \phi = \frac{2 D}{L} \dots \dots \dots (68)$$

$$C_{w1} = \pm \frac{e}{4.6 d} \frac{F D}{L} \tan \theta \dots \dots \dots (69)$$

*Stresses at Point (2).*—By analogy:

$$B_{w2} = \frac{e}{11.6 d} \left( \frac{F D}{L R} \sec^2 \theta - 8 f D \tan \theta \right) + \frac{f L}{2} \dots \dots \dots (70)$$

$$A_{w2} = - \frac{e}{11.6 d} F \sec \theta \dots \dots \dots (71)$$

$$C_{w2} = \pm \frac{e}{11.6 d} \frac{F D}{L} \tan \theta \dots \dots \dots (72)$$

Stresses at Point (3):

$$B_{w3} = - \frac{e}{11.6 d} \left( \frac{F D}{L R} \sec^2 \theta - 8 f D \tan \theta \right) - \frac{f L}{2} \dots \dots \dots (73)$$

$$A_{w3} = + \frac{e}{11.6 d} F \sec \theta \dots \dots \dots (74)$$

$$C_{w3} = \mp \frac{e}{11.6 d} \frac{F D}{L} \tan \theta \dots \dots \dots (75)$$

Stresses at Point (4):

$$B_{w4} = - \frac{e}{4.6 d} \left( \frac{F D}{L R} \sec^2 \theta - 8 f D \tan \theta \right) - f d \dots \dots \dots (76)$$

$$A_{w4} = + \frac{e}{4.6 d} F \sec \theta \dots \dots \dots (77)$$

$$C_{w4} = \mp \frac{e}{11.6 d} \frac{F D}{L} \tan \theta \dots \dots \dots (78)$$

Shears include the change in  $C_w$  minus the direct wind shear, as follows:

$$V_{w12} = \frac{e}{7.6 d} \frac{F D}{L} \tan \theta - 0.15 F, \text{ approximately } \dots \dots \dots (79)$$

$$V_{w23} = \frac{e}{5.8 d} \frac{F D}{L} \tan \theta - 0.21 F, \text{ approximately } \dots \dots \dots (80)$$

The moment in a horizontal element of the face equals  $\pm M$  (approximately)  $= \frac{B L^2}{12 d}$  due to thrusts. To this is added the moment due to wind directly applied: For Line (1) (1) and Line (4) (4) (Fig. 3),  $M = \frac{f L^2}{12}$ ; for Line (1) (2) and Line (3) (4),  $M = \frac{f L^2}{12 \sqrt{2}}$ ; and for Line (2) (3),  $M = 0$ .

The stresses due to these moments are to be added to the ring stresses found from Equations (66), etc.

Wind, spherical domes, etc., formulas analogous to Equations (43), etc., can be derived by substituting the factors for the sphere, cone, etc.

#### MAXIMUM STRESSES

It is possible, by the use of the foregoing equations, to obtain for any point in a dome the combined horizontal ring stresses, meridional thrusts, and shears on the horizontal plane, for dead, live, and wind loads. Only in extreme cases, such as unprecedented size or shape, would it be necessary, of course, to go into such detailed investigation. Supposing it to be desirable in a given case, having found the total stresses,  $B_T$ ,  $A_T$ ,  $C_T$ , and  $V_T$ , it remains to find the maximum or principal stresses, and the direction in which they lie. The following method is derived from Rankine.

Consider an elementary surface,  $o a b$  (Fig. 7), with its sides perpendicular to  $A_T$ ,  $B_T$ , and the principal stress,  $A_P$ .  $A_T$  and  $B_T$  are positive as tension in the directions,  $A o$  and  $B o$ ; the balancing stress,  $A_P$ , is positive as tension in the direction,  $o e = o f$ . The shear,  $V_T$ , is positive as clockwise on the vertical plane, and is, therefore, opposite in sign to the direct stresses,  $A_T$  and  $B_T$ .

Let  $d o$  and  $c o$  be the total components acting on the element parallel to the axes; their balancing force is the same as  $o f$ , the normal force, since there is no tangential force in a principal plane.

$$c o = A_T o b - V_T o a = A_T a b \cos \alpha - V_T a b \sin \alpha$$

$$d o = B_T o a - V_T o b = B_T a b \sin \alpha - V_T a b \cos \alpha$$

$$o f = d o \sin \alpha + c o \cos \alpha$$

$$f e = c o \sin \alpha - d o \cos \alpha$$

$$A_P = \frac{o f}{a b} = B_T \sin^2 \alpha - V_T \sin \alpha \cos \alpha + A_T \cos^2 \alpha - V_T \sin \alpha \cos \alpha$$

$$= A_T \cos^2 \alpha + B_T \sin^2 \alpha - 2 V_T \sin \alpha \cos \alpha \dots \dots \dots (81)$$

$$V_P = O = \frac{f e}{a b} = A_T \cos \alpha \sin \alpha - V_T \sin^2 \alpha - B_T \cos \alpha \sin \alpha$$

$$+ V_T \cos^2 \alpha = O \dots \dots \dots (82)$$

from which,

$$\tan 2 \alpha = \frac{-2 V_T}{A_T - B_T} \dots \dots \dots (83)$$

A similar demonstration will show that:

$$B_P = A_T \sin^2 \alpha + B_T \cos^2 \alpha + 2 V_T \cos \alpha \sin \alpha \dots \dots \dots (84)$$

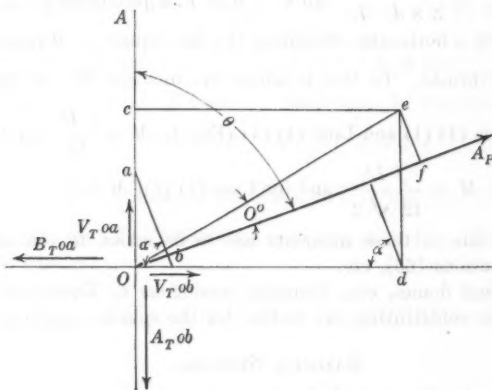

FIG. 7.

### EXAMPLES

The foregoing theory may be illustrated by the following examples.

**Example 1.—Unbalanced Load.**—Consider the dome shown in Fig. 8 having a spherical surface of radius, 200 ft., and  $r = 100$  ft.; let the dead load consist of 8-in. concrete weighing 100 lb. per sq. ft., and the live load, 10 lb. per sq. ft. on the right half only.

In Table 2, stresses are given for various values of  $\theta$ ,  $r$ , and  $e$ . (See Fig. 8.) They were determined by substituting the given data\* in Equations (20), (21), and (23).

\* The data given are approximate.

TABLE 2.—STRESSES DUE TO UNBALANCED LIVE LOAD.

y.	B.	A.	V.
$\tan \theta_1 = 1.74$ ; $\sec \theta_1 = 2$ ; $r = 100$ ft.; $e = 45$ ft.; $G = 170\,000$ lb.; and area of dome = $34\,000$ sq. ft.			
+100	- 630	- 1 030	0
0	- 330	- 540	425
-100	- 30	- 50	0
Dead load stress	-6 600	-10 800	0
$\tan \theta_2 = 2.65$ ; $\sec \theta_2 = 2.82$ ; $\sec^2 \theta_2 = 7.95$ ; $r = 71$ ft.; $e = 31$ ft.; area of dome above this level = $16\,400$ sq. ft.; and $G = 80\,000$ lb.			
+ 71	- 800	- 960	0
0	- 430	- 510	420
- 71	- 60	- 70	0
Dead load stress	-8 300	-10 400	0
$\tan \theta_3 = 5.6$ ; $\sec \theta_3 = 5.7$ ; $\sec^2 \theta_3 = 32.5$ ; $r = 35$ ft.; $e = 15$ ft.; area = $3\,700$ sq. ft.; and $G = 18\,500$ lb.			
+ 35	- 910	- 890	0
0	- 490	- 480	400
- 35	- 70	- 70	0
Dead load stress	-9 900	- 9 800	....

It is evident that the stresses due to unbalanced live load are not, in this case, very alarming as compared with those due to a balanced load. The distortion may be roughly computed as follows: Suppose the modulus of elasticity to be  $2\,000\,000$  for compression and  $1\,000\,000$  for shear.

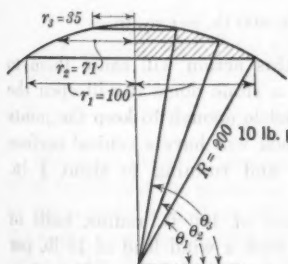

FIG. 8.

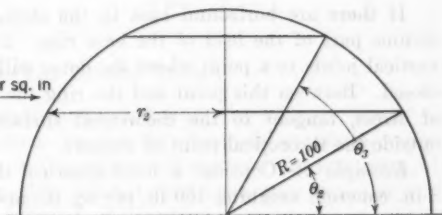

FIG. 9.

*Shear Distortion of the Neutral Axis from the Base Up to the Level of  $\theta_2$ .—*There is a stress of  $400$  lb. in  $8$  in. by  $12$  in., or  $4$  lb. per sq. in. The section is about  $400$  in. high along the profile. The distortion equals  $\frac{4 \times 400}{1\,000\,000} = 0.0015$  in.

*Compression Distortion of the Horizontal Ring at the Level,  $\theta_2$ .*—The right half is compressed under an average stress of about 600 lb. per ft. of height, or 6 lb. per sq. in. of concrete; its length is 2 640 in. The total strain

$$\text{on the right half is } \frac{6 \times 2\,640}{2\,000\,000} = 0.008 \text{ in. Similarly, the left side is strained, } \frac{2.5 \times 2\,640}{2\,000\,000} = 0.003 \text{ in.}$$

Therefore, the right half circle is about 0.005 in. smaller in arc length than the left, and at the same time has been moved toward the left about 0.00015 in. It is evident that these distortions are not alarming.

The distortions due to balanced loads and temperature may be treated here by a similar approximate method. If the dome and the ring at the base change their temperature equally, the distortion will obviously be slight. A temperature drop of 100° Fahr. on the dome only, would shorten the half

profile  $\frac{1}{1\,500}$ , or about 0.85 in., relative to the ring. The average meridional dead load thrust is about 105 lb. per sq. in. Using a modulus of elasticity of 2 000 000, this gives a shortening of the half profile of about 0.07 in. The ring, if designed for 12 000 lb., will lengthen 1 part in 2 500, and  $r$  will increase in the same ratio, or about 0.48 in. The center will drop down, due to all these factors combined, a total of  $(0.85 + 0.07 + 0.48) \frac{100}{27} = 5$  in.

A combination of the formulas for deflection and bending gives the formula,

$$\text{Stress} = \frac{4.8 D E d}{r^2}$$

$$\frac{4.8 \times 5 \times 2\,000\,000 \times 8}{5\,760\,000} = 64 \text{ lb. per sq. in.}$$

At the same time the stretch of the ring, amounting to  $\frac{1}{2\,500}$  will impose on the adjacent shell a tension of about  $\frac{2\,000\,000}{2\,500}$ , or 800 lb. per sq. in.

If there are horizontal bars in the shell, this action will cause them to assume part of the load of the base ring. In a stone dome it will open the vertical joints to a point where the dome will settle enough to keep the joints closed. Between this point and the ring the shell will have a conical surface of stress, tangent to the theoretical surface, and running to about  $\frac{1}{2}$  in. outside the theoretical point of support.

*Example 2.*—Consider a hemi-spherical dome of 100 ft. radius, built of 8-in. concrete weighing 100 lb. per sq. ft., and with a wind load of 10 lb. per sq. ft. of superficial area. (See Fig. 9.) The formulas used are Equations (61), (62), and (65), and the results are arranged for convenience in Table 3.

*Distortion.*—*Shear Deflection of the Neutral Axis Up to the Level of  $\theta_2$ .*—

The average shear  $\left( \frac{1\,500}{8 \times 12} \right) = 15$  lb. per sq. in. The length of the arc is 660 in. The deflection equals  $\frac{15 \times 660}{1\,000\,000} = 0.01$  in.

*Tension Distortion in Right Half of Ring at Level of  $\theta_2$ .*—The average tension is 480 lb. on a section 8 by 12 in., or 5 lb. per sq. in. The length of the half ring is 3 250 in. The strain =  $\frac{5 \times 3\,250}{2\,000\,000} = 0.008$  in. expansion.

Similarly, the left side has about 0.008 in. of contraction. The right semi-circle is then about 0.016 in. longer than the left one, and, at the same time, has been moved toward the right about 0.01 in. by shear deflection.

TABLE 3.—STRESSES DUE TO WIND LOAD.

$y$ .	$B_W$ .	$A_W$ .	$V_W$ .
$\tan \theta_1 = 0$ ; $\sec \theta_1 = 1$ ; $r = 100$ ft.; $e = 50$ ft.; $R = 100$ ft.; area = 63 000 sq. ft.; and $F = 630\,000$ lb.

## RELATION TO THE ELASTIC THEORY

The exact theory of domes, as distinguished from the common theory as given in this and the preceding paper, involves the elastic deformations caused by the stresses, and their effect on the stresses themselves. A treatment of the elastic theory as applied to conoids with balanced loads may be found in a paper by Dr. Peter Pasternak,\* of Zurich, Switzerland.

It is obvious that the elastic theory is of great value as a means of understanding the nature of the secondary stresses as well as for finding their exact amount. The common theory can be used with assurance only in those cases where the distortions are too small to be dangerous. The examples

\* "Die praktische Berechnung biegeester Kugelschalen, kreisrunder Fundamentplatten auf elastischer Bettung und kreiszylindrischer Wandungen in gegenseitiger monolither Verbindung," *Zeitschrift für angewandte Mathematik und Mechanik*, Band 6, 1926.

indicate a method of judging whether the dome can be designed safely by the common theory, or whether it must be studied by the more elaborate elastic formulas.

### SUMMARY

In this paper the theory covering symmetrical loads and stresses for domes is extended to include formulas for vertical loads occupying one side of the dome only, the area above a given level, or the area below a given level. There is also a set of formulas for wind stresses.

These give stresses which are in most cases necessarily less than those for symmetrical loads, or else they may constitute so small an addition as to be negligible in practice. Their value is chiefly in providing a means by which the engineer who is faced with a dome of unusual size or shape may assure himself in regard to the order of magnitude of the neglected stresses.

These formulas, taken in this way as safeguards rather than as "exact" equations, constitute a complete practical theory for domes of all kinds having a homogeneous surface and a polygonal or circular plan.

## DISCUSSION

A. FLORIS,\* Esq. (by letter).—It is rather doubtful whether a general theory of unsymmetrically loaded domes is much needed in a practical design of these structures. In domes the main loads are those due to their own weight and it is only in flat structures that the stresses produced by snow can be appreciable. Furthermore, domes which are relatively high in comparison with their span must be investigated also with regard to stresses caused by wind pressure. Any other loading condition is almost impossible in practice because domes, being mostly monumental structures, are symmetrical and symmetrically loaded, thus excluding in advance other possibilities. They possess not only symmetry of shape but, with the exception perhaps of wind pressure, symmetry of loading as well.

It is very fortunate that this is the case since the analysis of domes carrying eccentric loads arbitrarily chosen is not feasible to date. The theory of shells of rotation and especially of domes under axially symmetrical loading or wind pressure has received considerable attention abroad in recent years, and has been brought to a high degree of perfection. For reference, a bibliography of this subject is appended hereto. These investigations have revealed the important fact that the stress distribution in domes depends not only on their shape, but on the external loads as well, so that for any given load there is a stress variation corresponding to it.

These investigations have shown that the same law of stress distribution does not hold for various loading conditions. Navier's theory of bending as developed for prismatic bars cannot be assumed to apply in the case of domes. For this reason the author's fundamental assumption that the law of the trapezoid will be valid in the case of unsymmetrically loaded domes, which are systems in space, is more than a rough approximation; it is absolutely impossible to apply. Consequently, formulas derived under this assumption are of doubtful value in the design of domes and similar structures.

In addition, the author treats the analysis of wind stresses in a dome under the same assumption of the planar theory of flexure. The problem of wind stresses in domes has been solved by other writers for a certain distribution of wind pressure only. Assuming a pressure on the windward, and a suction on the leeward, sides of the dome, the stresses thus produced can be analyzed if the external loads are expressible in a Fourier series. They can be determined either by solving the differential equations of the problem, or, more simply, by statics, as has been shown recently by F. Dischinger.† This special wind loading with pressure on one and equal suction on the other diametrically opposed sides of the dome is sometimes called "anti-symmetrical".

*Theory of Stress Distribution in Beams with Anti-Symmetrical Wind Pressure.*—The thickness of a dome is usually small as compared with the dimensions of rise and span, so that it can be considered as a shell generated

about an axis of rotation. In such a shell the stresses due to the external loads are, under certain conditions, membrane stresses, that is, they are axial, acting in its mid-surface so that they can be determined by statics. This stress analysis for axially symmetrical loads was first given by Lamé and Clapeyron\* more than one hundred years ago and since then it has been repeatedly used by many writers. The stresses due to the boundaries (support, change of curvature, etc.) of the shell are caused mainly by bending moments and must be determined by taking into account the deformation of the structure. They are statically indeterminate and, at the same time, are independent of the external loads.

In a shell of rotation, with an axially symmetrical loading, the meridian and ring stresses are membrane stresses and, since they are normal to the corresponding sections of the shell, they are principal stresses. In an anti-symmetrically loaded shell of rotation, on the other hand, the meridian and ring stresses, although they are membrane stresses, do not act normal to the sections of the shell, but are inclined. By taking the components of these stresses, shearing stresses acting in the mid-surface of the shell are produced, in addition to the normal (meridian and ring) stresses. In the case of an anti-symmetrical loading the stresses due to the boundaries of the shell differ from those caused by an axially symmetrical loading.† However, they can be determined approximately by using the methods applied to such loading.‡

Neglecting the stresses due to the boundaries of the shell the rigorous analysis of the membrane stresses in a spherical shell has been given by H. Reissner§ in the case of loads expressible in a Fourier series. He has determined these stresses for a wind pressure following the sine law. Later, Dischinger|| discovered that, although this pressure distribution which is commonly assumed in design, is greater than the square sine law, nevertheless, the stresses produced by the former were found to be smaller than those due to the latter. This is true, however, only in the spherical shells. In shells with a polygonal base the greatest wind pressure produces also the greatest stresses, especially meridian stresses. These shells with polygonal rings but with curved meridians are a new type of dome possessing very favorable and, at the same time, interesting properties.

The important result in Dischinger's investigations as applied to the paper under discussion is the fact that only for the sine law of the wind pressure are the stresses in a spherical shell linearly distributed¶ In this case alone is there a neutral axis of the meridian—and ring—stresses, which is perpendicular to the wind direction. (See Fig. 10 (a).) The intensity of the

¶ *Loc. cit.*, p. 198.

shearing stresses, on the other hand, reaches its maximum in the neutral axis disappearing in the points where the normal stresses have their greatest values (see Fig. 10 (b).) In all other cases of anti-symmetrical wind pressure that follow various sine laws, the spherical shell possesses several neutral axes which not only do pass through the center of the parallel circles, but

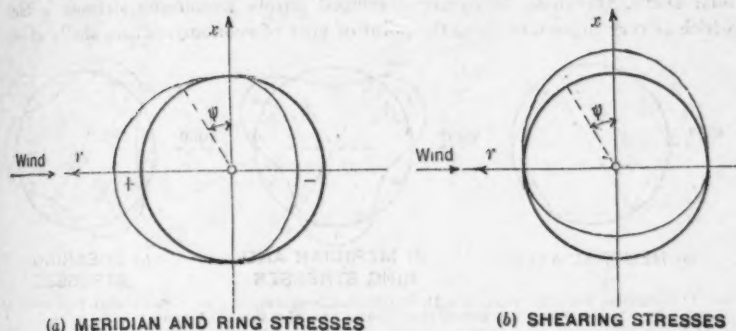

FIG. 10.—STRESS DISTRIBUTION IN A HORIZONTAL CROSS-SECTION OF A SPHERICAL DOME FOR A WIND PRESSURE FOLLOWING THE SINE LAW.

also connect the points of intersection of these axes with the circumference. (See Fig. 11 (a).) In this case, therefore, the distribution of the meridian and ring stresses is no longer linear. (See Fig. 11 (b).) The shearing stresses have their maximum values in the zero points of the normal (meridian and ring) stresses and *vice versa*. (See Fig. 11 (c).) Thus, for the various laws of wind-pressure distribution there are a certain number of corresponding neutral axes or points of change in the signs of stresses. For a few cases, these are as follows:

Wind pressure variation.	Neutral axes.
$\sin \psi$ .....	$1 = 1$
$\sin 3 \psi$ .....	$3^2 = 9$
$\sin 5 \psi$ .....	$5^2 = 25$
.....	.....
$\sin n \psi$ .....	$n^2$

In this list  $\sin \psi$  corresponds to the sine law of wind pressure, while  $\sin 3 \psi$  expresses the square sine law of this pressure\*.

The author apparently does not realize the great importance of the pyramidal domes, as he calls those with a curved meridian and a polygonal base. Thus, he treats an entirely new type of dome unaware of its remarkable properties with their far-reaching consequences in structural engineering. In these polygonal shells, as Dischinger was enabled to show, the stresses in any given point can be found from those developed in an inscribed spherical shell.† The "hips", that is, the intersection of two adjacent sectors of these

\* "Schalen und Rippenkuppeln," pp. 200 and 208.

† "Die Theorie der Vieleckkuppeln und die Zusammenhänge mit den einbeschriebenen Rotationschalen," von Franz Dischinger, *Beton und Eisen*, 1929, No. 5, pp. 100-107; No. 6, pp. 119-122; No. 8, pp. 150-156; and No. 9, pp. 169-175.

shells, remain free from bending stresses for axially symmetrical as well as anti-symmetrical loadings, provided the structure possesses a symmetry of shape. While in the shells of rotation the loads are transmitted to the abutment by the aid of the meridian stresses, the loads in the polygonal shells are sustained partly by the shell itself and partly by its "hips". In the polygonal shells, therefore, there are developed purely membrane stresses, a fact which is very important from the point of view of economy. These shells which

FIG. 11.—STRESS DISTRIBUTION IN A HORIZONTAL CROSS-SECTION OF A SPHERICAL DOME FOR A WIND PRESSURE FOLLOWING THE SQUARE SINE LAW.

are stressed mainly axially can have very thin sections because their weight does not increase appreciably with increasing span, as is the case, for instance, in rigid frames and similar structures. This discovery combined with that of the self-supporting arch barrel\* is the latest successful application of the advanced theory of statics to the problems of structural engineering.

With regard to the stress distribution of the polygonal shells the results of the theory developed by Dischinger for the anti-symmetrical wind pressure following the sine law will be sketched briefly. Owing to this law of pressure variation these shells have but one neutral axis.

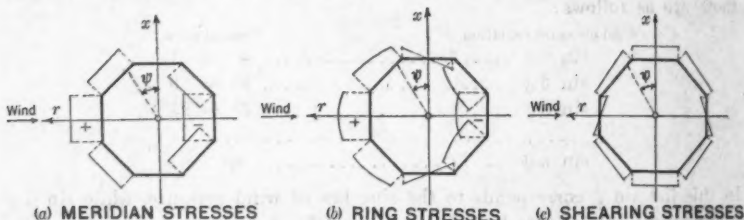

FIG. 12.—STRESS DISTRIBUTION IN A HORIZONTAL CROSS-SECTION OF A PYRAMOIDAL DOME FOR A WIND PRESSURE FOLLOWING THE SINE LAW.

The meridian stresses within a sector between two hips are constant and vary only from sector to sector according to the  $\sin \psi$  law (see Fig. 12 (a)). Consequently, by assuming that the resultants of the meridian stresses are acting in the middle of these sectors, the same law of stress variation is valid as in the shell of rotation.

\* "Schalen und Rippenkuppeln," p. 269; "Die Schalendächer des Elektrizitätswerkes in Frankfurt a. M." von U. Finsterwalder, *Beton und Eisen*, 1928, pp. 205-209; "Die Schalenbauweise Zeiss-Dywidag," von Fr. Dischinger und U. Finsterwalder, *Bauingenieur*, 1928, Nos. 44 to 46; also, "Self-Supporting Arch-Barrel," by A. Floris, *Western Construction News*, April 10, 1929.

Two kinds of shearing stresses are produced, namely, those due to the beam action of the shell between two adjacent hips and those caused by the dome action of the shell itself. The maximum values in the first case are reached in the sector,  $\psi = 90^\circ$ , while those of the second case take place at  $\psi = 0$ . The combined diagram of these two kinds of stresses is represented in Fig. 12 (b).

The ring stresses in a sector due to the beam action are composed of a parabolically and a linearly distributed stress. Both these stresses are zero at  $\psi = 0$  and maximum at  $\psi = 90$  degrees. The linearly distributed stress is constant within a sector. On the other hand the ring stresses due to the dome action of the shell, which are similar to those of a spherical shell, vary from hip to hip according to the  $\sin \psi$  law. However, the difference in this case will be that the ring stresses remain constant within a sector and have as in spherical shells a maximum value at  $\psi = 90^\circ$ , while they vanish at  $\psi = 0$ . The addition of the ring stresses is shown in Fig. 12 (c). With an increasing number of sides in a polygonal shell the ring stresses approach, but remain always greater than, those of a shell of rotation.

The properties of the polygonal domes herein outlined are manifestly of outstanding importance for the future development of reinforced concrete structures. Due to the combination of beam and dome actions in these shells the loads can be transmitted to the foundations by the aid of columns only, without the aid of intermediate supporting members, walls, beams, or arches, to a maximum distance of 130 ft. approximately between columns.

It is very doubtful therefore, whether domes designed with ribs subjected to bending can compare favorably with the shells of rotation or with those of a polygonal base which have to sustain largely axial stresses. The remarkable self-supporting ability of the polygonal shells is best illustrated by the fact that each of the three reinforced concrete domes of the Great Market in Leipzig, Germany, has an inscribed diameter of 245 ft., a maximum thickness at the abutment of 4½ in., and weighs only 2 380 tone.\*

In conclusion, the writer wishes to express his regret for having criticized this practical and carefully prepared analysis of the unsymmetrically loaded domes. In doing so he intended merely to state known facts which have possibly escaped the attention of the author.

*Bibliography of Studies on Domes.*—The following bibliography of the subject is given for those interested. References to the few English, Italian, French, and American sources must purposely be omitted because the most important advances made in the theory and design of these structures are largely due to German and Swiss mathematicians and engineers.

DAVID C. COYLE,\* M. AM. SOC. C. E. (by letter).—The tendency of American engineers to insist on rough and "practical" formulas for use in actual work is naturally irritating to many who are accustomed to the everyday employment of the elastic theories, for example, those who have been trained in Continental Europe. There is, however, some little justifica-

\* Cons. Engr., New York, N. Y.

tion for roughly approximate methods, a fact which was brought out in the discussion of the paper by Albert W. Ross, Jr., Jun. Am. Soc. C. E., and Clyde T. Morris, M. Am. Soc. C. E., in 1928, on the modified slope-deflection theory in wind bracing.\*

Briefly, the writer's point of view is one of frank though respectful skepticism as to the relation between the admirable mathematical systems propounded and the data to which they are applied. Concrete on the job is so likely to have occasional lapses from that perfect homogeneity which the elastic theories presuppose. As for the  $n$  neutral axes which would exist in a spherical dome anti-symmetrically loaded with a wind of the degree,  $\sin n\psi$ , there is no probable reason to doubt the mathematics of the matter, but it is questionable whether in actual construction a wind of such a special character needs to be considered.

The difference in point of view is very well illustrated by Mr. Floris' comment on the trapezoidal distribution of pressures due to unbalanced loads, which he quite correctly states has no logical basis in its analogy to the stresses in a prism. The fact remains, however, that the stresses obviously have a distribution which is of the same general form as the assumed distribution; a reference to his Figs. 10 and 12 will indicate at once that the results obtained by advanced statics are indistinguishable at small scale from those shown by the rough formulas. It is evident that the difference between the trapezoidal distribution and any other probable distribution of the stresses is similar to that between a five-centered oval and an ellipse. The mathematics of the two are very unlike, but the numerical results come very close to each other. As for the wind effects shown in Fig. 11, it is permissible to wonder whether the purity of the mathematics may not have obscured the inconsequence of the practical application.

The older theories of domes on the Continent seem to have involved originally the assumption of bending moments in the ribs of a pyramid. No doubt the development of advanced statics which has justified mathematically the use of a center-line stress system has seemed to be a radical liberation. It may be fair to remark, however, that the common theory in the United States has always been too inexact to take the secondary bending into account. For this reason Mr. E. Schmitt's formulas for pyramids, published in 1904† were based on the absence of bending in the ribs. The further elimination of bending from the shell between the ribs or "hips" is interesting, but the results are perhaps unfortunate. There is a constant danger that the growth of mathematical methods, the accuracy of which exceeds the homogeneity of the materials, may lead to economy which is based on an illusion. The domes of the Great Market in Leipzig, Germany, are illustrative of this point. By a mathematical process the builders have convinced themselves that practically no thickness at all was required. Similarly, it has always been recognized that the theoretical required thickness of a spherical dome is practically zero, the live load being small. It has not followed, however, that zero thickness was the best for the purpose.

\* Proceedings, Am. Soc. C. E., May, 1928, Papers and Discussions, p. 1395.

† Transactions, Am. Soc. C. E., Vol. LII (1904), p. 293.

In the building of actual structures, the proper function of mathematics is to check the general validity of the practical formulas used for the work itself; but if the accuracy of the mathematical methods used is allowed to become the main object, it is dangerous. The stresses having been computed to four places of decimals, what if a storm blows the covers off some night and the previous day's pour is frozen? Or what if there is sugar in one load of sand? Or what if two out of sixteen footings settle  $\frac{1}{8}$  in. more than the other fourteen? Or how about the indications that in some concrete the ratio between concrete and steel stresses is not equal to  $n$ , but to a function of time? What happens to the elastic theory if  $n$  is incorrect?

It is evident that the formulas given in this paper have a real approximate relation to the actual stresses in the structure. The close correspondence of the general shape of the stress diagrams with those of the more accurate theories indicates that the paper is not widely at variance with the facts. If their algebraic derivation is free from error, these formulas are suitable to give the engineer an idea of whether his design is well on the safe side. At the same time, they are free from the disadvantages of the high mathematics, of taking an unconscionable time, and of producing the illusion that their results are more accurate than their data.

Paper No. 1754

### ENGINEERING APPLIED TO NATIONAL PARKS\*

By STEPHEN T. MATHER,† Esq.

With Discussion by MESSRS. H. K. BISHOP AND W. W. CROSBY.

Beginning in 1872, with the setting aside of the Yellowstone National Park "as a public park or pleasuring ground for the benefit of the people", the fundamental principle underlying the National Park System has been the preservation of scenery—the natural objects and wonders and their retention in their natural condition. Congress re-affirmed this principle in creating the National Park Service in 1916, by stating‡ that the Service, in its administration of the National parks and monuments, was "to conserve the scenery and the national and historic objects, and the wild life therein, and to provide for the enjoyment of the same in such manner and by such means as will leave them unimpaired for the enjoyment of future generations".

In order that the people might enjoy the National parks it was necessary that roads be constructed to and within them to permit access to their treasure troves. At first, these roads were haphazard wagon trails, in existence at the time of the reservation of the parks, and it is the conversion of these old wagon roads into adequate automobile highways, or the construction of new roads, that forms one of the principal engineering problems confronting the National Park Service. This does not mean the establishment of a gridiron of roads, nor over-development. Large areas must always be preserved in their wilderness character.

#### DEVELOPMENT OF THE YELLOWSTONE ROAD SYSTEM

Due to the foresight and engineering ability of the late Gen. H. M. Chittenden, U. S. A. (*Retired*), M. Am. Soc. C. E., who, as an officer in

\* Presented at the Joint Meeting of the City Planning and Highway Divisions, New York, N. Y., January 19, 1928.

† Director, National Park Service, U. S. Dept. of the Interior, Washington, D. C. Mr. Mather died on January 22, 1930.

‡ Act of August 25, 1916 (39 Stat., 535) establishing the National Park Service.

the Engineer Corps, was placed in charge of the road work in Yellowstone Park in 1883, the system of roads laid out in that Park is now a standard for general rational park road development. The main loop road, which embraces in a general circuit all the important centers of interest in the Park, and the connecting gateway roads, are the work of General Chittenden. This system provides 303 miles of roads in an area of 3 348 sq. miles. For a number of years after 1883, Congress annually appropriated \$40 000 for road work, part of which was spent in actual construction and the remainder in the preparation of plans and in the making of surveys. Finally, in 1902, Congress adopted a definite program of road work and appropriated the sum of \$250 000 per year for three years.

While the road system laid out by General Chittenden is still in use (1928), it was not constructed to bear the modern vehicular traffic it now sustains. That it could continue to be used by automobiles after the opening of the Park to motor traffic in 1915 speaks volumes of praise for his engineering ability, and indeed as an engineer he was ahead of his day and age. Many of the roads laid out by him will continue to be used after they have been widened and surfaced. Only in places will changes have to be made in grade and alignment to bring them up to modern standards. It is doubtful whether extensions of the present road system to regions not now served by roads will be needed.

#### EXTENSION THROUGHOUT NATIONAL PARKS

Federal road construction under the Army Engineer Corps was extended to Crater Lake and Mount Rainier National Parks, but then came to a standstill. When the writer first began, in 1915, to co-ordinate National Park work, he was met with decided views on park road building in the Appropriations Committee of Congress, the members of which did not realize the importance of adequate highways. One Chairman of a House Appropriations Committee suggested that 14-ft. dirt roads, with frequent turnouts for passing vehicles, would serve park needs amply. It was not until members of the Committee had ridden over the old narrow road from El Portal, Calif., into Yosemite Valley, that the first appropriations for rebuilding this road were forthcoming.

During the fiscal years 1917, 1918, and 1919, a total of \$160 000 was received for the El Portal Road. From this time until 1924 only small annual appropriations were available for road construction, scattered in the separate park appropriations, while outside the parks, the States with Federal Aid and the Federal Government in the National Forests were building modern approach roads. These roads were bringing increasing numbers of motorists to park boundaries, only to find poor roads to bear the concentrated traffic from the far superior approach roads.

#### BEGINNING OF PARK ROAD PROGRAM

Under these conditions the road situation was becoming very acute. Therefore, in 1924, the Park Service presented to Congress a road program calling for authorization of appropriations of \$2 500 000 per year over a three-year period. This bill passed the House and Senate unanimously and became

a law. In the first year, however, the National Park Service was permitted to submit a deficiency appropriation of only \$1 000 000, and even this sum was temporarily lost because of the defeat of the deficiency measure by a filibuster in the closing hours of the last session of that Congress. In December, 1924, the new Congress passed the deficiency bill with the item of \$1 000 000 for park road work and in the spring of 1925 the first road contracts were let.

The plans had been prepared in 1922, but actual work did not commence until 1925. Meanwhile, road standards had changed rapidly. States which previously had led the Nation in road building were beginning to rebuild their highways to accommodate the motor traffic that had been created with the popularization of the automobile. It is perhaps just as well that funds were delayed, because the Park Authorities were able to profit by the mistakes of others. Higher standards were adopted for park roads and previous estimates were scrapped.

After a short working period, it became clear that, for the Park Service to handle its road building properly, it would need an engineering force of high caliber. The most competent highway engineers had been developed by the United States Bureau of Public Roads and were either in its employ or with State highway organizations. The U. S. Bureau of Public Roads was then busy in its Federal Aid and other work, getting into mountain road construction comparable to conditions found in the National parks. In the interests of Federal co-operation and co-ordination and the elimination of duplication and waste, an agreement was made between the Secretaries of the Interior and Agriculture whereby the resources of that splendid engineering organization, the Bureau of Public Roads, were made available for the carrying out of the park road program.

It is a splendid working agreement. Since 1925, the Bureau and the Park Service have spent or obligated a total of \$9 000 000. They have "taken stock" of the problem and know what they have ahead. Preliminary plans based on reconnaissances have been prepared and presented to the Bureau of the Budget, and to the Appropriations Committee of Congress. The program calls for an ultimate expenditure of \$50 000 000. The House of Representatives, in passing the Interior Department Appropriation Bill on January 13, 1928, has made \$5 000 000 available for the year 1928-29, and if the appropriations are continued on this basis, the road program will be completed in ten years.

This program does not involve gridironing the parks with roads. It contemplates the reconstruction and surfacing of nearly all old existing roads and the construction of only a few new ones. Nearly all the parks are located in high mountainous regions where road construction is an expensive proposition and where the scenery must be conserved and at all costs left as little scarred as possible. That is the job of the Bureau and the Park Service and that is where the trained Landscape Force of the Park Service is indispensable.

#### LANDSCAPING OF PARK ROADS

One important requirement is the preservation of park landscapes. In the lower elevations, rigid standards calling for railroad cuts must give way

to rolling grades; straight alignments must be sacrificed for graceful curves where trees or other beauty spots should be saved (Fig. 1). There is no necessity for speedways in the parks. Bridges must fit into the landscape. Where construction must be carried along sheer mountain sides (as in Fig. 2) the excavated material cannot be dumped over to scar the whole terrain. Contracts must provide for end-hauling where necessary, and contractors and sub-contractors must be watched to see that they comply with this provision. Rock is being blasted from a cliff along the old Garden Wall Trail at Glacier National Park as shown in Fig. 3. This is typical of some of the difficulties encountered.

The proposed Big Oak Flat Road reconstruction in Yosemite, a contract for the park section of which will be let early in 1929, will be specially guarded in this respect. This road ascends the north wall of the Yosemite Valley. Permitting the excavated material to be dumped off the right of way and to crash down the precipitous granite walls would cause a scar that Nature would require generations to efface. End-hauling on this project will increase the cost, but spread out over a hundred years this will be very little, and compared to the value of the magnificent scenery the cost is infinitesimal.

An example of what it is possible to accomplish along this line can be noted in the work completed in Yellowstone Park in 1927. Years ago, when funds were limited, Army engineers started to build a cut-off between Madison Junction and Old Faithful down the Firehole River. This project is located through a precipitous canyon which affords wonderful views of the rushing river. The work was partly completed, but the excavated rock was tumbled down into the river, making an unnatural ragged bank. Ten years later, when the final mile was completed by park force account, authority was given to preserve the natural beauty of the canyon. A dry rock wall was built up from the river; cut and fill were balanced. The contrast between the old and the new work shows that the cost of \$100 000 for this mile of construction was more than justified. On some of the famed roads of Switzerland, it is this attention to landscaping detail—to making the road fit into the picture—that has helped year after year to bring visitors from all parts of the world to enjoy the beauty of the Alps.

Trees must be protected, and side-hill cuts must be made with a consideration as to whether they will become covered with fern, or flower, or shrub. Parapets and rock walls must be designed to harmonize and yet give a feeling of safety in high places.

#### THE ZION PARK ROAD

The Zion-Mt. Carmel Road is one of the most important in the park program. It links the scenic attractions of Southwestern Utah, including Zion National Park, Bryce Canyon, and the North Rim of the Grand Canyon National Park. It reduces the distance between Zion and Bryce from 165 miles to 85 miles and between Zion and the North Rim from 150 miles to 130 miles. It ascends from the floor of Zion Canyon to the East Rim—a rise in elevation of nearly 4 000 ft.—in a distance of 8.75 miles. Contracts for Sections 1

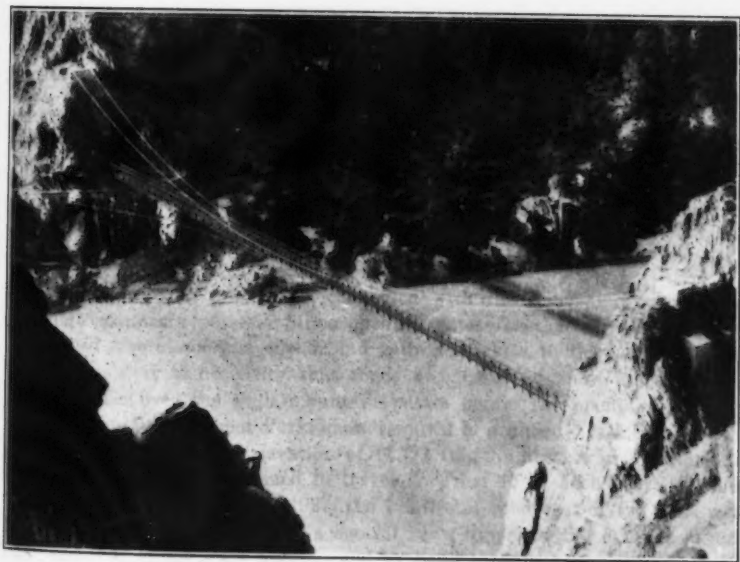

FIG. 4.—KAIBAB TRAIL BRIDGE.

VIEW OF THE MOUNTAINS

and 2 of this project were let in September, 1927, calling for the construction of 5.02 miles, including 5 582 lin. ft. of tunnel excavation. The cost of this section with an additional small contract will be \$800 000. It is estimated that the remainder of the project (3.65 miles) will cost \$450 000, or for the total construction, \$1 250 000. In addition, the State of Utah is constructing 16 miles of road connecting the east boundary of Zion Park with the Town of Mt. Carmel.

Another interesting feature of park road work is found in Mesa Verde National Park, Colorado, where Navajo Indians constitute the bulk of the laboring forces. There is never any difficulty in securing sufficient Navajo help, for when they get word that a construction job is to be started, they drift into the park, build their little "hogans" up against a near-by cliff, and are ready to start work when needed. Some of these same laborers, after the day's work is done, give sections of their "Yeibachai", or medicine dance, at the evening camp fire.

#### PARKING OF AUTOMOBILES

With the construction of roads comes the ever-increasing problem that all communities to-day are trying to solve—the parking of automobiles. In a restricted area like Yosemite Valley, this has become one of the most important of immediate problems. Mr. Frederick Law Olmsted made a preliminary study of parking conditions in Yosemite Valley. As a result he suggests\*:

"\* \* \* a principle which ought to be applied generally in the Valley, namely: That wherever there is occasion for the concentrated parking of a considerable number of cars, space should, as far as practicable, be provided for them, having these conditions: (1) Entirely separate from, and screened from, the roads used in moving about the valley; (2) so arranged that no parked car will be blocked in by subsequent arrivals; (3) so interspersed with trees (pre-existing or planted for the purpose), protected from injury (by the use of posts or racks or other guards close to the trunks), that the space and the cars will be largely covered by the foliage and unnoticeable in the plunging views into the valley; and (4) when the limit of such parking is reached, no further parking to be permitted in the vicinity."

#### SNOW REMOVAL

Another pressing problem is connected with the removal of snow from the high mountain passes. Since opening dates for the various parks are announced several months ahead, and railroad tickets to the parks are sold on this basis, it is necessary that roads be cleared of snow sufficiently to permit traffic over the high mountain passes before the opening date. In Rocky Mountain National Park, snow removal is a difficult task, because the Fall River Pass, with an elevation of 11 797 ft. (the highest in the National Park System), must be opened to travel on June 15 of each year, which is the official opening date. In 1927, the 7 miles of road east of the Pass were opened by a steam shovel with a special snow dipper, while 6 miles beyond the west side of the Pass were opened by hand shoveling.

\* From unpublished informal memorandum submitted by Mr. Olmsted to National Park Service Official.

Sylvan Pass, in the Yellowstone, also presents a difficult snow-removal problem. In 1927, due to the heaviest snowfall in years, more than 15 tons of explosives were used in clearing snow from Sylvan and Dunraven Passes, the Mount Washburn Loop, and the South Entrance Road. Crater Lake also had a serious problem, and the last impassible snow on the rim road was not removed until the middle of August, 1927. Sections of the river road must be rebuilt to avoid these heavy drifts of snow.

#### DUST PREVENTION

Until the parks roads are rebuilt, there will be the problem of alleviating the intolerable dust nuisance on some of the existing roads. An innovation in maintenance work in Yellowstone Park in 1927, was the substitution of a light road oil, instead of water, to lay the dust. This was a much more efficient method, although more costly. The entrance roads and the main loop were oiled for a distance of 126 miles with from  $\frac{1}{8}$  to  $\frac{1}{2}$  gal. per sq. yd. Old wooden tank trucks were used to haul the oil from cars to the distributor and about twenty wooden storage tanks were set up and used to store the oil. The water sprinkling system is being dismantled as rapidly as possible, as the tanks were an eyesore along the road. Four of the steel ammunition bodies that came with the trucks from World War surplus were covered with steel plates and welded and mounted on trucks and used to haul oil. Nine tank trucks and one distributor truck were used during June, July, and part of August, in transporting and spreading approximately 300 000 gal. of road oil.

#### SANITATION

One of the outstanding perplexities has been the providing of the necessary sanitary arrangements and safeguards for the traveling public. In the early days of Park Service history, when there were comparatively few visitors, common earth toilets and the burning of garbage in open pits—after first allowing the bears to work over it as an attraction to the tourist—were found to be sufficient. In the more modern days, however, this problem has the same phases as in large cities. Toilet facilities are being gradually changed to the most modern of city systems and garbage is being disposed of by especially designed incinerators. In conjunction with the garbage disposal, there are can-mashers to reduce the refuse cans to small bundles of unrecognizable metal, which are easily disposed of in such small compact masses.

The water systems are modern in every way. Originating in undefiled mountain streams and springs, the water is safeguarded by frequent analyses, and every precaution is taken to keep it free from contamination until it reaches the consumer. Inspections of the culinary arrangements in all hotels, camps, and concessions where public food is handled and sold are made regularly. In Grand Canyon National Park, where the water supply is a serious problem, and water has to be hauled for many miles in tank cars, a system has been perfected which purifies the waste water to the extent that it may be safely used over and over for flushing toilets, washing automobiles, and for many other non-domestic purposes. This effects a saving of thousands of dollars each year in haulage costs alone.

In Mesa Verde National Park where there is no live water during the summer the Park Service authorities have had to resort to the development of the water supply by catchment and storage. One unit has been constructed which provides for a corrugated, galvanized-iron catchment area, 1 acre in extent, with two steel frost-proof storage tanks, each with a capacity of 125 000 gal. The catchment area gathers, by means of a flume, the snow and rain falling thereon and conducts them through a rapid sand filter to the steel storage tanks. These steel tanks have not proved entirely satisfactory because when warmer weather prevails the water has a decided flatness and taint, possibly due to pollen from pinon trees. Funds have been included in the new Appropriation Bill for the construction of a second unit, in which concrete storage tanks will be substituted for the steel tanks. Plans for this work are now (1928) being drawn.

All this sanitary work has been accomplished by the able assistance and splendid co-operation of the expert sanitary engineers of the United States Public Health Service.

#### POWER, TELEPHONE, AND TELEGRAPH

In many of the National Parks there are hydro-electric systems which furnish light, power, and heat for administrative purposes within the boundaries. In numerous instances where it would be difficult, if not impossible, to obtain electricity from other sources, the surplus is furnished to the operators of the public utilities at reasonable rates. Most of the parks are abundantly supplied with possibilities for development along these lines, and local systems to supply the needs of a park are being augmented from time to time as funds become available. These problems are handled individually and frequently are difficult to solve since neither water-falls nor cascades can be used, and all installations must be made so as to mar the scenery as little as possible.

In order to provide adequate long-distance telephone service in Yellowstone, the American Telephone and Telegraph Company, using the Hotel Company and National Park Service pole lines, strung a two-wire, No. 128, copper, metallic circuit from Mammoth Hot Springs to Old Faithful and West Yellowstone, and another circuit from Mammoth Hot Springs to Yellowstone Lake *via* the Grand Canyon, and new magneto switchboards were placed at Mammoth Hot Springs, Old Faithful, the Grand Canyon, and Yellowstone Lake. These new copper circuits are built through to Helena, Mont., and give the park high-class, exclusive service. The new system when completed will cost about \$150 000.

In the Carlsbad Cave National Monument, New Mexico, there is an entirely different electrical lighting problem. This is the largest and probably the most beautifully decorated cave known in the world. The trip through the cave requires about five hours and proper lighting is of paramount importance. Congress is granting funds for this work and members of the Appropriations Committee who have visited the Caverns have taken a great interest in the problem. They have suggested that Park Officials consult with some of the best known electrical and stage lighting experts, with a view to

developing a system so that the lights will come on slowly until full illumination is obtained and then gradually die down to add to the impressiveness of the scene.

#### TRAIL CONSTRUCTION

Great wilderness areas must be retained in all the parks to be entered only by trail. These are for the horseback rider and hiker, as well as the administrative forces on game and fire patrol. Trail-building plans must go hand in hand with the road-building program. Some trail construction that is not equalled anywhere else in the world has already been completed. The trail across the Grand Canyon, according to travelers familiar with all parts of the world, is the best construction to be found. A view of Kaibab Trail Bridge is shown in Fig. 4. The lower cable is provided to support the suspension bridge against wind.

#### DIVERSE ENGINEERING PROBLEMS

This paper illustrates some of the diverse engineering problems which confront the National Park Service. They involve the expert services of the highway engineer, the landscape engineer, the sanitary engineer, the electrical engineer, and the mechanical engineer. A point has now been reached in park development where the same problems are encountered as in town planning.

To a great extent, visitors in the National Parks are gregarious and desire to herd together in the large public camp grounds. Streets must be laid out, sanitary conveniences located, water lines installed, and community buildings erected, where visitors may gather during inclement weather and in the evenings. Incidentally, these community buildings have become centers for educational work. With the increased crowds comes the necessity for hospitalization. In a few of the parks there are already some hospital facilities and these are now being extended into other parks.

#### CONCLUSION

The writer would also like to mention wild life preservation, and methods of combating insect infestations by means of power sprayers and in other ways, because although park work is primarily based on preserving the natural features of these reservations while at the same time developing them for tourist use, engineering along some lines is an important factor in nearly every phase of the Park Service activities. Park Officials could not continue to serve the public were it not for the engineers.

## DISCUSSION

H. K. BISHOP,\* M. Am. Soc. C. E. (by letter).—The author has covered this subject so thoroughly that little has been left to discuss. The writer agrees entirely with Mr. Mather.

The U. S. Bureau of Public Roads has benefited greatly by its co-operation with the Park Service. In the beginning the personnel of the Bureau was perhaps a bit inclined to think too much of economy in road construction and too little of scenic effects and the preservation of the beauty of the country through which the roads ran. Through the National Park Service the Bureau has been brought into contact with landscape engineers, and consequently a new appreciation of scenic factors will be evident in the character of the roads built hereafter in the National Parks and National Forests of the West.

The writer has a great admiration for the work that the Park Service is doing. Those who have visited the Western parks will appreciate it. The Service is opening trails and roads to scenes of beauty that were hitherto inaccessible.

Mr. Mather mentioned two projects: The Transmountain Road in Glacier National Park, and the road in Zion National Park, each of which will cost more than \$1 000 000. The State of Arizona is now building a bridge across the Grand Canyon at Lee's Ferry which will change entirely the situation in that part of the United States. The impassable canyon that heretofore has cut off highway travel between the north and south and, to some extent, between the east and west, will be bridged at Lee's Ferry, and a road will probably be constructed from Flagstaff, Ariz., to Zion National Park, Bryce Canyon, and Salt Lake City, Utah. The writer predicts that this road, in time, will be one of the heavy traffic roads of the West.

Mr. Mather describes the snow-removal problem. There has been a great deal of trouble in opening some of the passes through the Rocky Mountains in time for the traffic in the spring. Great strides have been made since 1925, but snow removal work is still a new problem in the parks.

In the Western States the best road surfacing is obtained from fine crushed rock or gravel; but experience has taught the Bureau of Public Roads that it must do something to eliminate the dust which becomes a serious nuisance when the traffic increases. For that purpose a method has been developed of mixing a road oil in place, which is believed to be something new in road building. After the crushed rock road has been built and traffic-bound, it is scarified to a depth of 2 or 3 in. Then it is treated with just an ordinary fuel oil in two or three applications, the harrows being run over it after each time. A blade machine is used to move the material back and forth on the road until it is thoroughly mixed, as indicated by the color of the mass. After mixing in this manner the loose material is spread uniformly over the width to be surfaced and the road is opened to traffic, by which it is consolidated.

\* Chf., Div. of Constr., U. S. Bureau of Public Roads, Washington, D. C.

This kind of surfacing costs from \$800 to \$1500 per mile for the oil and mixing process, and it is very effective. The writer has seen some sections that appeared as if they were paved with bituminous concrete.

W. W. CROSBY,\* M. Am. Soc. C. E. (by letter).—For some years the writer has been protesting against a dogmatic assertion, to the effect that "the return in the form of economic transportation is the sole measure of justification for road improvement". This idea has been more or less widely spread and apparently is supported by National organizations the endorsements of which are expected to carry great weight.

The paper emphasizes the fact that other considerations beside relative economics are important in determining highway improvements. It is commended, therefore, to the careful attention of all highway engineers.

Paper No. 1755

### USE OF WATER ON FEDERAL IRRIGATION PROJECTS\*

By E. B. DEBLER,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. ROBERT A. MONROE, IVAN E. HOUK, GEORGE N. CARTER, RALPH L. PARSHALL, AND E. B. DEBLER.

#### SYNOPSIS

From the initiation of each of the irrigation projects of the United States Bureau of Reclamation it has been customary to ascertain and record the use of water. Operation and maintenance charges have always been based on the quantity of water delivered to individual farms, a method which was made mandatory by Act of Congress approved August 13, 1914. Other justifications for the measurement of water have been: The desirability of securing data for use in designing distribution systems; the necessity for obtaining data to use in determining project areas; and the desire to foster the most economical use of the available irrigation supply.

The results of field measurements of water delivered to farms are assembled annually in the project offices and are summarized in their respective project histories.

The project histories, together with supplemental data otherwise obtained, constitute the source of information from which the data incorporated in this paper have been compiled. In abstracting the results of the field measurements many of the original compilations were revised so that comparable data for all projects could be presented herein.

In tabular form are given the quantities of water delivered to the farms on the various projects each month during the different years of operation, the data being arranged chronologically and one table being devoted to each

NOTE.—The subject of this paper is one of several selected by the Special Committee on Irrigation Hydraulics for study and research. The paper was prepared for the consideration of the Committee in order to make available for general use much valuable data heretofore found only in the files of the United States Bureau of Reclamation.

\* Published in March, 1929, *Proceedings*.

† Engr., U. S. Bureau of Reclamation, Denver, Colo.

project or each important sub-division thereof. The tables also include pertinent related data, such as total irrigated areas, total mileage of canals and laterals operated, precipitation during the irrigation season, mean air temperatures, percentages of irrigated areas in different crops, canal and lateral losses, waste, etc. A summary gives the average use of water on the various projects during the 10-year period from 1917 to 1926, inclusive. Pertinent related data and information are also shown, as in the more detailed tabulations.

It is believed that the data included in the tables will be found useful to most engineers engaged in irrigation work. The results of the field measurements of use of water cover a wide range in climatic and soil conditions as well as several years of project operation under varying stages of development. The tabulated data do not possess a high degree of scientific accuracy. Nevertheless, they are believed to be sufficiently accurate for the purposes for which they were obtained.

From the hitherto unpublished records of the U. S. Bureau of Reclamation, considerable data have been assembled and tabulated, to show the variation in use of irrigation water. The many projects included are indicated on Fig. 1, a map of the western part of the United States showing the locations of the Federal irrigation projects. Numbers enclosed in circles correspond to the numbers of the tables containing the detailed data on the use of water.

Compilations for these twenty-four projects are given in Tables 1 to 25, inclusive, corresponding. The data selected are those considered most useful to an engineer in designing or reviewing an irrigation plan. In general, the information is self-explanatory and hence many of the tables require no comment. However, a few remarks may well be given dealing with the particular aspects of the general problem and of this special investigation.

#### METHODS OF MEASUREMENT

Reliable gauging stations are maintained at the diversion points on all projects. Discharge measurements at the heads of laterals are often complicated by canal structures. Waste, as the term is used in this compilation, is the water returned to natural streams through wasteways operated in connection with the project system. It does not include water delivered to the user and by him permitted to leave his farm unused. Project waste is measured by the project operation forces. The data on waste and losses are made to portray conditions without internal reservoirs by eliminating the reservoir losses where such reservoirs are present.

Farm deliveries are ascertained in a number of ways and with varying degrees of accuracy. In general, they are measured at, or very close to, the farm border; but in a few cases complications attending such observations have resulted in a practice of making measurements nearer the main canals with allowance for losses in transit to the farm border. The most common form of measurement is by means of the Cipolletti weir. However, a lack of adequate heads often precludes this method, so that the use of submerged weirs or current meters becomes necessary. The cost of current-meter work pre-

cludes the securing of accurate delivery records where this method is required. The use of the current-meter method is practically limited to parts of the Rio Grande and Yuma Projects.

In addition to the difficulties of water measurement, the procurement of records truly reflecting the use of water is complicated on many projects by human factors, in that the ditch rider is constantly besieged by individuals to reduce their water charges. On many projects there is, therefore, a recognized factor of under-measurement of farm deliveries, with a corresponding increase in apparent canal and lateral losses, because diverted waters not accounted for in waste and deliveries, are charged to canal loss. At numerous times and places, measurements have been made to ascertain the loss in feet of depth per day for various types of canal materials, but the utilization of these results for an estimate of total canal losses in an operating system is impractical, by reason of cost and changing conditions.

FIG. 1.

#### MEANING OF THE DATA

Referring to the tabulations for the individual projects, the area commanded by the constructed canal system represents the irrigable area to which

water could have been supplied. The irrigable area, with minor deviations on various projects, excludes rights of way for section-line roads, highways, railroads, main canals, principal laterals, and drains. It also excludes all lands that cannot be cultivated at moderate costs for land preparation and farm lateral construction, or lands that are unworthy of cultivation by reason of inferior soils. House and barn yards have not been excluded. Areas that are temporarily non-irrigable by reason of seepage are included. Declining areas are usually due to elimination of lands on account of inferior agricultural values or on account of permanent seepage. The lag in the irrigated area is due to delayed settlement and delayed development of individual holdings.

The comparison of irrigated and commanded lands, together with data on the character of canal construction and length of canals, is given as a guide for the interpretation of canal losses and project waste which can usually be expected to decline as full development is approached. In many cases the main canals have been constructed to a capacity that is considered adequate for the ultimate irrigable area, so that their operation to partial capacity is productive of undue losses.

The farm deliveries represent, in general, the quantities for which charges are made. On a few projects, "off-season" deliveries are customarily made to supply stock water and on others the use of "off-season" water is at times encouraged for leaching purposes and for conserving the limited supplies available during the irrigation season. The general practice is to make a small charge, or no charge at all, for "off-season" deliveries. The tabulation excludes such deliveries and the attendant losses, in so far as possible without research into the original water records. The column headed, "Actual Delivery Percentage Larger", represents the required increase necessary in the tabulated farm deliveries to ascertain actual deliveries, on account of the recognized factor of under-measurement. The indicated correction factor to ascertain actual deliveries has been supplied by the operating personnel. This is necessarily an opinion only, but it is supported by long experience and familiarity with project conditions, and in most cases by numerous although discontinuous measurements for the purpose.

Data on temperature, precipitation, character of crops, and character of soils, have been added to aid in interpreting the results. The growing season mentioned comprises the months in which, if rainfall were inadequate, it would be necessary to resort to irrigation. As a further guide, the precipitation during the non-growing months preceding the growing season also has been shown, because in many cases it replenishes soil moisture used in the growing season.

Alfalfa and forage crops, together with irrigated pastures, are heavily irrigated throughout the season—as a rule, by surface flooding. Fields of small grains, although usually irrigated by flooding, require the least total water because the growing period during the irrigation season is short and plant requirements are relatively small. Furrow crops, of which potatoes, sugar-beets, corn, and small fruits are predominant, require more water than small grains, but generally less than the forage crops. Trees, usually fruit orchards, have a low water requirement except when intercropped and then such requirement is largely determined by the character of the intercropping.

<sup>1</sup> Climatological records, mean of Orman and Vale, S. Dak.

<sup>2</sup> 1912-19, total cropped area; irrigated area considerably less in years of high rainfall.

<sup>3</sup> Project charges based on these deliveries; actual deliveries estimated as 15% greater.

<sup>4</sup> Actual losses estimated as averaging 7% less than shown, due to under-measurement of deliveries.

<sup>5</sup> Waste not measured, but included in loss.

<sup>6</sup> 49% of total diversions wasted in order to lower reservoir water surface for dam repairs.

<sup>7</sup> Actual deliveries estimated as averaging 7% more than shown, due to under-measurement.

<sup>8</sup> Irrigable area originally estimated at 90 000 acres; reduction due to suspension of construction and to elimination of poor lands.

## USE OF IRRIGATION WATER

TABLE 2.—USE OF WATER ON THE BOISE IRRIGATION PROJECT OF IDAHO.

(Average elevation, 2 500 ft.; chiefly in volcanic ash and sandy loam soil; 37 miles of pipe, flume, and concrete-lined canals.)

DELIVERED TO FARMS, IN HUNDREDS OF ACRE- FEET PER ACRE. <sup>4</sup>													PERCENTAGE OF AREA IN DIFFERENT CROPS. <sup>1</sup>				PERCENTAGE OF TOTAL DIVERSIONS FOR SEASON. <sup>5</sup>

<sup>1</sup> Based on crop census for an average of 75% of irrigated area.<sup>2</sup> Climatological records at Caldwell, Idaho.<sup>3</sup> Arrowrock Reservoir under construction, placed in operation in 1915, with supply to lands above Deerflat Reservoir limited prior thereto.<sup>4</sup> Project diversions based on these deliveries: actual deliveries estimated as 5% greater.<sup>5</sup> Total diversions from Boise River at Boise Diversion Dam above Boise, Idaho, plus outflow from Deerflat Reservoir minus inflow to Deerflat Reservoir except for 1912 when there was other inflow to the reservoir: Deerflat Reservoir is served by main canal.<sup>6</sup> Actual losses estimated as averaging 3% less than shown due to under-measurement of deliveries.<sup>7</sup> Includes only wasteways where records were kept. No records after 1922. Waters wasted from upper system but caught in Deerflat Reservoir not charged as waste.<sup>8</sup> Actual deliveries estimated as averaging 3% more than shown due to under-measurement.<sup>9</sup> Final irrigable area 167 780 acres (under Government canals, with water supply from Boise River).

TABLE 3.—USE OF WATER ON THE CARLSBAD IRRIGATION PROJECT OF NEW MEXICO.  
(Average elevation, 3 100 ft.; in sandy loam and gravel; 25% of system concrete-lined.)

<sup>1</sup> Climatological records at Carlsbad, N. Mex.

<sup>2</sup> Project charges based on these deliveries; actual deliveries estimated as 10% greater.

<sup>3</sup> Total diversion at Avalon is estimated by adding 5% to sum of measured discharges at Main Canal flume over Pecos River and East Canal Head-Gate. Diversions from Black River also included.

<sup>4</sup> Actual losses estimated as averaging 4% less than shown, due to under-measurement of deliveries.

<sup>5</sup> Actual deliveries estimated as averaging 4% more than shown, due to under-measurement of deliveries.

<sup>6</sup> The project that may permanently be irrigated is limited by water supply and in years of abundant run-off may be exceeded as additional arable lands are commanded by the existing distribution system. The final irrigable area is 25 000 acres.

<sup>7</sup> Irrigation in these months is largely done in anticipation of shortages later in season and with waters that would otherwise be wasted.

<sup>8</sup> Largely cotton.

<sup>9</sup> Indicated waste is largely at ends of season and of waters which can not be conserved.

TABLE 4.—USE OF WATER ON THE GRAND VALLEY IRRIGATION PROJECT OF COLORADO.

(Average elevation, 4 700 ft.; much of system specially puddled-lined; main canal largely in highly pervious strata; many of laterals in sand, with porous subsoil.)

<sup>1</sup> Climatological records at Grand Junction, Colo.

<sup>2</sup> Project lands only; Fallsade, Mesa Company, and Orchard Mesa Irrigation Districts not included.

<sup>3</sup> Project charges based on these deliveries; actual deliveries estimated as 5% greater.

<sup>4</sup> Discharge of main canal at head less deliveries to Fallsade, Mesa County, and Orchard Mesa Irrigation Districts.

<sup>5</sup> Includes main canal loss on deliveries to Districts in 1919 and subsequent years, carried a distance of about 5 miles in canal which is largely lined.

<sup>6</sup> Water supply, except on rare occasions, far in excess of project requirements.

<sup>7</sup> Actual losses estimated as averaging 3% less than shown, due to under-measurement of deliveries.

<sup>8</sup> Actual deliveries estimated as averaging 5% more than shown, due to under-measurement.

<sup>9</sup> Final irrigable area—45 000 acres—will require material extension of lateral system.

<sup>1</sup> Climatological records at Huntley, 1912-18; at Ballantine, thereafter.

<sup>2</sup> Project charges based on recorded deliveries; actual deliveries estimated as 15% greater.

<sup>a</sup> Includes diversions for operation of pumps.

\* Actual losses estimated as averaging 5% less than shown, due to under-measurement of deliveries.

5 Includes all waste except diversions for operation of pumps.

<sup>a</sup> Diversions for operation of pumps only, no waste included.

7 Actual deliveries estimated as averaging 5% more than shown, due to under-measurement.

Final irrigable area estimated at about 32 000 acres, contains much adobe land which may prove infeasible of agricultural development.

TABLE 6.—USE OF WATER ON THE KING HILL IRRIGATION PROJECT OF IDAHO.

<sup>1</sup> Climatological records, Glens Ferry, Idaho.

<sup>2</sup> Project operated prior to 1921 by King Hill Irrigation District, which again took over operation in January, 1927.

<sup>3</sup> Unrecorded diversions and deliveries, April 4 to May 18, 1921, prior to operation by U. S. Reclamation Bureau, not included.

<sup>4</sup> Project has a fixed uniform supply of available water, waste occurring largely at ends of season of waters that could not be conserved.

<sup>5</sup> Loss and waste not segregated in 1926 and 1927.

<sup>6</sup> Irrigable area, 16 890 acres, but will probably remain to a large degree unirrigated on account of unexpectedly heavy deliveries required.

1 Climatological records, mean of Klamath Falls and Merrill, Ore.

<sup>2</sup> Private districts included, 1918 and 1919, 5 000 acres; 1920, 6 700 acres; 1921, 7 800 acres; 1922, 1923, 1924, 8 920 acres; 1925, 8 408 acres; 1926, 9 883 acres.

<sup>3</sup> Deliveries to private districts at heads of laterals instead of farms.

\* Private districts not included. Quantities shown are for project lands only.

<sup>5</sup> Project charges based on these quantiles; actual deliveries estimated as 20% greater.

<sup>6</sup> Total diversions from Upper Klamath Lake, Lost River, and Lost River return flow.

7 Losses in private district laterals not included (about 16% of irrigated area in private districts 1918-23).

<sup>5</sup> No record.

Actual losses estimated as averaging 8% less than shown, due to under-measurement of deliveries.

<sup>9</sup> Based on an estimate of lateral loss on deliveries to private districts.

<sup>1</sup> Based on quantiles delivered to private district lands as well as project lands.

<sup>2</sup> Actual deliveries estimated as averaging 8% more than shown, due to under-measurement.

<sup>a</sup> Final irrigable area, 95 000 acres, including lands in private projects served by project main canals.

<sup>1</sup> Mean of Glasgow and Malta, Mont., climatological records, 1912-26.

<sup>2</sup> From letter of March 17, 1925, from Project Superintendent.

<sup>a</sup> Protect charges based on these deliveries; actual deliveries estimated as 10% greater.

4 Total diversions from Milk River plus canal diversions from Nelson Reservoir.

3 Includes loss in Main Canal on diversions for Nelson Reservoir, but not loss in Nelson Reservoir.

Actual losses estimated as averaging 5% less than shown, due to under-measurement of deliveries.

7 Includes loss due to priming new canals and filling Nelson Reservoir below elevation of zero storage of 52.5 per cent.

Includes waste to Bowdoin Lake and to Alkali Creek to facilitate river-bank protection work (6.9 per cent.).

29 Actual deliveries estimated as averaging 5% more than shown, due to under-measurement

Actual densities estimated as averaging 0.9 more than shown, due to larger insects caught.

Final irrigable area, 140 100 acres.

<sup>1</sup> Climatological records at Fallon, Nev.

<sup>2</sup> Based on crop report for entire project. Grain percentage would be slightly higher for Carson Division alone.

<sup>3</sup> Water shortage; Lahontan storage first available in 1914.

<sup>4</sup> Project charges based on these deliveries; actual deliveries estimated as 10% greater.

<sup>5</sup> Losses below Carson River diversion dam.

<sup>6</sup> Actual losses estimated as averaging 5% less than shown, due to under-measurement of farm deliveries.

<sup>7</sup> Actual deliveries estimated as averaging 5% more than shown, due to under-measurement.

<sup>8</sup> Final irrigable area not determined, but may not exceed 70 000 acres.

\* Six miles lined in 1912 and increased gradually to 30 miles in 1925.

† Distribution system extended to provide individual farm deliveries. Shrinkage in irrigable and irrigated areas resulted from inadequate water supply which became evident in the 1912-25 period of sub-normal stream flow.

1 Climatological record at Omak, Wash.

2 Average for all lands under project; shortages for the new lands occurred in 1918-20, 1922-24, and 1926.

3 Includes some water used in October and November for concrete lining and unrecorded deliveries.

4 Some project waste combined with reservoir spill in records.

5 Percentage of losses increased by shortage of water.

9 Divisions to North Platte Canal and Colonization laterals considered as farm deliveries.  
9 Exclusive of North Platte Canal and Colonization Company lands, 16 000 acres irrigable, receiving water from Interstate Canal near its head; final irrigable area, 237 000 acres.

## USE OF IRRIGATION WATER

TABLE 14.—USE OF WATER ON THE ORLAND IRRIGATION PROJECT OF CALIFORNIA.

<sup>1</sup> Climatological records at Orland, Calif.

<sup>2</sup> Severe water shortages, supply in some other years slightly limited.

<sup>3</sup> Covers distribution system only, Seven Mile Reservoir feeder canal omitted.

<sup>4</sup> High rate of loss due to water shortage and resulting small canal discharges.

<sup>5</sup> Severe water shortage but rate of loss normal as most of canal system was dry from July 8 to November 9.

<sup>6</sup> Practically all waste occurred in November and December, after water shortage was over.

<sup>7</sup> Final irrigable area, 20 659 acres; irrigated area in past limited by water supply; additional storage to become available in 1929.

TABLE 15.—USE OF WATER ON THE RIO GRANDE IRRIGATION PROJECT OF NEW MEXICO AND TEXAS.  
(Average elevation, 3 700 ft.; 10 miles concrete-lined, remainder chiefly in silt.)

Calendar year.	Irrigated area, total for year.	Area commanded by constructed canals. <sup>1</sup>	Miles of canals and laterals operated. <sup>2</sup>	DELIVERED TO FARMS, IN HUNDRETHS OF ACRE-FEET PER ACRE. <sup>3</sup>												Precipitation, February to November, in feet.	Water delivered plus precipitation, February to November, in feet.	Precipitation, December, to January, preceding, in feet. <sup>4</sup>	Mean temperature, February to November, in degrees Fahrenheit. <sup>5</sup>	PERCENTAGE OF AREA IN DIFFERENT CROPS. <sup>1</sup> Mean of climatological records at El Paso, Tex., and Agricultural Coll., New Mexico.

<sup>2</sup> Includes losses in community ditches, 1912 to 1918, by considering deliveries to community ditches as deliveries to farms. No data on use under community canals.

<sup>3</sup> Charges for water deliveries changed from flat rate to acre-feet basis which was thereafter used.

<sup>4</sup> Project charges based on these deliveries; actual deliveries estimated as 25% greater.

<sup>5</sup> Loss in community ditches not included, 1912 to 1918.

<sup>6</sup> Returned to river and largely available for re-diversion.

<sup>7</sup> Waste unmeasured, included in loss.

<sup>8</sup> Actual losses estimated as averaging 7% less than shown, due to under-measurement of deliveries.

<sup>9</sup> Mileage increase disproportionate to irrigated area, due to gradual taking over of community ditches.

<sup>10</sup> Actual deliveries estimated as averaging 7% more than shown, due to under-measurement.

<sup>11</sup> Final Irrigable area, 155 000 acres.

## USE OF IRRIGATION WATER

TABLE 16.—USE OF WATER ON THE FRANNIE DIVISION OF THE SHOSHONE IRRIGATION PROJECT, WYOMING.  
(Average elevation 4 150 ft.; in sand and clay loam; no lining.)

Calendar year.	Irrigated area, total for year.	Area commanded by constructed canals. <sup>4</sup>	Miles of canals and laterals operated.	DELIVERED TO FARMS, IN HUNDREDS OF ACRE-FEET PER ACRE. <sup>1</sup>												Precipitation, April to September, in feet. <sup>3</sup>	Water delivered plus precipitation, April to September, in feet.	Precipitation, October to March, preceding, in feet.	Mean temperature, April to September, in degrees Fahrenheit.	PERCENTAGE OF AREA IN DIFFERENT CROPS.				PERCENTAGE OF TOTAL DIVERSIONS FOR SEASON.				
				January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.					Total.	Alfalfa, hay, and pasture.	Small grains.	Purrow crops.	Trees.	Canal and lat- eral losses. <sup>2</sup>	Waste.	Delivered to farms. <sup>5</sup>

<sup>1</sup> Project charges based on these deliveries; actual deliveries estimated as 10% greater.

<sup>2</sup> Actual losses estimated as averaging 5% less than shown, due to under-measurement of deliveries. Available data prior to 1922 do not aggregate losses for Frannie Division. Indicated data after 1921 are based on losses within division only.

<sup>3</sup> Actual deliveries estimated as averaging 5% more than here shown, due to under-measurement.

<sup>4</sup> Final irrigable area, 28 000 acres; indicated reduction in past commanded areas due to elimination of poor land.

<sup>5</sup> Climatological records at Deaver, Wyo.

TABLE 17.—USE OF WATER ON THE GARLAND DIVISION OF THE SHOSHONE IRRIGATION PROJECT, WYOMING.  
(Average elevation, 4 400 ft.; in gravel and loam; 4 miles of tunnel and other concrete-lined conduit.)

Calendar year.	Irrigated area, total for year.	Area commanded by canals. <sup>6</sup>	Miles of canals and laterals operated.	DELIVERED TO FARMS, IN HUNDREDS OF ACRE- FEET PER ACRE. <sup>1</sup>												PERCENTAGE LOSS IN DIFFERENT DIVISIONS FOR SEASONS.

<sup>1</sup> Project charges based on these deliveries; actual deliveries estimated as 10% greater.

<sup>2</sup> Includes losses from Ralsdon Regulating Reservoir. From 1918-21, inclusive, represents combined loss on Garland and Framme Divisions. After 1921, represents losses within Garland Division alone, with aggregate quantity of water delivered to Framme Division deducted from diversion.

<sup>3</sup> Actual losses estimated as averaging 6% less than shown, due to under-measurement of deliveries.

<sup>4</sup> Losses and waste not segregated, the total amounting to 46 per cent.

<sup>5</sup> Actual deliveries estimated as averaging 6% more than shown, due to under-measurement.

<sup>6</sup> Final irrigable area, 42 000 acres; indicated past reductions in commanded areas, due to elimination of poor land.

<sup>7</sup> Climatological records at Powell, Wyo.

## USE OF IRRIGATION WATER

TABLE 18.—USE OF WATER ON THE FORT SHAW DIVISION OF THE SUN RIVER IRRIGATION PROJECT, MONTANA.  
(Average elevation, 3 700 ft.; wholly in earth.)

Calendar year.	Irrigated area, total for year.	Area commanded by constructed canal system. <sup>1</sup>	Miles of canals and laterals operated.	DELIVERED TO FARMS, IN HUNDRETHS OF ACRE-FEET PER ACRE. <sup>2</sup>												PERCENTAGE OF AREA IN DIFFERENT CROPS.					PERCENTAGE OF TOTAL DELIVERIES FOR SEASON.

<sup>1</sup> Data cover Part No. 1 of Greenfields Division only; in general, about 94% of indicated total irrigated area.

<sup>2</sup> Project charges based on these deliveries; actual deliveries estimated as 5% greater.

<sup>3</sup> Measured at Fairfield Drop, losses from Sun River Diversion Dam to Drop excessive on account of small part of division area irrigated.

<sup>4</sup> Below Fairfield Drop, only.

<sup>5</sup> Actual losses estimated as averaging 2% less than shown, due to under-measurement of deliveries.

<sup>6</sup> Actual deliveries estimated as averaging 2% more than shown, due to under-measurement.

<sup>7</sup> Final irrigable area, 100 000 acres.

<sup>8</sup> Climatological records at Fort Shaw, Mont. for 1919; other years at Fairfield, Mont.

TABLE 20.—USE OF WATER ON THE UMATILLA IRRIGATION PROJECT OF OREGON.  
(Average elevation, 470 ft.; 157 miles of pipe or lined canal, remainder in sandy loam.)

<sup>1</sup> Climatological record at Hermiston, Ore.

<sup>2</sup> Project charges based on these deliveries; actual deliveries estimated as 10% greater.

<sup>3</sup> Not including feed canal, which is 25 miles long with an average annual loss of 9 per cent.

<sup>4</sup> Sum of discharges at heads of Maxwell, A. and West Division Main Canals.

<sup>5</sup> Loss in West Division Canals estimated at 2%; system is largely concrete-lined or piped.

<sup>6</sup> Includes some water used for construction purposes.

<sup>7</sup> Actual losses estimated as averaging 5% less than shown, due to under-measurement of deliveries.

<sup>8</sup> Actual deliveries estimated as averaging 5% more than shown, due to under-measurement.

<sup>9</sup> Final irrigable area, 28 300 acres.

TABLE 21.—USE OF WATER ON THE UNCOMPAGNE IRRIGATION PROJECT OF COLORADO.

<sup>1</sup> Climatological records at Montrose, Colo.

<sup>2</sup> Not recorded.

<sup>3</sup> Additional area irrigated from private canals contracted to be turned over to the U. S. Bureau of Reclamation and supplied with Gunnison water: 1912, 4513 A; 1913, 6004 A; 1914, 6000 A; 1915, 4500 A; 1916, 700 A; 1917-23, 1000 A.

<sup>4</sup> Project charges based on these deliveries; actual deliveries estimated 5% greater.

<sup>5</sup> Prior to 1923 water delivered on continuous flow basis. For 1923 and subsequent years water delivered on demand basis.

<sup>6</sup> Total diversions from Uncompaghe and Gunnison Rivers less Gunnison water delivered to Uncompaghe River.

<sup>7</sup> Losses small because of unmeasured seepage and farm waste entering canals and laterals. Some return flow charged to canals.

<sup>8</sup> Actual losses estimated to average 3% less than shown, due to under-measurement of deliveries.

<sup>9</sup> Waste included.

<sup>10</sup> Actual deliveries estimated to average 3% more than shown, due to under-measurement.

<sup>11</sup> Final Irrigable area, 97 064 acres.

# USE OF IRRIGATION WATER

<sup>1</sup> Climatological records at Sunnyside, Wash.

<sup>2</sup> Irrigation districts included, 1916 and subsequent years.

<sup>3</sup> Shortage of storage water.

<sup>4</sup> Deliveries are not generally measured at farms. Lateral losses have been determined to average 15% and the indicated deliveries are 85% of quantities flowing at heads of laterals where water is always measured.

<sup>5</sup> Project charges based on these deliveries; actual deliveries estimated as 5% greater.

<sup>6</sup> Slight shortage.

<sup>7</sup> Lateral losses assumed 15% of discharge at heads of laterals; canals receive unmeasured inflow of waste and seepage water, which has gradually increased in recent years.

<sup>8</sup> Actual losses estimated to average 4% less than shown, due to under-measurement of deliveries.

<sup>9</sup> Actual deliveries estimated to average 4% more than shown, due to under-measurement.

<sup>10</sup> Final irrigable area, 107 600 acres.

TABLE 28.—USE OF WATER ON THE TETON DIVISION OF THE YAKIMA IRRIGATION PROJECT, WASHINGTON.  
(Average elevation, 1 500 ft.; in sandy loam and gravel; lined sections totaling 80 miles in 1913 and 92 miles in 1924.)

Calendar year.	Irrigated area, total for year.	Area commanded by constructed canals. <sup>6</sup>	Miles of canals and laterals operated. 1 1924 and 1925 omitted from average on account of water shortages.

2 Umatilla and Grand Valley data cover years, 1916-25.

3 King Hill data cover years, 1921-27.

4 Okanagan data average for 1921, 1923, and 1925, on account of shortages in all other years since 1917.

5 Orland data omit years of heavy water shortage, 1918, 1920, and 1924.

6 Rio Grande data cover years, 1919-26.

7 Shoshone-Franklin Division data cover years, 1922-25.

8 Shoshone-Franklin Division data cover years, 1919-26.

9 Data are for years, 1917 to 1925, inclusive, except as noted.

10 Data are for years, 1917 to 1925, inclusive, except as noted.

Canal and lateral losses do not include losses in canals used solely as reservoir feeders. A case of this type is the Hermiston Division of the Umatilla Project (Table 20), the losses in the Echo Feed Canal being disregarded. Where irrigation deliveries are made both above and below reservoirs served by project canals, as on the Interstate Division of the North Platte Project (Table 12), no attempt to correct for canal losses on water subsequently lost by evaporation and seepage has been made. Reservoir losses by evaporation and seepage are not included in the canal and lateral losses. Where the available data permit, the diversions include—in addition to waters from primary sources of supply, such as rivers and reservoirs—waters diverted from artificial and natural drainage courses within the project, although these may have been included once before with waters diverted from primary sources of supply.

### PROJECT NOTES

Special conditions on the projects and their effect in the submitted data may be mentioned as follows.

*Belle Fourche Project.*—The climate is semi-arid and many farmers irrigate only a part of the area to which water is delivered, thereby making it impossible to determine the actual irrigated areas, except at considerable cost. This practice is gradually being abandoned as increasing irrigation charges necessitate better farming. (See Table 1.)

*Boise Project.*—A considerable area of this project is dependent on Deerflat Reservoir which is filled through the project main canal when its capacity is not needed for the irrigation of lands above the reservoir. (See Table 2.) The reservoir also receives much waste water and some seepage from the higher lands. For some years records of such inflow have not been obtained. The data presented do not include losses from the main canal, which, from data obtained in earlier years, appear to average approximately 5% of the diversions.

*Carlsbad Project.*—The storage facilities are inadequate to control stream flow during the non-irrigation season. (See Table 3.) The stream flow during the irrigation season, together with impounded waters, is often less than desired. Pre-season deliveries are, therefore, prevalent.

*King Hill Project.*—A uniform supply of water is available throughout the season, and while it is inadequate for the irrigation of the entire project, it permits extensive waste at the beginning and end of the irrigation season. (See Table 6.)

*Newlands Project.*—A limited water supply in 1924 and 1926 caused a material reduction in project waste as compared with earlier years when elimination of such waste was not necessary and the wasting of water was permitted to continue in the interest of superior water service at lowest cost. Recent general increases in farm deliveries are in part traceable to drainage construction. (See Table 11.)

*Rio Grande Project.*—The apparent great waste of water on this project results from its physical arrangement. (See Table 15.) The project consists of three successive valleys served by six diversions from the Rio Grande. It is customary to run canals at almost maximum capacity in the upper valleys

through a large part of the irrigation season with surplus water wasted back to the stream and re-diverted at lower points.

*Shoshone Project.*—Waters for the Frannie Division (Table 16) are first carried through the main canals of the Garland Division (Table 17), and the resultant losses are included with local losses on the Garland Division. Drainage construction under way on the Garland Division may be expected to result in augmented farm deliveries.

*Sun River Project.*—The Greenfields Division (Table 19) has a soil and climate adapted to the production of grain by dry-farming methods. Lack of adequate storage reserves has deterred initiation of the collection of construction charges while operation and maintenance charges have been collected only when water was requested and used. The result has been a haphazard farming practice with little reliance on irrigation. With the completion of the Gibson Reservoir now under construction (1929), it is expected that irrigation will be placed on a more stable basis.

*Umatilla Project.*—The water supply for the East Division of this project, comprising more than one-half the project area, is furnished by Cold Springs Reservoir, which is served by a feed canal from Umatilla River. The indicated canal losses (Table 20) do not include feed-canal losses, which average about 9 per cent.

*Yakima Project.*—On the Tieton Division (Table 23), the main canal, which is largely concrete flume or concrete-lined, lacks sufficient capacity to meet project demands at the height of the irrigation season. The maximum rate of delivery is, therefore, unduly prolonged. Corresponding data for the Sunnyside Division are given in Table 22.

*Yuma Project.*—The heavy waste of water on this project (see Table 24) is in part occasioned by the operation of a power plant within the canal system from which the used water is returned to the river when irrigation requirements are small. The main canal is usually operated at near maximum levels in order to minimize silt deposition and the necessity for frequent sluicing. Conservation of water is no object except for occasional short periods when the requirements of the Imperial Valley Canal, diverting below the power-plant return, make the return of all project waste above the Imperial Intake desirable.

The summary compilation in Table 25 gives the average use of water during the past ten years in which water supply was fully adequate. In addition, it classifies the projects as to their predominant soil types. It should not be inferred, however, that the indicated soil type is present to the practical exclusion of others, as, in fact, the soils present in each project in almost every case vary from some form of clay to sand. Were this condition not present, the indicated variation in water use would be even greater than that shown.

#### SUMMARY

In this compilation, the quantities shown on the individual sheets have been modified in the case of the Belle Fourche, Huntley, Klamath, and Rio Grande Projects to correspond with an under-measurement of 5% in delivery

to farms. With these changes, the farm deliveries shown on the summary sheet (Table 25) are then believed to be from zero to 10% less than the actual delivery, and the losses are actually correspondingly less.

The indicated use of water may be considered to represent closely the maximum quantities that the irrigator can use advantageously. Financial considerations have had little influence in engendering a high duty of water because the construction repayment burden on Federal projects is relatively light. On most projects the lands now in cultivation are prone to use waters more freely than will be possible with the project fully developed. Only the Okanogan and Orland Projects have experienced shortages of sufficient severity to influence development. On the whole, it is probable that a higher duty of water prevails on private projects where financial considerations exert a strong influence on the canal and reservoir capacities provided.

Continuous efforts are being made to reduce the excess quantities of water delivered to the farms as well as the transmission losses. However, in practically all cases both excesses are returned to the streams, either as surface run-off or drain discharges, at points such that the unused water is available for re-diversion and beneficial use by other irrigators.

The data indicate project waste and canal losses that may appear surprisingly large to many engineers. Canal losses join the underlying water-table and return to natural channels. Wasted waters so return on the surface. With minor exceptions such return flow is utilized by other projects with a resulting small net loss of waters. Where physical conditions are favorable for project extension, increasing land values in time will foster higher water duties through elimination of waste and reduction in canal losses and farm deliveries. Drainage problems will thereby be minimized and soil fertility conserved with extensive benefits unless carried to the extreme of an insufficient application of water to prevent injurious accumulations of deleterious salts. Reduction in waste, use, and losses will be accompanied by a reduction in return flow with increasing salt content to the detriment of projects that may have become dependent on such supplies.

Much credit is due the various project superintendents for their aid in the preparation of the data and to the Assistant Engineers, C. C. Elder, Assoc. M. Am. Soc. C. E., and Mr. T. R. Smith, to whom much of the work was entrusted and who, by their unflagging interest, have made the completion of this compilation possible. The operation and maintenance of Federal irrigation projects, as well as all engineering and construction work, is under the direction of R. F. Walter, M. Am. Soc. C. E., Chief Engineer of the U. S. Bureau of Reclamation, with headquarters at Denver, Colo.; and all activities of the Bureau are under the general charge of Elwood Mead, M. Am. Soc. C. E., Commissioner, with headquarters at Washington, D. C.

## DISCUSSION

ROBERT A. MONROE,\* M. AM. Soc. C. E. (by letter).—This paper should be very useful to engineers engaged in irrigation work since it presents reliable long-term records showing the duty of water for a large area and under wide variation of climatic and soil conditions. Since all these twenty-four Reclamation Service Projects are under one central authority, it is possible to have systematic and complete records kept, and the data presented can be accepted unquestionably as accurate and dependable.

Only two of these projects are located in California: The Klamath Project which lies on the boundary between Oregon and California, and the Orland Project at the upper end of the Sacramento Valley. A great many valuable data along the same lines as those presented by Mr. Debler have been collected by the State of California and are available in published form.†

The Pacific Gas and Electric Company with which the writer was connected in 1929 supplies irrigation water to a large area of land in Placer County, California, and while complete statistical data, such as are presented by Mr. Debler, are not available, it is thought that the following information will be of value in indicating the duty of water in this section.

The area irrigated lies at an elevation of from 300 to 1 500 ft. and is in the rolling foothills in a fan-shaped section of land lying between the American and Bear Rivers. The crops raised consist almost entirely of deciduous fruits; it has been estimated that 99% of the net area irrigated is covered by orchards. The soil can be classified as largely granitic in origin.

The water supply system was originally developed for hydraulic mining operations which were formerly very extensive in this region. After the mines were closed the water was naturally diverted to irrigation use, and with the advent of hydro-electric development between 1890 and 1900 several small plants were constructed to utilize the flow through such head as could be developed cheaply en route. In recent years both storage and conduit capacity have been greatly increased; there is now (1929) a sustained water supply of approximately 350 sec-ft., which is first used for power through a chain of plants under a total head of 3 700 ft., and finally becomes available for irrigation use at the tail-race of the lowest plant.

The storage is located high in the Sierras, where there is a total of more than 150 000 acre-ft. impounded in about 22 reservoirs. There are also 23 regulating reservoirs on the system. The canal system consists of 326 miles of conduit, of which 58 miles may be considered as the main conduit carrying water for both power and irrigation, and the remaining 268 miles are irrigation laterals. The topography is broken, and the irrigation laterals include many long stretches of pressure pipe.

\* Hydr. Engr., Aluminum Co. of America, Pittsburgh, Pa.

† *Bulletin No. 6* issued by the Department of Public Works, Division of Engineering and Irrigation, entitled "Irrigation Requirements of California Lands", being Appendix B to a Report to the Legislature of 1923 on the Water Resources of California, contains much information pertaining to the duty of water, and *Bulletin No. 8*, entitled "Cost of Water to Irrigators in California", by Harry F. Blaney, Assoc. M. Am. Soc. C. E., issued by the Department of Public Works, Division of Engineering and Irrigation in 1925, presents data showing the cost of irrigation for nearly every irrigation system of the State.

The gross area that lies under the ditch system approximates 85 000 acres. The area actually irrigated has shown a rather steady annual increase from 13 500 acres in 1914 to 27 100 acres in 1928. Water deliveries for irrigation purposes are made to the consumers at a uniform rate during five months of the year beginning May 1 and ending September 30. No record is available as to the actual quantity of water used each month, as the consumer contracts for a certain number of inches for the season and rotates it on his land as he sees fit. Frequently, several owners who take water from a common lateral will combine to rotate the water on their holdings.

The duty of water is well established and the contracted delivery is almost generally estimated on the basis of 1 miner's in. of water (0.025 sec.-ft.) to 5 acres of land, which for uniform flow is 0.3 acre-ft. per acre per month, or 1.5 acre-ft. per acre for the season. The price which the Company receives for this water is \$45 per miner's in. per season of 5 months, which makes the cost of water \$9 per acre per year, or \$6 per acre-ft. No charge is made for water furnished during the non-irrigation season and most of the canals are kept in service the entire year to deliver the small quantity of water necessary for domestic purposes.

The conduit loss was formerly about 45%, but this has been reduced in recent years due to extensive concrete lining and plastering of sections of canals and replacement of wooden flumes with metal; for 1928 this loss was estimated at 37 per cent.

The water supply to date has been ample for the area irrigated, no curtailment having been necessary even in years of extreme drought, such as occurred in 1924, and in most years a substantial quantity is by-passed into the American River. This volume of spill is gradually decreasing as the irrigated area increases, but it seems that the water now available will substantially supply all the irrigable area which is immediately tributary to the system.

IVAN E. HOUK,\* M. Am. Soc. C. E. (by letter).—Comprehensive data on the use of irrigation water are needed by all engineers engaged on the design or investigation of irrigation systems. Therefore, the detailed information presented so concisely in this paper, will be a valuable aid to all practicing irrigation engineers in the Western United States.

The data regarding irrigated areas, miles of canals operated, soil conditions, monthly deliveries, character of crops, canal losses, etc., included in Tables 1 to 25, have a pertinent value in showing the conditions under which irrigation is conducted on the various widely scattered projects. However, the most valuable data included in the tables are the total depths of water delivered to the farms plus the depths of rainfall during the growing season. Reference to Table 25 shows that with the exception of the Umatilla Project, of Oregon, the Uncompahgre Project, of Colorado, and the King Hill Project, of Idaho, the average quantities delivered, plus the growing season precipitation, vary from a minimum of 1.56 ft. on the Milk River Project, of Montana, to 4.09 ft. on the Grand Valley Project, of Colorado.

\* Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

The corresponding quantities for the Umatilla, Uncompahgre, and King Hill Projects are 5.37, 6.31, and 7.36 ft., respectively. The latter values are relatively high because of the sand and gravelly soils and excessive waste of irrigation water.

The total depths of precipitation during the growing season apparently are not very great as compared with those of irrigation water delivered to the farms plus the depths of growing season precipitation. These quantities may be referred to as "total depths of water applied to the farms", or, simply, "total depths applied". The average values of growing season precipitation recorded in Table 25 are usually less than one-third the total depths applied, the only two exceptions being the Belle Fourche Project, of South Dakota, where the growing season precipitation amounts to approximately 41% of the total depth applied, and the Milk River Project, of Montana, where it amounts to about 58% of the total depth applied. The actual depths of rainfall during the growing season vary from an average of 0.16 ft. on the Tieton Division of the Yakima Project, Washington, to an average of 0.91 ft. on the Milk River Project, Montana.

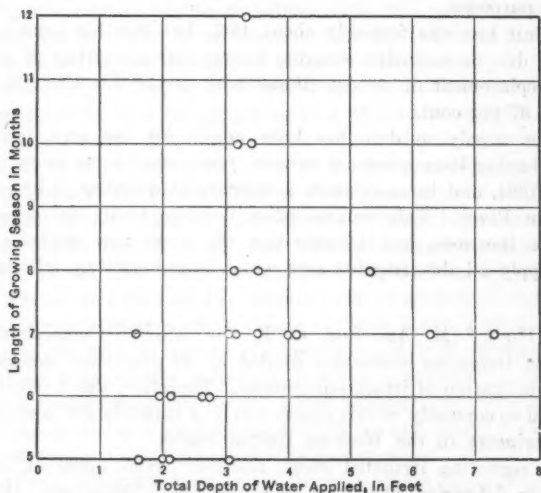

FIG. 2.—RELATION OF AVERAGE DELIVERY OF IRRIGATION WATER, PLUS RAINFALL, TO LENGTH OF GROWING SEASON.

The total depths of water applied to the farms would be expected to vary, in a general way, with the length of the growing season, although, of course, no mathematically definite relation could be anticipated because of variations in soil conditions, character of crops, elevation of project lands, mean annual temperature, and other meteorological conditions, all of which are interrelated in a more or less complex manner. In Fig. 2 the total depths of water applied are plotted as abscissas against the lengths of the growing seasons as ordinates, the lengths of the growing seasons being taken the same as in Tables 1 to 25. Although the plotted points are somewhat scattered, as would be expected,

they indicate a general increase in total depth applied with an increase in length of growing season, especially in the case of projects where the length of the growing season does not exceed eight months. In the case of the Rio Grande and Carlsbad Projects, of New Mexico, where the length of the growing season is ten months, and in that of the Yuma Project, of Arizona and California, where it is twelve months, the increased length of the growing season does not require an increased application of water. Apparently, there are two reasons for this: First, a reduction in the quantities of water delivered to the farms during the winter months, when the meteorological conditions are relatively less favorable for plant growth than during the other months of the year; and, second, a reduction in the quantities delivered during some of the summer months, due to a period of dormancy in plant growth caused by the existence of unusually high temperatures. Of course, the points representing the total depths applied on the Umatilla, Uncompahgre, and King Hill Projects, where waste of water and return flow are excessive, fall at the right of the diagram, some distance from the points representing the total depths applied on the other projects.

A question that naturally arises in considering Fig. 2 is as to what proportions of the quantities applied constitute consumptive use. The same conditions that affect the depths of irrigation water delivered to the farms affect the depths of consumptive use, although not necessarily in the same degree. For instance, the mechanical texture of the soil which is probably the most important factor as regards quantity of water delivered, assuming an unlimited supply, has relatively little affect on consumptive use, other things being equal. If accurate information regarding depths of consumptive use were available for the different projects, and if the values were plotted on Fig. 2, the points would probably fall somewhere at the left of those representing total depths applied, the exact position depending on the definition adopted for consumptive use. If consumptive use is defined as the sum of plant transpiration and soil evaporation during the growing season, the consumptive use points would necessarily fall at the left of those representing total depths applied, since some return flow undoubtedly occurs on all projects. However, if consumptive use is defined as the sum of plant transpiration and soil evaporation during the entire year, as would appear to be more reasonable, it is conceivable that some of the consumptive use points might fall at the right of those representing total depths applied, since the total depths of rainfall during the non-growing season, which would be added to the total depth applied during the growing season, in determining the consumptive use, might be greater than the total depth of return flow, which would be subtracted.

In either case the writer would expect the consumptive use points to be more consistently grouped than the points representing total depths applied, assuming, of course, that proper corrections are made for variations in soil storage. Adding the non-growing season precipitation to the total depths applied, as given in Table 25, and leaving out of consideration the three projects on which total deliveries are excessive, gives total yearly depths applied ranging from an average of 1.74 ft. on the Milk River Project, Montana, to

an average of 4.57 ft. on the Orland Project, California. These values would be the sums of the consumptive use and the return flow, assuming the variations in ground-water storage to be rendered negligible through the averaging process.

In regard to the depths of consumptive use required for the satisfactory growth of crops, the writer believes that much useful information can be obtained by a study of rainfall and run-off records in Central and Eastern United States.\* There are appreciable differences between the Central and Eastern sections of the country and the Western irrigation projects as regards some of the meteorological conditions which affect plant growth, particularly relative humidity and percentage of cloudiness, not to mention rainfall which, of course, is more or less equalized by the delivery of irrigation water. However, it is not believed that the total depths of water required to raise the same crop are materially different in the two sections of the country. Experiments on the water requirements of plants by Montgomery and Kiesselbach, Heinrich, and Sorauer, referred to by Messrs. Lyman J. Briggs and H. L. Shantz, showed that the quantity of water used per pound of dry matter produced was greater in the dryer atmosphere.† However, they also showed that the number of pounds of dry matter produced was greater in the humid atmospheres, so that the total quantities of water used were not so greatly different. Cloudiness seems to reduce the rate of transpiration, but to increase the total water requirement per pound of dry matter produced, although there is some uncertainty in this respect due to the varying rates of photo-synthesis.

Table 26 gives some data on depths of annual consumptive use in the Miami Valley of Southwestern Ohio, for the five years from 1915 to 1919, inclusive, compiled from one of the Technical Reports of the Miami Conservancy District.‡ The consumptive use values were computed from carefully determined isohyetal maps and elaborate stream flow measurements, and, consequently, are believed to be more accurate than most consumptive use data thus far published. The drainage areas represented in the table are more than 90% agricultural land, only comparatively small areas being occupied by cities, towns, farm buildings, roads, rivers, lakes, reservoirs, etc. The length of the growing season, which is approximately the same in all parts of the valley, averages about six months, and paying crops are produced each year. Crops consist primarily of corn, wheat, rye, oats, barley, alfalfa, and tobacco. The acreages of the three classes of crops considered in the author's Tables 1 to 25 are approximately equal and are, therefore, about the same as on the North Platte Project, of Wyoming and Nebraska. The topography of the Miami Valley may be described as gently rolling with the ground elevations of the uplands varying from about 800 ft. above mean sea level near the mouth of the river to about 1 100 ft. near the head-waters.

‡ "Rainfall and Run-off in the Miami Valley," by Ivan E. Houk, M. Am. Soc. C. E., Miami Conservancy Dist. Technical Repts., Pt. VIII, pp. 134 to 150, Dayton, Ohio, 1921.

The slopes are comparatively flat near the head-waters but they increase more or less gradually toward the southwest, being comparatively abrupt near the Ohio River. The mean annual temperature of the valley is approximately 53° Fahr., the mean annual relative humidity about 67%, the mean annual rainfall about 37 in., the mean annual run-off about one-third the rainfall, and the mean annual evaporation, or consumptive use, about two-thirds the rainfall.

\* Including interception, evaporation from soil and water surfaces, and plant transpiration.

† Ending September 30.

Rainfall and run-off records were compiled for years ending September 30, that being the time of the year when the quantity of water stored in the ground is least variable. Average yearly totals for the different drainage areas, based on the five years from 1915 to 1919, are included in Table 26. Differences between the yearly rainfall and run-off totals, heretofore usually termed "evaporation", but which are really consumptive use values, are given in Table 26 for each of the five years mentioned. The drainage areas in the table are arranged according to location, beginning at the upper end of the valley. The drainage area of 3 672 sq. miles above Hamilton, the last station in the table and the one farthest down stream, for which rainfall and run-off data were compiled, includes all the other drainage areas listed in Table 26. Consequently, the values of average rainfall, run-off, and consumptive use for Hamilton are really averages for all the other stations in the table. For this reason no final line of average data for all stations has been included. However, a final column of average consumptive use for the five years of record has been added.

The average values of consumptive use are seen to vary from a minimum of 1.68 ft. on the Seven-Mile Creek drainage area to a maximum of 2.32 ft.

on the Buck Creek drainage area, averaging 2.13 ft. for the entire valley above Hamilton. Values for single years vary through slightly greater ranges, but at least a part of the yearly variations are undoubtedly due to variations in ground-water storage, a factor which is believed to be negligible as far as the 5-year averages are concerned. The consumptive use values include plant transpiration, soil evaporation, interception losses, and evaporation from river, lake, and reservoir surfaces, all but the first two being of minor importance. Since the data were compiled for the yearly periods, they include evaporation from soil, snow, and ice surfaces during the winter months, quantities which amount to about 4 in. on the average, or to about 15.5% of the average annual consumptive use in the valley above Hamilton. R. E. Horton, M. Am. Soc. C. E., who has made elaborate studies of interception, estimated that the seasonal interception losses on an average Michigan farm were equivalent to an average depth of 1 in. of rainfall over the entire farm, which would correspond to about 4% of the average consumptive use above Hamilton.\* It is interesting to note that the 5-year average consumptive use of 2.13 ft. for the drainage area above Hamilton, is not greatly different from the 9-year average of 2.06 ft. for the same area; and, also, that the 5-year average of 2.10 ft. for the drainage area above Dayton, Ohio, is exactly the same as the 25-year average for the same area.† These comparisons of the 5-year averages with the averages based on longer periods supports the claim that the data in Table 26 have been accurately determined.

GEORGE N. CARTER,‡ M. AM. SOC. C. E. (by letter).—The author has assembled and presented a vast amount of data gleaned from actual irrigation practice rather than from theory.

To one well acquainted with the project to which any one of the detail twenty-four tabulations may relate, the information is especially valuable. However, to apply these figures to the design of a new project, without intimate knowledge of all the details which affect the demand and use of irrigation water, quite likely might result disastrously. It is just as dangerous to project from such data into the development field as to apply wrongly any highly involved engineering formula in design.

It is to be noted that the use of water varies widely, between the limits of 0.65 acre-ft. per year (the minimum on the Milk River Project, in Montana) and 7.01 acre-ft. per year (the maximum on the King Hill Project, in Idaho). Between these limits are found two projects that are successful and well-balanced in every respect, the Yakima Project (Sunnyside Division), in Washington, and the Boise Project, in Idaho, with an average annual use of 3.29 and 3.60 acre-ft., respectively.

By the expression, "well-balanced," is meant that soil conditions are normal, if there is such a thing as normal soil; that temperature and growing season are conducive to maturing numerous and diversified crops, indigenous to the temperate zones; that no reliance may be placed on rainfall and plant growth

\* "Hydrology of the Great Lakes," by R. E. Horton, M. Am. Soc. C. E., in collaboration with C. E. Grunsky, Past-President, Am. Soc. C. E., Rept. of Engineering Board of Review of the Sanitary District of Chicago, 1927, Pt. III, Appendix II, p. 46.

† *Loc. cit.*, pp. 140 and 142.

‡ Commr. of Reclamation, Boise, Idaho.

is entirely dependent on irrigation; and that the physical irrigation system is well designed and permits of good distribution and control of the water available.

Factors which contribute to the wide variations are explained, but it would have been quite helpful if the author could have enlarged upon his description and classification of soils of the various projects. For example, on the King Hill Project, the use of water (see Table 6) greatly exceeds that of other projects and may appear excessive and wasteful to one unacquainted with conditions; but a brief description of the predominating soil characteristic is quite illuminating. The top-soil, averaging from 2 to 3 ft. in depth, is light and sandy, and is underlaid by Snake River black lava sand to great depths. The water-consuming possibilities of this soil and subsoil are obvious; likewise is the problem that such a condition imposes upon the farmer. Irrigations must be very frequent. The writer examined a field of alfalfa seeding on the King Hill Project, planted with a nurse crop of wheat, and found the young alfalfa plants wilting six days after thorough irrigation. Furthermore, the application of such large quantities of water is rapidly leaching all plant food elements out of the soil, as demonstrated by the fact that each year the use of water is increasing, while crop yields are gradually decreasing.

The methods of securing field data and reducing them to as accurate forms as possible, are in keeping with good practice. The Twin Falls North Side Land and Water Company while constructing a 185 000-acre Carey Act irrigation project in Idaho, carried on for five years what was perhaps as comprehensive and thorough a study of the use of water for irrigation as has ever been undertaken in the United States. The under-measurement of water delivered to the farmer was found to be 5%, occasioned in large part by the tendency of the Cipolletti weir to under-read due to velocity of approach, caused by silting of weir pools. It was found more satisfactory to calibrate the weirs in their actual operating condition, employing expert hydrographers for the purpose, than to attempt to maintain them in ideal physical condition.

The author finds the expression "loss in feet of depth per day" over exposed water surface or wetted perimeter "impractical." It occurs to the writer that this is a most rational measure of canal loss. Expressed on this basis, a unit is afforded which may be applied to any operating condition between peak load and no load. A canal system may carry full load with a net delivery of 70% and half load with net delivery of only 40 or 50 per cent. Under these two conditions, the loss in feet of depth per day will be practically the same, while the percentage of loss varies greatly. Wide, shallow, low-velocity canals will have a much higher percentage loss than when the same quantity of water is conveyed in a deeper and higher-velocity channel, while the loss in depth of feet per day over wetted perimeter of exposed water surface is the same for either type of canal, all other conditions being equal.

Some elaboration might well be made as to the quantities of waste expressed as "Percentages of Total Diversions for Seasons", in Tables 1 to 24. An efficiently operated canal system should not waste out of the lower end much more than 4 or 5% of the total supply. Through careful operation, this figure is often reduced to 2 or 3 per cent. Any waste of more than 4% is ordinarily

avoidable. Therefore, in using the author's data on this item, it may be understood that the large percentages are voluntary and need not be admitted as a necessary part of the available supply.

The collection and intelligent application of data such as the author has presented, are invaluable in a consideration of any irrigation project, especially a large one. Owners and operators quite frequently under-estimate the value of such a survey and hesitate to appropriate funds for the purpose. Nevertheless, the characteristics of the various parts of the water-distribution system, with respect to the use of water, as revealed by detail hydrographic records, will locate places of excessive loss and point the way to a remedy, thus saving many times the cost of such work.

Given favorable soil and climatic conditions, the prosperity of an irrigation project is reflected almost entirely by the quantity of water it has available. Despite extravagant and wasteful use, water-logging of land, and other difficulties ordinarily credited to over-use of water, the project's well-being and financial success will be in proportion to the quantity of water used. Land values, diversity and intensity of farming, and crop yields, all go down in proportion as the available water supply diminishes, and almost without exception the greatest use of water is found to be coupled with the most prosperous project.

The popular and numerous investigations undertaken throughout the irrigated West about twenty years ago to determine the duty of water have been harmful. They were predicated on laboratory methods rather than actual field conditions, and they aimed at a result which would be the minimum, in order that the irrigated acreage of the Western States might be extended to a maximum. Knowledge of the conditions under which the farmer would perpetually be compelled to till these extended acres was lacking. The experience of the last twenty years of irrigation activities has well demonstrated the fallacy of the original object.

In the beginning of irrigation on a large scale throughout the Western States it seemed desirable to produce a maximum of crop per unit of water, but now it is evident that the maximum per unit of land is the only basis upon which the irrigation farmer can remain. Otherwise, taxes, overhead, labor, and equipment costs, carry the farmer to the point of "diminishing return" and frequently beyond it.

Witness the voluntary efforts and expenditures of many co-operative irrigation companies to enlarge their water supplies after they have received control of their projects from the builders. They have learned, during the years of pioneering, that only with a generous and dependable water supply can they expect to prosper.

RALPH L. PARSHALL,\* ASSOC. M. AM. SOC. C. E. (by letter).—In presenting this paper with its official records of the use of water on Federal irrigation projects, the author has made available data of great value to irrigation engineers. Because of its importance, however, it is thought that he should have gone more into detail in explaining the underlying causes for the large per-

\* Irrig. Engr., U. S. Dept. of Agriculture, Fort Collins, Colo.

centage of the total diversion that is returned to the parent stream, since a study of the data presented might lead to the belief that project waste and canal losses are much greater than should have been expected; and to those not thoroughly familiar with irrigation requirements, it might appear that such wastage showed inefficient operation.

In practically all the irrigated areas in the West, the matter of sand and silt carried into both main canals and laterals is of grave concern from the standpoint of operation. It is the usual practice to provide one or more waste-gates at suitable points along the main canals and, through these openings, to flush out the accumulated deposits. The water used for sluicing purposes is, in many cases, a large proportion of the total diversion. Thus, Table 25 indicates marked wastage for the Rio Grande and Yuma Projects. These items are explained by the author as necessary in supplying other areas at lower elevations and providing water for hydro-electric power. Such expenditures in water might not be looked upon as waste, since they are put to a useful purpose. The use of the word, "waste", is not in accordance with the general meaning, which is "loss without equivalent gain." In this restricted sense, the writer is of the opinion that Table 25 might be misleading to some in presenting these large percentages. With the irrigation canals diverting from the Arkansas River in Colorado, for example, it is the usual practice to sluice occasionally for the purpose of scouring out the accumulated deposits. In some cases this is done each day for a period of 1 hour, an actual waste of water to the users amounting to about 4 per cent. In no case would this waste exceed 10 per cent. The water used in sluicing constitutes a direct loss to the canal. Another fruitful source of waste occurs through leaky farm and lateral head-gates, as well as from poor structures, such as flumes, siphons, or other artificial channels.

The canal and lateral losses appear to be large, especially for some of the projects having large percentages of lined canal or pipe lines. In the case of the Umatilla Project, the miles of pipe and lined section together approximate the total miles of canals and laterals; yet the losses are recorded as being not greatly different in percentage from those on other projects with a much smaller proportion of lined channel and with similar soil conditions. Concrete-lined canals are not entirely immune from seepage losses.

The measurement of water from the standpoint of duty requires a fair degree of accuracy. Because of the great variety of conditions and limitations imposed in the measurement, the author assumes that the actual amounts measured are somewhat less than 10% smaller than those stated in the tables. Unless the conditions are extremely adverse, the writer believes the deviation ought not to exceed 5%, provided suitable devices are used in the measurement. The calibrated rating flume is usually a poor means of securing dependable measurements. The filling and scouring of the channel and the accumulation of aquatic growth, all tend materially to affect the accuracy of this type of device. The rating flume, if only occasionally checked for performance, may introduce considerable error in the final result. In some cases constant attention to check gaugings is necessary to determine the daily rate of change in the calibration. The necessary hydrographic expense of keeping abreast of

such conditions may not be warranted because of allowable limits assumed in the management or administration of the water supply. Because of aquatic growth some Colorado canals equipped with the ordinary rectangular rating flume have changed between June and September as much as 75% in the calibration. Infrequent check gaugings, in such cases, would involve considerable error in estimating discharge. In many parts of the irrigated West, where the value of water is becoming increasingly greater, better and more dependable measurements of flow are much needed.

The use of the standard weir for the measurement of farm deliveries is generally unsatisfactory. For correct measurements the weir must be provided with standard distances, crest to floor and side of weir to bank or wall. Weirs without end contractions eliminate one of these sources of error. Almost without exception, in the case of the farmer's weir, the pool or basin up stream is found to be filled with sand or silt nearly or actually to the crest line. This tends to a greater delivery than is apparent from the indicated head or depth over the crest. The farmer is scientific enough to know that this defect is advantageous to him, and is, therefore, not overly ambitious to maintain standard conditions.

Submerged weirs and orifices are also subject to a varying degree of accuracy; however, in such cases, the errors will be compensating. Ordinarily, in farm practice, no instrument record is maintained of the variation in the upper and lower heads, where a change in either or both results in a corresponding change in the flow. Thus, in using a submerged device, the chance of error is greater than in the single head measurement. A standard weir submerged to about 70% will reduce the rate of discharge approximately 35 per cent. In endeavoring to obviate the double-head submerged flow over weirs or through orifices, it is found that the improved Venturi flume, when operating at about 70% submerged flow, will be discharging according to the free-flow law and thus only involves a single head. In this respect it is believed that this type of device is superior to other commonly used methods of measurement.

In the study of the duty of water, there is a question as to whether or not it is proper to add the total precipitation over a period of months to the quantity or depth of water applied as irrigation to represent the acre-feet per acre application to the crop. When storms occur in moderation and the soil can absorb the precipitation, such depth of rainfall can be legitimately charged. For an intense downpour, when the top soil is dry, it has been observed that the surface becomes packed or crusted, due to the impact, thus causing a considerable run-off. It is further known that, for showers of 0.1 to 0.2 in., the penetration is not sufficient to be of any benefit from the standpoint of adding moisture to the soil; in fact, quite the contrary is true. Observations on soil moisture after a moderate shower show a depletion of moisture instead of an increase. The question as to what amount of the total rainfall can be justly accredited to useful soil moisture has not been determined, the soil itself being an important factor. It is logical, therefore, to assume that to give full weight to the total rainfall is misleading. The question deserves thorough study.

E. B. DEBLER,\* M. Am. Soc. C. E. (by letter).—Interesting data are presented by Mr. Monroe on a class of projects which is quite common in California, but is rarely found outside that State. California has large areas characterized by deep finely textured soils of unusual water-holding capacity. The winter rains are stored in these soils, and, to a large degree, furnish the water needs in the succeeding growing season with a resulting high duty of irrigation water. Furthermore, these lands are in nearly every case adapted to fruit culture and so escape the need for the liberal water supply required for the growing alfalfa and similar crops of high water requirement which must necessarily be the backbone of irrigation in the inter-mountain States.

Mr. Houk graphically presents the relation of depth of water applied to length of growing season. The most important feature controlling application of water is the mechanical texture of the soil and subsoil. Soils of great porosity require heavy applications wherever general farming is practiced. On the Orland Irrigation Project, in California, annual applications of water vary from 2 to 6 ft. per acre, and in the Snake River Valley, in Idaho, from 2 to 10 ft. per acre. The lack of fertility which is so characteristic of most soils of extreme porosity precludes, in individual cases, the production of fruits in the one area and of sugar beets in the other, as these crops are seldom profitable except in fertile soils of considerable depth.

The effects of continual application of large quantities of water in the reduction of soil fertility has been mentioned by Mr. Carter and has been noticed in many localities on the Federal projects. The only way of escape where this is the case appears to be the adoption of crops requiring intensive cultivation and permitting a comparatively heavy expenditure in the control of water so that application will not exceed greatly the water-holding capacity of the surface soils. This course, however, can be adopted only to a limited extent in that a very large part of the irrigated area is not adapted to the production of such crops by reason of unfavorable climate and marketing difficulties.

Mr. Houk has presented much data bearing on consumptive use, a subject even more far-reaching than that of the delivery of water, to which the paper applies. Where development is governed by water supply the undeveloped resources in the way of non-irrigated lands will lead to a study of the ways and means to reduce consumptive uses to a minimum for each unit of crops that can be produced profitably.

Mr. Carter suggests that canal losses might well be estimated from exposed water surface. The U. S. Bureau of Reclamation conducted experiments for a number of years on constructed canals in order to ascertain the coefficients of loss, in feet per day, over the wetted area. The loss through soils was found to vary from amounts as low as 0.25 ft. to more than 1 ft. of depth per day. Over the same section of canal the losses were also found to vary greatly from one year to another. For a type of soil given the same description by different engineers, the range in losses reported varied between very wide limits. A part of the difference is due no doubt to variance in definitions of soils by

\* Engr., U. S. Bureau of Reclamation, Denver, Colo.

different men. In order to obtain a uniform definition it would be necessary to make a mechanical analysis of the soils; but it is also well known that mechanical properties alone will not tell the entire story, since the nature and distribution of soil chemicals and humus are very important factors.

The depth to ground-water is important because, with a very high water-table there is a back pressure from the water-table to the canal. Where silty waters are carried, an impervious skin coat forms on the canal banks and the leakage is determined, not by the soils through which the canal passes, but by the thickness and character of the deposit of silt. Where it is customary to remove the silt from a canal at the end of each irrigation season there may be a very great variation in losses through the season. On the other hand, if a canal is originally built with excess capacity, it may be the practice in operation to leave a large part of the silt coat undisturbed.

Aside from interpreting the data obtained on operating systems, many assumptions are necessary in applying such formulas as might be evolved to the conditions that will obtain on a system proposed for construction. The combined result of all these features is that the observed losses cannot practically be converted into formulas or coefficients that can be applied in designing a new canal system. On the whole, it has been found more practicable to make a direct estimate of the percentage of loss on new projects, with such percentage greatest at the end of the irrigation season. This, however, can be only considered a practical application of the theory that losses are largely dependent on the wetted areas which do not differ materially through the irrigation season. Except where conservation of water is of no interest, losses on the average project do not vary greatly from 35 to 40% of the waters diverted. Where a reduction in losses becomes desirable, either for the prevention of seepage or on account of limited stream supply in comparison with area, leading to the adoption of canal lining, the loss may be materially less than the percentages indicated.

Mr. Carter mentions the desirability of a description of classification of soils on the various projects. This matter was given consideration, but it was found that nearly every one of the projects has soils and subsoils ranging from heavy to loose and that two observers will seldom give the same classification for any one kind of soil. It would be difficult to convey to the reader an accurate picture of soil and subsoil types. While soil is the most important factor in determining the water duty, it would also be very desirable to have full descriptions of irrigation methods, crops, liberality of water supply, etc. Impracticability of precise descriptions for these factors within the limits of a paper of moderate length, precludes their discussion.

Attention has been directed to the apparent large waste. Contrary to the understanding of Mr. Parshall, the indicated data do not include sluicing waste at the point of diversion. On some projects stream flow far exceeds all irrigation requirements and excess waters are carried through a large part of the season for greater ease in operation, with the irrigator permitted to receive and reject water practically at will. A similar condition prevails on projects where stream flow is merely passed through project canals for the

use of other areas. On projects where conservation of water and canal capacity are important, waste is not heavy except in years of surplus supply. The Boise Project, with an average waste of 2%, is of this type.

Mr. Parshall appears to have gained the impression that the arbitrary correction in recorded deliveries was made to offset estimated errors in measurement. This, however, was not the case. Measurements have not been disturbed. The increases were made to offset deliberate practice in the field of reporting less delivery than is actually made, in the interest of improved business relations between the farmer and the ditch-rider.

The magnitude of precipitation during the growing season has been found to be very material in fixing irrigation requirement. Along the eastern slope of the Rocky Mountains, growing season precipitation averages 10 in., while in the Great Basin, it averages 2 in. The latter, and possibly an equal part of the former, occurs largely in small showers without benefit to crops except as relative humidity is temporarily increased. The remainder of the larger amount materially reduces the irrigation requirement. In fact, on some projects, a little farther east, in the so-called "semi-arid" belt with normally 12 to 15 in. of rainfall in the growing season, irrigation is considered an adjunct to farming rather than the mainstay, and is so practiced.

Paper No. 1756

### WATER SUPPLY FROM RAINFALL ON VALLEY FLOORS\*

By A. L. SONDEREGGER,† M. A. M. Soc. C. E.

WITH DISCUSSION BY MESSRS. HAROLD C. TROXELL, HARRY F. BLANEY, C. W. SOPP, W. P. ROWE, IVAN E. HOUX, CHARLES H. LEE, AND A. L. SONDEREGGER.

#### SYNOPSIS

This paper presents an analysis of the phenomenon of rainfall penetration on valley floors in semi-arid areas and a discussion of methods for the quantitative determination of the resulting water supply, with special reference to conditions in Southern California.

The following specific examples are discussed:

- 1.—Determination of rainfall penetration from soil moisture tests and from springs in the Murrietta-Temecula Area.
- 2.—Determination of penetration on valley floors by comparison with mountain run-off in San Bernardino Valley.
- 3.—Determination of penetration from rainfall and irrigation rise of water in test wells in Pauba Valley.

#### INTRODUCTION

In the semi-arid West, particularly in the valleys of Southern California where seasonal rainfall varies from 6 to 24 in., the water supply resulting from deep penetration of rainfall on the valley floors is of great economic importance.

NOTE.—The Special Committee on Irrigation Hydraulics has selected the subject of "Evaporation from Soils" as one of ten for study and research. This paper was submitted to the Committee by its author, and the Committee has recommended its publication (see Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1929, Society Affairs, p. 96).

\* Published in May, 1929, *Proceedings*.

† Cons. Engr., Los Angeles, Calif.

In the past, engineers have sometimes under-estimated this source of water supply, while in the people's mind the safe yield of ground-water sources has been confused with the capacity of the basins and the supply has been considered unlimited. Recent investigations would indicate that under favorable conditions of rainfall and soil formation the permanent recharge of ground-water basins from this source may amount to as much as 1 acre-ft. per acre in one season and during a period of years to as much as the supply from the tributary mountain water-shed.

The disposal of rainfall is as follows: (1) Storm run-off; (2) evaporation losses; (3) transpiration losses; and (4) deep penetration. Items (2), (3), and (4) may be grouped under the general term, "absorption", for comparison with Item (1). With closed basins, the resulting water supply represented by Items (1) and (4) may be determined by direct measurement (making allowance for consumptive use and evaporation losses from moist areas); while with open valleys indirect methods may have to be resorted to by assigning values to the different factors. Measurements and other information leading to the determination of any of the factors are, therefore, of general interest. Certain studies made for the alluvial valleys of Southern California, the methods applied, and here presented, may be useful to other investigators.

#### GENERAL CONDITIONS AFFECTING PENETRATION

Among the general conditions that affect penetration may be listed the character of alluvial deposits, the topography of the ground, the use made of the soil for purposes of agriculture, and the intensity of storms.

*Character of Alluvial Deposits.*—Seepage water that penetrates intermittently below the limits of evapo-transpiration activity must ultimately cause the wetting—to field capacity—either of the entire formation overlying the water-table, or of well-defined ducts reaching from the surface to the water-table. If there is additional seepage from above, there must be a corresponding addition to the ground-water body.

Alluvial deposits are essentially heterogeneous in formation so that the percolating fluid will naturally find lines of least resistance. Therefore, a uniform saturation over large areas is not likely to occur, but rather the formation of more or less defined ducts. When percolating water strikes an impervious stratum, movement downward is interrupted and a suspended water-table is formed. Gradually, lateral percolation and a circuitous route for the percolating fluid are then established until another pervious deposit again permits a more or less vertical movement. Whenever a suspended water-table has been formed, the drainage from it will occur over the edges of the impervious stratum and is likely to collect into trickling streams, as illustrated in Fig. 1. These conclusions are supported by the fact that during the process of excavating shafts in alluvial fills it is quite common to strike dry materials alternating with moist materials and occasional streams of water. Inasmuch as alluvial deposits almost invariably show an alternation of pervious and impervious strata, the phenomenon indicated in Fig. 1 is probably that most commonly encountered. Under such conditions, only a part of the alluvial mass between the surface and the ground-water table will be saturated.

The recharge of the ground-water may be hastened or delayed by impervious strata. Large clay bodies may not only cause a regulation of an irregular water supply, but they may also provide storage of a magnitude not appreciated because it is not readily traced.

Absorption is favored by the wedging action of roots, especially decayed roots, which have a tendency to drain a saturated mass along defined canals.

It is concluded, therefore, that both the heterogeneous character of alluvial soils and the action of roots tend to concentrate percolation along lines of least resistance and that a uniform wetting of the soil over large areas to the depth of the root zone is not likely to occur.

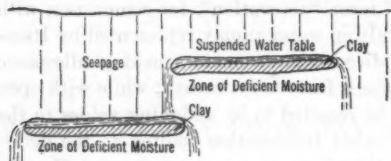

FIG. 1.—EFFECT OF IMPERVIOUS STRATA ON DISPOSAL OF SEEPAGE.

FIG. 2.—CONCENTRATION OF RAIN WATER DUE TO TOPOGRAPHICAL CONDITIONS.

*Topographical Conditions.*—The effect of a rainstorm is intensified by irregularities of topography, whether they are the gentle undulations which occur on an apparently true plane, or hog-wallows and hummocky undulations, as in Fig. 2. It is apparent that some of the rain falling on Points A and C will flow on the surface to the depression, B. A 3-in. rain may produce at B a depth of water of as much as 6 in. and a seepage greatly in excess of that at Points A and C. This concentration of rain water, therefore, induces a corresponding concentration of seepage and may be responsible, in part, for deep penetration when the seasonal rainfall, uniformly absorbed, is not sufficient to satisfy the moisture deficiency and evapo-transpiration losses.

*Intensity of Storms.*—The all-important factor appears to be the intensity of storms; that is, rain falling in consecutive days, or within intervals not exceeding two days. Generally speaking, the number and intensity of storms vary with seasonal rainfall. Dry years with rainfall as great as 12 in. are generally devoid of heavy storms and seldom have a storm of more than 3 in. Very wet years generally produce one storm of outstanding intensity and a number of minor storms, although there are exceptions to this rule. Inasmuch as the rate of evaporation is a maximum immediately after a rain, and since even showers foster the growth of grasses, the light rains of a dry winter are, as a rule, immediately wasted, while on the other hand, the lighter storms of a wet winter may saturate the soil to field capacity, and subsequent heavy storms may produce nearly 100% penetration. The superior effects of one heavy storm over a number of light ones becomes magnified when the soil is non-uniform.

Fig. 3 shows the distribution of rainfall into storms of varying amounts based on seasonal and daily records of four stations in the Murrietta-Temecula Area (Riverside County), of Southern California. This is an undulating area, ranging in altitude from 1 000 to 1 600 ft., with isolated peaks reaching eleva-

tions of 3 000 ft. It is an interior valley and, comparatively speaking, it is arid (Fig. 4). Seasonal rainfall records are available for a number of stations in the valley area, indicating a long-year mean of 14.5 in., the minima approaching 6 in. and the maxima, 28 in. The distribution of storms for the station at Wildomar (Elevation 1 254), for three characteristic years, is listed in Table 1.

TABLE 1.—RECORD OF STORMS AT WILDOMAR, CALIF.

SEASON.		Seasonal rainfall, in inches.	Total, 2 in., or less.	2 in. to 4 in.*	4 in. to 6 in.*	6 in., or more.*
Year.	Description.					
1922-24	Dry	7.37	4.41	2.96	.....	.....
1916-17	Normal	14.84	6.76	.....	.....	5.08
1921-22	Wet	27.89	4.61	{ 2.00 2.73 2.55 }	4.5	11.46

\* One storm each.

The important feature of this analysis is the illustration of the occurrence each season of one storm of outstanding intensity, necessitating the insertion of a special curve of "maximum storms". Example 1 explains the curves in Fig. 3.

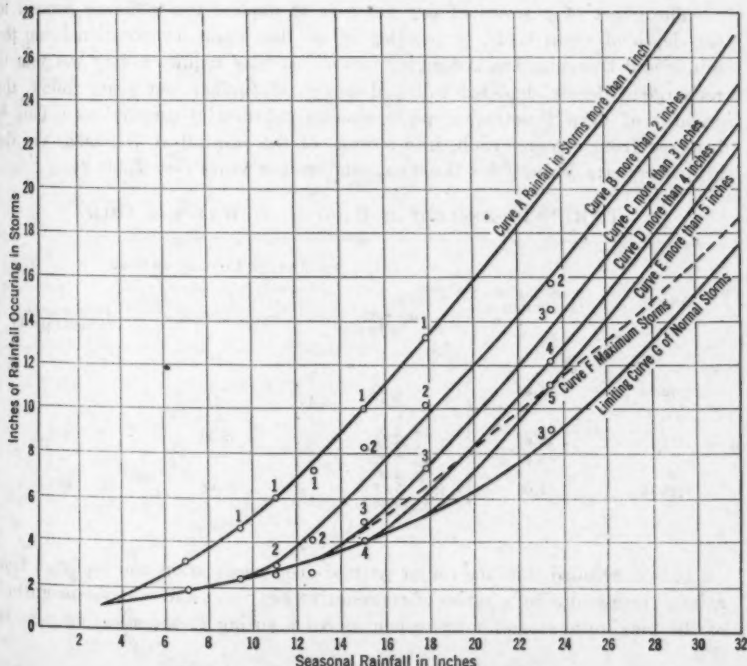

FIG. 3.—DISTRIBUTION OF SEASONAL RAINFALL.

## Example 1.—

Given a seasonal rainfall of.....	22.0 in.
From Curve <i>B</i> , the rain falling in storms of more than 2 in., is.....	14.4 "

Therefore, rainfall in storms of less than  
2 in., is..... 7.6 in.

From Curve *C*, the rain falling in storms of more than  
3 in., is..... 12.0 in.

From Curve *F*, the possible maximum rain storm is.... 9.9 "

Therefore, the rainfall in storms of more than  
3 in. and below maximum, is..... 2.1 in.

From this it may be concluded that, for a seasonal rainfall of 22 in., there may occur:

One storm of .....	9.9 in.
Storms from 2 in. to 3 in. (14.4 — 9.9).....	4.5 "
Storms of less than 2 in.....	7.6 "

Total ..... 22.0 in.

The effect of a series of dry years is to deplete the moisture content to the depth of plant roots, or possibly below that point, evaporation being the minor and transpiration the major factor. It may require a very wet year to recharge a deeply depleted soil. However, if further wet years follow, the amount of deep penetration must assume substantial proportions. This is inferred from a segregation, into storms, of the rainfall at Wildomar (in the arid Murrietta Valley) for three consecutive wet years (see Table 2).

TABLE 2.—ANALYSIS OF RAINFALL AT WILDOMAR, CALIF.

Season.	Seasonal rainfall, in inches.	STORMS OF 2 INCHES, OR MORE.		
		One each, in inches.	Total, in inches.	Percentage of seasonal rainfall.
1913-14	21.38	3.14 5.50 6.81 2.73	15.45	72
1914-15	22.65	2.00 2.58 7.89	15.30	67
1915-16	21.06	2.20 5.15 9.33	16.68	80

It is concluded that the major part of deep penetration and recharge from rainfall occurs during a series of consecutive wet years and that the magnitude of the maximum storms may be considered a ruling factor affecting penetration.

*Consumptive Use of Cover.*—The investigators of the U. S. Department of Agriculture have published the results of great numbers of experiments relative to evaporation and transpiration losses for different types of soils and crops. On the basis of these findings, values for the determination of deep penetration may be assigned to moisture deficiency at the beginning of a rainy season, and to the losses by evaporation, transpiration, and run-off in connection with a study of the individual storms of a season. This method, of necessity, is based on the assumption that rain will remain uniformly distributed over the area after it falls; that the moisture depletion at the end of the season is more or less uniform over the area in question; and that the soil is of uniform texture to the depth to which such depletion occurred. These assumptions, in all probability, will result in excessive values for losses and low values for penetration. On the other hand, if based on daily rainfall records and carried through an entire season, this method will take into account the character of individual storms in a manner no other method will permit, so that the results must be considered as reliable, although too low. Each season, however, must be studied separately.

Harry F. Blaney, Assoc. M. Am. Soc. C. E., has estimated\* the total average transpiration for all active growing vegetation in the northern valleys of Southern California for the six winter months (rainy season) as 1 acre-in. per acre per month. For bare lands, vineyards, and deciduous orchards which are clean cultivated, no transpiration losses occur in the winter. Furthermore, the deficiency of soil moisture at the end of the summer is, for various crops:

Irrigated grain and citrus.....	2 to 4 acre-in. per acre
Non-irrigated grain, grass, and weeds. 4 to 6	" " " "
Deciduous, grapes, walnuts, peaches..	6 to 8 " " " "
Brush .....	6 to 8 " " " "

Evaporation losses are 0.5 in. per acre after each rainstorm, or from 4 in. to 8 in. per season. From these data the water supply that may be required to satisfy the moisture deficiency at the beginning of the rainy season and the evapo-transpiration losses during the same time, is estimated by Mr. Blaney as follows, depending on the wetness of the preceding years and the type of soil:

Bare land.....	6 to 10 in.
Irrigated grain and citrus.....	12 to 16 in.
Non-irrigated grain and weeds.....	12 to 18 in.
Deciduous orchards, grapes.....	10 to 16 in.
Brush .....	12 to 18 in.

#### DETERMINATION OF PENETRATION FROM SOIL MOISTURE TESTS ON NORTH MESA, MURRIETTA-TEMECULA AREA

Penetration from rainfall may be ascertained, both as to quantity and depth, by soil moisture tests made before and after a wetting. Test samples are obtained by soil auger or soil tube, and the holes of successive tests as a rule are within a few inches of each other. The test holes are then plugged

\* Bulletin 19, "Santa Ana River Investigation," State of California, Dept. of Public Works, Div. of Eng. and Irrig., 1929.

by tamped earth. For fairly uniform soils the results may be considered accurate for the area in the immediate vicinity of the test holes and sufficiently reliable for general conclusions regarding larger areas. In many citrus orchards of Southern California, soil moisture tests are a matter of routine, made to determine the immediate irrigation needs.

\* One storm.

Some irrigation and rainfall penetration tests were made\* in February and March, 1927, on the North Mesa of the Murrietta-Temecula Area in Riverside County, Southern California. Fig. 4 is a map of this area. These experiments were made in conjunction with the determination of the water supply available from the rainfall which was indicated by springs in the same general locality. The region is comparatively arid and the soil is an ancient, rather compact alluvium, a combination which would lead the casual observer to the conclusion that no deep penetration could occur. Table 3 gives the seasonal rainfall and storms for a period of years for the station at Wildomar in Murrietta Valley. The altitude of Test Plot No. 1 (see Fig. 4), is 1400 ft. and the average seasonal rainfall at that place is about 14.5 in. Water was applied by irrigation and by rainfall. Moisture determinations were made from soil-auger samples and were averaged from observations on three holes. The soil is a sandy clay loam, or silt loam, with strata of pure sand at depths of 12 to 15 ft. After a rain, the mesa shows many shallow puddles, from which the water seeps away or evaporates. The land had been dry farmed. The water-table stands at a depth of about 200 ft. The size of test plots was 20 by 20 ft. They were banked on the edges and flooded.

\* By Willard G. Babcock, Agricultural Chemist, Riverside, Calif.

The values for Table 4 were obtained from undisturbed cores of soil taken on March 16, 1927. The moisture equivalent test was made to obtain a value for the "specific retention", which is a term used to express the quantity of water which a soil or rock will retain against the pull of gravity if it is drained after having been saturated.\*

TABLE 4.—CHARACTERISTICS OF SOIL IN TEST PLOT No. 1.

Factor.	DEPTH BELOW SURFACE:	
	2 ft.	4 ft.
Specific gravity (volume weight).....	1.57	1.81
Wilting coefficient.....	5.8	6.0
Moisture equivalent.....	10.7	11.0
Porosity, in percentage by volume.....	37.2	29.0
Probable yield, in percentage by volume.....	20.3	9.1

The moisture equivalent† is equal to  $100 \frac{c}{W}$ , in which,  $c$  is the weight of the water that remains in the soil after it has been saturated and then subjected to a centrifugal force 1 000 times the force of the gravity, and  $W$  is the weight of the soil when dry. It is an arbitrary ratio used in indirect determinations of the hygroscopic and wilting coefficients of soils and may also be found useful for estimating the specific retention.‡

The approximate limits are given by Meinzer§ as follows:

Coarse sand.....	1.5 to 2.5%
Fine sand.....	2.5 to 7.5%
Sandy loam.....	7.5 to 24%
Clay loam.....	24 to 31%

Quoting from a report|| by O. W. Israelsen and F. L. West, Associate Members, Am. Soc. C. E.,

"Correlation between the moisture equivalent and the maximum amounts of water found after irrigation show a gratifying agreement and suggest that the moisture equivalent might be made a basis of judging maximum capillary capacities (essentially specific retention)."

In other words, the moisture equivalent is approximately the field capacity of the soil. The wilting coefficient, as defined by Mr. L. J. Briggs, is equal to the moisture equivalent divided by 1.84.

Table 5 shows the moisture equivalent from determinations made on the test plot at North Mesa (see Fig. 4) during February and March, 1927. Table 6 contains a record of the quantity of water applied on the test plot. Assuming an average specific gravity of 1.69 for the dry soil, 1% of moisture is equivalent

to 0.2028 surface in. of water. The values given in Column (2), Table 5, indicate a heterogeneous soil, the thirteenth foot being sandy, the top foot, a sandy loam, and the fifteenth, a loam. From Column (2), Table 5, the total field capacity for the first 9 ft. is computed at 20.16 surface in. of water, or a column of water, 20.16 in. high. The total moisture content on February 4, for the same 9 ft. is obtained from Column (3), Table 5, and computed at 8.66 in. Consequently, there was a moisture deficiency in the first 9 ft. of 20.16—8.66, or 11.50 surface in., which had to be satisfied before penetration below the ninth foot could take place.

.....	14.82	.....	Total water applied on plot.

From Column (3), Table 5, it is apparent that at the test plot the heavy rain of December, 1926, did not penetrate below the second foot and that as a

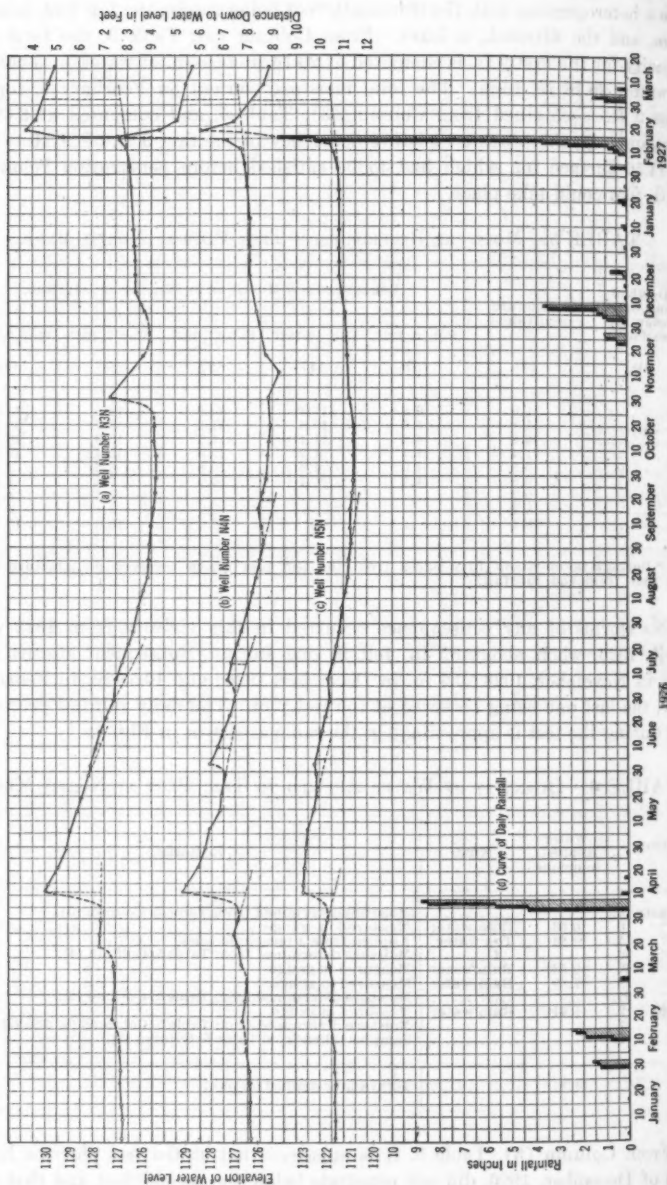

FIG. 5.—FLUCTUATIONS OF WATER LEVELS IN TEST WELLS, PAUBA VALLEY, CALIFORNIA.

result of a series of dry years the soil had dried out to the ninth foot, or lower, because, on February 4, the moisture content from the third to the ninth foot was below the wilting point. The increase in moisture after February 4 is indicated in Columns (4), (5), and (6), (Table 5). By February 21, moisture in the test plot had reached the seventh foot and by March 7, probably the fifteenth foot.

Column (7), Table (5), gives the penetration from 10.58 in. of rainfall at a point on flat ground fifty paces from the test plot. It is certain that moisture had reached the fifth foot. The excessive moisture found in the fifteenth foot may have existed prior to February 4.

A bore hole was made on February 26 in a "hog wallow" near the test plot where some water had been standing prior to that date. The log showed a dark brown sandy loam and gravelly loam to 15 ft., where a pure sand was struck. The soil was either moist or wet to 16 ft., indicating deep penetration from rainfall of 9.14 in., which occurred from February 5 to 21, 1927, due to the effect of the concentration of rain water in a depression.

Expressing the values of Columns (3) and (6), of Table 5, in surface inches of water, the writer has computed the penetration, in inches, below the ninth foot as follows:

March 7, total moisture in the top 9 ft.....	18.17
February 4, total moisture in the top 9 ft.....	8.66
Gain in moisture.....	9.51
Total water applied.....	14.82
Unaccounted in top 9 ft. of soil.....	5.31
Estimated evaporation losses, four separate wettings at 0.5 in.....	2.00
Penetration below ninth foot.....	3.31

The foregoing results lead to the conclusion that deep penetration occurred in depressions. This is also indicated by the reaction of the water-table, underlying this mesa, to the February storm, and registered in the depth to water as shown in Table 7 (see Fig. 4).

The mesa formation is alluvial, unassorted, interpacked gravel and clay, alternating with strata of granitic gravel, probably laid down by sheet floods under a desert climate, and now under erosive action. Water-bearing gravels in five wells, which range from 200 to 600 ft. in depth, average about 30 per cent. Outcrops indicate that individual strata cover large areas, which may explain the lag and irregularity observed in the rise of the water-plane and point to temporary storage on top of clay strata.

It is reasoned that, with two or three consecutive wet years as they have been recorded in this region, deep penetration would have been general over the mesa and that an appreciable portion of the rainfall would have reached the water-table. Positive proof of this is furnished by the flow of certain springs which issue at the foot of the steep southwesterly escarpment of the

North Mesa and by the output of some artesian wells near the springs which have been flowing for several years. The location of these artesian springs and wells is marked on Fig. 4 near Well No. 14. Careful analysis of surface-water and ground-water conditions indicate that there is no extraneous, or distant, source for this water supply and that local rainfall alone is responsible therefor. There is corroborative testimony that the flow of the wells and springs varies little over a period of years, the inference being that the comparatively compact formation acts as a regulator of an otherwise erratic recharge.

\* This reading was made in August, 1926.

Measurements of flow were made on March 11 and October 26, 1927. On the latter date, the output was slightly less than in March which was thirty days after a heavy storm. In October, the springs proper flowed 0.191 sec-ft., and the artesian wells, 0.1672 sec-ft. (total flow, 0.3582 sec-ft.). Making a further allowance for evapo-transpiration losses in swamps and for wild growth in the vicinity of the springs, the total visible water supply may be estimated at 0.40 sec-ft., which is equivalent to 290 acre-ft. per year. The surface water-shed tributary to these springs and wells was computed to be 5.5 sq. miles.

The ground-water basin extends from Murrietta Creek easterly to the line marked "Granite" in Fig. 4. The direction of percolation is indicated by arrows and, in some places, crosses the surface drainage lines. The probable ground-water area tributary to the springs and wells is estimated at 7.34 sq. miles. Assuming that there is an average drainage area of 6.5 sq. miles, that the springs and wells represent the entire supply available at the bluff, and that there is no by-passed underflow, the yield is 45 acre-ft. per sq. mile, or 0.07 acre-ft. per acre.

Table 3 shows that for the 14 years from 1913 to 1927 the mean rainfall in this vicinity was 14.57 in. and that there were 5 very wet years, with an

average of 22.76 in. (= 1.9 ft.). If the recharge is assumed to have taken place in these 5 years, the mean percentage of deep percolation of a wet year

$$\frac{14 \times 0.07}{5 \times 1.9} = 10.3\% \text{ of the seasonal rainfall of 22.76 in.}$$

#### DETERMINATION OF DEEP PENETRATION AND STORM RUN-OFF BY COMPARISON WITH MOUNTAIN RUN-OFF

The quantity and general character of the rainfall, as well as the physical characteristics that might be peculiar to an individual mountain water-shed, are expressed in the rainfall-run-off relations, and these relations can be applied with modifications to conditions on adjacent alluvial plains. A study is here presented with this end in view and illustrated for a concrete case, namely, the application of the observed rainfall-run-off relations of the San Bernardino Mountain water-shed in Southern California to the determination of deep penetration from rainfall in the San Bernardino Valley.

Reliable run-off measurements of mountain water-sheds are generally available while rainfall records, as a rule, are incomplete. The reverse is the case for valleys. Rainfall increases with altitude, in Southern California, up to about Elevation 6 000 ft. The average rainfall of a water-shed can be determined from available records, either by the construction of isohyets lines or the use of formulas.

*Effect of Different Soil Formations.*—The modern alluvial valley fill which has its origin in the residual soil of a granitic range is generally more open and, for similar storm and cover conditions, should produce a larger percentage of deep penetration than the residuum. Similarly, the product of erosion of an ancient alluvium will be more porous and subject to more rapid penetration than its mother deposit. An ancient compact alluvium has a larger specific retention than a modern stream deposit and will hold larger volumes of water, subject to evapo-transpiration losses, and, therefore, will produce less available supply. This is demonstrated in Fig. 6\* by comparing the run-off curves of the Santa Ana River water-shed with those of the water-sheds of Lytle, Mill, San Antonio, Devil Canyon, and Waterman Canyon Creeks.

The water-shed of Santa Ana Canyon is characterized by flats and valleys covered with an ancient alluvium, while in the water-sheds of the other streams mentioned residual soils and slides are the predominant features, and although the Santa Ana River has a higher mean seasonal rainfall, nevertheless its percentage of run-off is less than in the case of the other water-sheds.

*Comparison of Physical Features Affecting Penetration and Run-Off.*—On a mountain water-shed with residual soil cover, seepage water may strike bed-rock at a depth of 4 to 12 ft. or more, where it will be diverted down-hill as illustrated in Fig. 7 (a). On this down-hill course it must run the gauntlet of absorption by the roots of trees, brush, and herbs which may have penetrated fissures to depths of 20 to 30 ft. Abstraction is, therefore, extremely active until the percolating water reaches the stream bed. Despite this continued tapping, however, seepage run-off is produced in dry years, although this may be due partly to over-year storage and partly to absorption on slides, which, owing to their unstable and porous formation, readily admit the rain water.

\* Drawn by A. D. Edmonston, Assoc. M. Am. Soc. C. E.

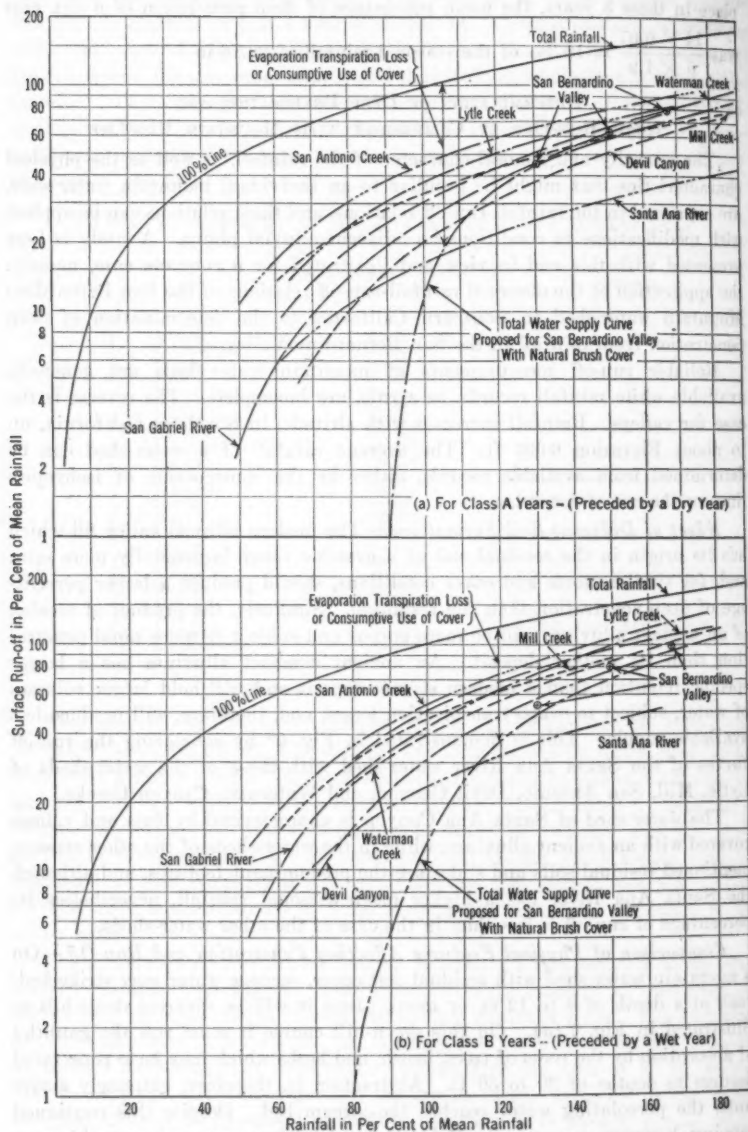

FIG. 6.—RELATION BETWEEN TOTAL SEASONAL RUN-OFF AND SEASONAL RAINFALL.

Different conditions prevail on valley floors. Bed-rock may be at depths of 20 ft. or more, and water that percolates to 10 or 15 ft. is, as a rule, permanently out of reach of plant growth and, therefore, must reach the ground-water plane. With given rainstorms of equal intensity, the valley floor with its flatter gradient, undulating surface, and heterogeneous fill, therefore, should receive a larger percentage of seepage than the mountain water-shed.

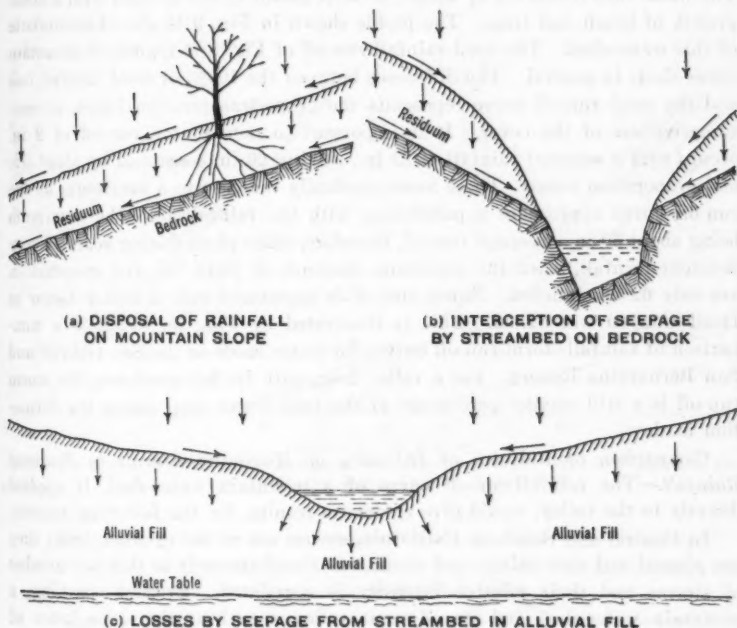

FIG. 7.

A similar relation obtains in regard to seepage from stream beds. Mountain streams run on bed-rock, receiving seepage from the banks as well as surface run-off and, as a rule, they suffer no percolation losses. In valley streams the reverse is the case, there being substantial seepage losses through the sides and bottom of the stream bed (see Fig. 7 (b) and Fig. 7 (c)).

Other conditions being equal, physical conditions are, therefore, more favorable to the absorption of rainfall and the conservation of seepage in valley areas than in mountain water-sheds.

*Analysis of the Rainfall-Run-Off Curve.*—The run-off of a mountain water-shed can readily be segregated into surface or storm run-off and seepage or normal run-off by an analysis of the daily hydrograph and records of daily discharge. Seepage run-off is defined herein as that portion of the rain which seeps into the ground and, subsequently, is the source of the more or less

perennial flow of a stream; it corresponds to deep penetration in the valley. Storm-water or surface run-off is that portion of the rainfall that reaches a stream bed on the surface during a storm and for a few days thereafter, and produces the flood flow.

Fig. 8 shows the total mountain run-off curve and its segregation into storm and seepage run-off for Devil Canyon in the Arrowhead water-shed north of San Bernardino and for which the rainfall of Squirrel Inn Station is characteristic. The water-shed covers 6.3 sq. miles; is steep, granitic, and covered with a dense growth of brush and trees. The profile shown in Fig. 9 is also characteristic of this water-shed. The total rainfall-run-off of Fig. 8 is typical of mountain water-sheds in general. The difference between the 100% or total rainfall line and the total run-off curve represents the evapo-transpiration losses, or consumptive use of the cover. It is important to note that a run-off of 2 in. occurs with a seasonal rainfall of 22 in., leaving 20 in. consumed by plant life and evaporation losses. These losses gradually increase to a maximum as the run-off curve approaches a parallelism with the rainfall line, the maximum being about 30 in. Seepage run-off, therefore, takes place during years of very deficient rainfall, when the maximum demands of plant life and evaporation are only 62.5% satisfied. Storm run-off is apparently only a minor factor at Devil Canyon water-shed. This is illustrated by Fig. 10, which is a comparison of rainfall-storm run-off curves for water-sheds in the San Gabriel and San Bernardino Ranges. For a valley floor, with its flat gradients, the storm run-off is a still smaller percentage of the total water crop unless the formation is clay.

*Comparison of Relation of Intensity of Maximum Storms to Seasonal Rainfall.*—The rainfall-run-off curve of a mountain water-shed, if applied directly to the valley, would give erroneous results, for the following reasons.

In Central and Southern California, storms are of the cyclonic type; they are general and visit valleys and mountains simultaneously so that the number of storms and their relative intensity is correlated. Broadly speaking, a mountain water-shed and its adjacent valley area bear the same index of wetness\* for any one season. The same quantity of seasonal precipitation may be produced in the valley by a wet year and on the mountain water-shed by a dry year, but the number and intensity of storms will be quite different, to the effect that the resulting water supply will be larger for the valley. This is illustrated in Fig. 11 by a comparison of the relation of seasonal rainfall to maximum storms for the Valley of San Bernardino and the Arrowhead Mountain water-shed which is immediately to the north. Rainfall at the City of San Bernardino has been taken as representative of the valley and that of Squirrel Inn Station on the crest as representative of the mountain water-shed.

Fig. 9 shows the topographical relation of the rainfall stations in the valley and the Arrowhead water-shed. Fig. 11 shows the relation of seasonal rainfall to maximum storms. Although the points indicating individual years are irregularly located, the curves, nevertheless, depict the general character

\* The "index of wetness" is the percentage of the long-period mean. A seasonal rainfall of 20 in. would have an index of wetness of 125 for a long-period mean of 16 in.

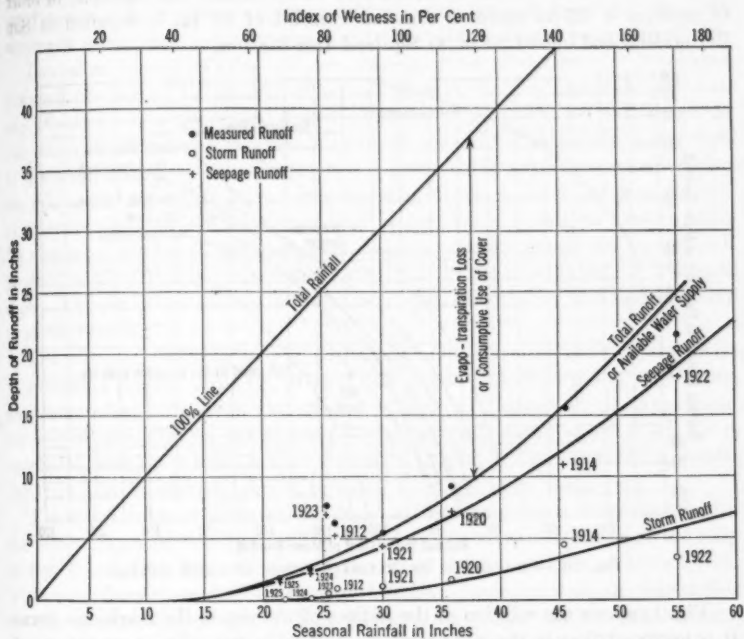

FIG. 8.—RELATION OF SEASONAL RAINFALL TO MEASURED TOTAL RUN-OFF SEEPAGE AND STORM RUN-OFF FOR DEVIL CANYON WATER-SHED.

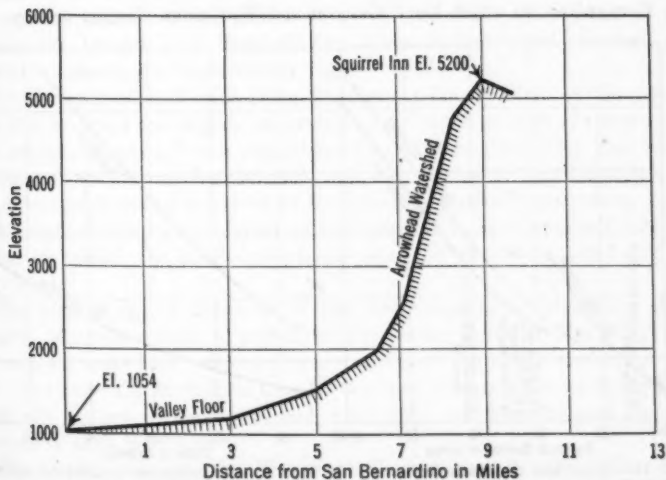

FIG. 9.—PROFILE OF ARROWHEAD WATER-SHED.

of the correlation between mountain and valley rains. For example, in order to produce a 7.5-in. storm a seasonal rainfall of 21 in. is required at San Bernardino and one of 30 in. at Squirrel Inn Station.

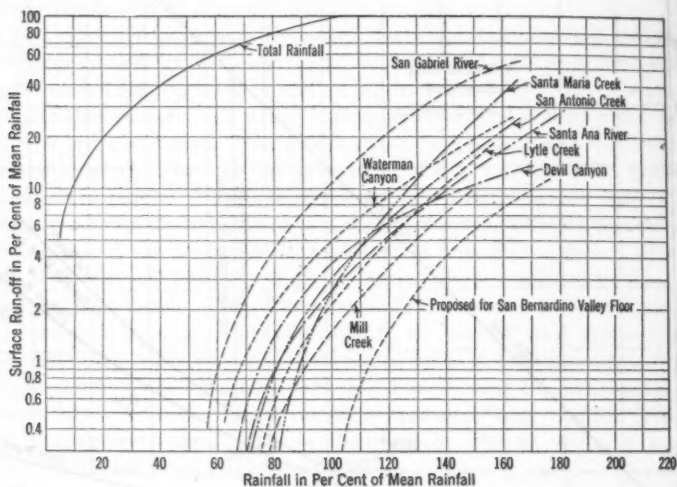

FIG. 10.—COMPARISON OF RAINFALL-STORM RUN-OFF CURVES.

Fig. 12 shows the relation of the indices of wetness to the maximum storms. It is apparent that in the mountains, as well as in the valley, heavy storms do not occur for seasonal rains below normal. In Fig. 11, the dashed line represents the "maximum storm-rainfall curve" for the Arrowhead water-shed near San Bernardino, to which Devil Canyon and Waterman Canyon belong.

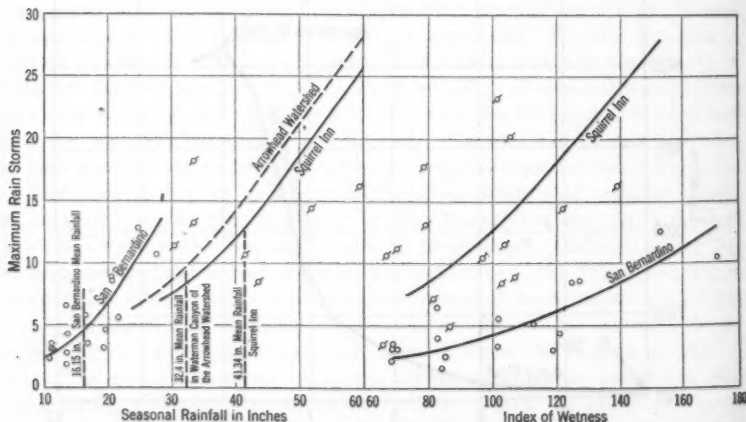

FIG. 11.—RELATION BETWEEN SEASONAL RAINFALL AND MAXIMUM STORMS.

FIG. 12.—RELATION OF INDICES OF WETNESS TO MAXIMUM STORMS.

A study of Figs. 9, 11, and 12, leads to the conclusion that, for equal seasonal rainfall, the valley receives storms of much greater intensity than the mountain water-shed and produces a correspondingly larger water supply.

*Determination of Valley Water Supply from Relation of Maximum Seasonal Storms of Valley and Mountain Water-Sheds.*—Inasmuch as intensity of storms is a governing factor affecting penetration, as well as storm run-off, deductions from the rainfall-run-off curve of a mountain water-shed to the water supply of an adjacent valley area should take into consideration the relation of maximum storms of equal magnitude, at least as far as seasons of excessive rainfall are concerned. It is not unreasonable to assume that, for similar character of soil and cover, seasons of equal maximum storms will produce in the valley as large a water supply as in the mountains. It has been shown that conditions are more conducive to deep penetration and less conducive to storm run-off.

For example, referring to Fig. 11, a maximum storm of 10 in. corresponds to a seasonal rainfall of 24 in., at San Bernardino and of 33 in. on the Arrowhead water-shed. The total run-off curve for Devil Canyon, in the Arrowhead water-shed (see Fig. 8) gives, for a 33-in. rainfall, a run-off of 7 in. It is concluded, roughly speaking, that the water supply at San Bernardino, resulting from a 24-in. rainfall, should be equal to, if not more than, 7 in.

For the purpose of illustration, there is here presented a determination of the water supply of San Bernardino Valley in the general vicinity of the City of San Bernardino, from the known run-off of the water-sheds of Lytle Creek, Waterman Canyon, and Devil Canyon Creeks. These streams are responsible for the modern valley fill of San Bernardino. They are of granitic and schistose formation and have a dense brush and tree cover. The Valley of San Bernardino is a sloping plain and for the purpose of this illustration is assumed to have a natural brush cover. The characteristics of seasonal rainfall and the analysis of the storms of a wet season for the stations of San Bernardino, Devore, and Squirrel Inn—representing valley, foothill, and mountain water-sheds—are given in Tables 8 and 9.

The determination is made along two distinct lines: First, on the assumption that, for areas comparable in formation and cover, seasons of equal storms will produce in the valley a supply equal to, if not larger than, that in the mountains; and, second, on the basis that the relation of seasonal rainfall to the consumptive use of the cover is the same for kindred water-sheds.

Example 1.—The water supply of the valley is to be determined for three seasons in which the maximum storms were 7.5 in., 10 in., and 12.5 in., respectively.

The rainfall-run-off relations of the three mountain water-sheds—Devil Canyon, Waterman Canyon, and Lytle Creek—are shown in Fig. 6. Values for each water-shed are expressed in percentage of the long-period mean rainfall. The curve for Waterman Canyon Creek represents a fair average for the three. It belongs to the Arrowhead water-shed (see Fig. 11) and its mean seasonal rainfall is 32.4 in.

To simplify matters, the Waterman Canyon run-off curve (Fig. 6) is assumed to represent the average run-off conditions, and the Arrowhead water-

On Fig. 6 (b), the points marked "San Bernardino Valley" correspond with the values in Column (8) of Table 10. These points might serve as the basis for a water supply curve of the valley for wet years.

*Comparison of Evapo-Transportation Losses.\**—In general, it must be assumed that the character and volume of water supply of a country are reflected in the type of its natural vegetation. The water supply of a watershed is expressed by the average seasonal rainfall or the long-period mean. The average water needs of the vegetation sustained by this mean should bear a more or less fixed relation to the supply.

In a semi-arid country like Southern California, with a pronounced dry and rainy season, and erratic fluctuations of rainfall—not only from day to day, or month to month, or year to year, but also over periods of years—a type of vegetation is produced that is capable of living through a series of comparatively dry years as well as of responding to a wet winter. For a valley area like that at San Bernardino, with a seasonal supply varying from 8 in. to 26 in. and an average of 16 in. (see Fig. 11), the natural vegetation produced would be chaparral, growing to heights of 3 to 4 ft., besides a variety of grasses and herbs, with a consumptive use of 15 to 18 in. At Squirrel Inn the seasonal rainfall averages about 42 in., with a minimum of 26 in. and a maximum of about 80 in. This rainfall, combined with an altitude of more than 5 000 ft., produces chaparral as high as 10 ft. and pine timber requiring for its support a water supply of 25 to 30 in. In both instances the type of vegetation would seem to bear a definite relation to the water supply.

If water-sheds have similar soil formation and are under like climatic conditions, and particularly under the régime of the same cyclonic storms, it is

\* In co-operation with A. D. Edmonston, Assoc. M. Am. Soc. C. E., and J. H. Peaslee, Esq.

concluded that the relation of the consumptive use of their cover to their respective water supply is approximately the same, and that for the same season each water-shed will consume about the same percentage of its seasonal supply. The relation of seasonal rainfall to consumptive use is indicated by the rainfall-run-off curve in Fig. 6. If, then, for a series of neighboring water-sheds, both the seasonal rainfall and the total run-off—or its complement, the consumptive use—are expressed in percentage of the long-period mean rainfall, the resulting run-off curves are reduced to a common basis and should not only assume the same shape, but should also fall close together. That this is actually the case for seven water-sheds studied by the writer, is demonstrated by the curves in Fig. 6. The characteristics of these water-sheds are listed in Table 11.

TABLE 11.—CHARACTERISTICS OF WATER-SHEDS.

Name.	Area, in square miles.	ELEVATION.			Mean seasonal rainfall,* in inches.	Description.
		Mini- mum.	Maxi- mum.	Mean.		
San Gabriel River...	222.0	1 000	10 080	4 400	31.0	Steep granitic; some cliffs; flats of old alluvium a minor factor; generally well forested; flashy floods.
San Antonio Creek..	16.9	2 000	10 080	6 600	43.5	Granitic; steep; absorbent detrital slopes; well wooded; flashy floods, but also relatively good summer flow.
Lytle Creek.....	47.7	2 210	10 080	5 500	32.7	South fork, steep and barren, with flashy floods; middle fork, steep and wooded; north fork (the main summer water supply), absorbent detrital slopes; wooded.
Devil Canyon.....	6.1	1 750	5 250	3 600	32.7	Granitic; steep; some old alluvium flats and detrital slopes; heavy brush cover; alders and sycamores in bed.
Waterman Canyon..	4.5	1 500	5 100	3 600	32.4	Granitic; steep; heavy brush cover; alders and sycamores in bed; no flats, but good detrital slopes at the upper end.
Santa Ana Canyon..	199.0	200	11 500	6 700	37.2	Extensive flats and suspended valleys of ancient alluvium; in the upper water-shed, slopes above flats are broken quartzite and schist which is very absorbent; upper water-shed to the east shows typical desert mountain forest; slopes generally well wooded; extensive meadows.
Mill Creek.....	48.3	300	11 500	6 700	35.8	Steep; granitic; well forested; absorbent broken schist in the upper slopes.

\* Estimated from available records for valley stations.

The higher of these water-sheds receives snow above Elevation 5 000 which, in wet years, is a factor that favors late run-off. Many have absorbent detrital slopes which are well wooded.

The close relation of the run-off curves of these water-sheds, both as to alignment and position, particularly those of similar characteristics, is striking and supports the contention that the known rainfall-run-off relation of a water-shed will permit of deductions as to this relation, not only of a neighboring mountain water-shed, but also of a valley floor of kindred formation and cover. In the application to a valley floor, it is to be considered that, for wet years, conditions in the valley favor larger penetration but less run-off. On

the other hand, it is not likely that any water supply will become available for indices of wetness less than 70, because the rainfall of very dry years falls in light storms and is consumed. The character of the cover and its relative consumptive use as well as the over-year effect of the preceding year has an important bearing on the whole question.

Another solution for the determination of the water supply of San Bernardino Valley is outlined in Example 2.

Example 2.—Reference is again made to the run-off curves of Fig. 6, of which the Waterman Canyon curve presents a fair average for indices of wetness greater than 100. The proposed valley water supply curve, therefore, should be located near the Waterman Canyon curve. Equal weight must be given to the points marked "San Bernardino Valley", which were obtained in Example 1 on the basis of the rainfall-storm relations.

For dry years, (Fig. 6 (a)), the position of the curve is governed by the zero point. For ordinary dry years the rainfall at San Bernardino is about 11 in., or about 70% of the mean, with maximum storms of 2.5 to 3.5 in. On the assumption that the valley has a natural brush cover, the zero point has been estimated as follows: For Class A years, at 90% of normal, or 14.5 in.; and for Class B years, at 80% of normal, or 12.9 in. The curves have been drawn to follow the general alignment of the mountain run-off curves and marked "Proposed for San Bernardino Valley" (see Fig. 6).

*Comparison of Storm Run-Off.*—The relation of seasonal rainfall to storm run-off, expressed in percentage of the long-period mean, is shown in Fig. 10. Santa Maria Creek, in San Diego County, has an average seasonal rainfall of 19.4 in., and is characterized by a fringe of low granitic mountains and a comparatively flat valley of a clayey, rather impervious soil.

The data shown on Fig. 6 demonstrate that storm run-off is a minor factor, even for steep water-sheds. As indicated in Fig. 12, the valley floor will receive no storms for seasonal rainfall below normal which would produce surface run-off. The zero point of the valley storm run-off curve, therefore, has been assumed at the 100% point; otherwise, it has been drawn parallel to the general alignment of the mountain storm run-off curves. The water supply resulting from rainfall on the valley floor of San Bernardino Valley, as indicated by the proposed curves in Figs. 6 and 10, is given in Table 12. The methods presented permit of modifications which may be necessary, due to differences in the character of soil and cover between mountain water-shed and valley floor.

#### DETERMINATION OF RAINFALL PENETRATION FROM TEST WELLS IN PAUBA VALLEY, ON TEMECULA RIVER, RIVERSIDE COUNTY, CALIFORNIA\*

Quantitative determinations of deep penetration from rainfall may be made from the rise of the water level in wells. With a water-table relatively close to the surface so that intervening clay strata will not unduly interfere with percolation, the reaction on the water-table from individual storms can be traced distinctly and may serve as a basis for computations of the quantity of recharge.

\* In co-operation with B. C. Williams, Assoc. M. Am. Soc. C. E.

Observations to this end, which were made on about fifty test wells covering an area of 400 acres in Pauba Valley, and the analysis of the results, are believed to be of general interest. Incidentally, the volume of return water from irrigation was also determined for the same area.

Pauba Valley is located on the Temecula River at an elevation of about 1 100 ft. above sea level (see Fig. 4). It has a width of  $\frac{1}{2}$  mile to 1 mile and a length of more than 5 miles. The average seasonal rainfall is 15.5 in., the minimum 6 in., and the maximum 24 in.

The bottom-lands on which the observations were made consist of a modern alluvium of alternating layers of fine micaceous silt and sand with a top stratum of either silt or sand mixed with humus. The adjoining mesa lands rise about 200 ft. above the valley; they have a gravelly clay loam soil and contribute to the top soil of the bottom-lands.

The following is the log of a test hole in the bottom-lands:

Distance, in feet, below surface.	Material.
0-2 .....	Medium silt loam.
2-4 .....	Sandy loam.
4-6 .....	Heavy silt.
6-7 .....	Fine sand.
7-8 .....	Coarse sand.
8-9 .....	Heavy silt.
9-10 .....	Sand medium.
10-14 .....	Coarse sand.
14 .....	Water-table.

Ground-water stands from 12 to 20 ft. below the surface. The land is planted to alfalfa and is irrigated monthly 4 to 5 in. in depth, for 8 months per year, a record of the water applied being available.

In order to observe the penetration of bottom-lands by rainfall or return water, a large number of 2-in. test wells were driven to depths of 20 ft., perforated at the bottom. These wells are located along lines marked *G*, *F*, *H*, *I*, etc., in Fig. 4, and cover an area of 420 acres. Well observations were made, as a rule, once each week during the period from January, 1926, to March, 1927.

Southern California experienced a series of dry years from the summer of 1922 to April, 1926. An 8.75-in. storm in April, 1926, produced rainfall seepage. In February, 1927, a storm of abnormal magnitude (14.65 in.), occurred which also left a perfect record, while the 3.70-in. storm of December 9, 1926, was a sudden downpour of which a large part ran off.

Representative curves of well observations for 1926-27 are given in Fig. 5, which show the fluctuations of the water-plane along parts of the *N* line (Fig. 4), resulting from rainfall and irrigation. The daily rainfall (accumulative for a storm) and the approximate location of irrigation applications and of the pumping operations at Well No. 30 on the *E* line, about 6 000 ft. up stream from the *N* line, are also shown.

The effect of a storm was determined by measuring the rise in the well some time after the storm when the normal movement (drop or rise) had been re-established. The points of measurement are marked by light, dotted lines

in Fig. 5. A porosity factor of 25% was allowed. This would permit some loss of water by plant life. In some instances the measurements indicated a rise due to run-off, from adjoining mesa lands. On the other hand, there was a compensating run-off away from bottom-lands.

On the basis of an average rise of the water-plane for the entire area, the curve, Fig. 13 (a), was constructed, which shows the relation of intensity of storm to the quantity reaching the water-table. The total effect of the seasonal rainfall in 1926-27 of 23.70 in. on an area of 420 acres, was estimated at 215 acre-ft.

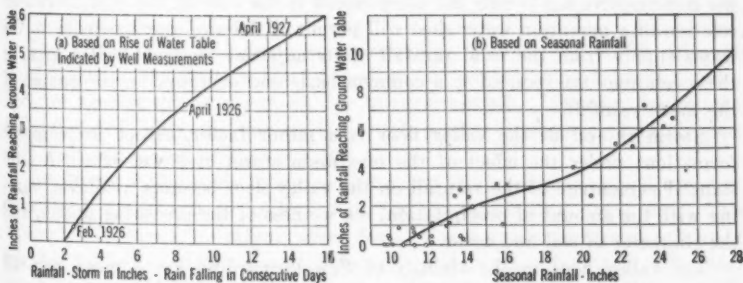

FIG. 13.—PERCOLATION FROM RAINFALL IN PAUBA VALLEY, CALIFORNIA.

The relation of deep penetration to seasonal rainfall was determined by segregating the latter into storms and applying the results to the curve in Fig. 13 (a). By this process the curve in Fig. 13 (b) was obtained. It is based

on seasonal rainfall at Aguanga (Elevation 1986), Elsinore (Elevation 1300), Greenwood (Elevation 1400), and Station C at Pauba Ranch (Elevation 1050), and the fluctuations of Pauba Valley test wells.

The location and effect of irrigation applications are also clearly shown in Fig. 5, and were determined in like manner as that from rainfall, the conclusion being that the irrigation return waters over a large area planted to alfalfa and receiving a seasonal application of 3.5 acre-ft., were 38.4%, or 1.34 acre-ft. per acre.

#### CONCLUSIONS

For an alluvial valley fill of crystalline origin, the distribution and rate of penetration of moisture from rainfall over large areas are essentially non-uniform, and percolation will concentrate in numerous well-defined ducts.

Deep penetration may occur during years of deficient rainfall when the maximum consumptive use of the cover is not satisfied; particularly is this true when the formation is modern.

Rainstorms in Southern California are principally of the cyclonic type and cover the entire country. Each season is characterized by a storm of outstanding intensity that is chiefly responsible for the water supply which becomes available.

For like seasonal rainfall, the intensity of the maximum storm of a season is greater in the valley than in the mountain water-shed and so is also the resulting water supply.

For like intensity of the maximum seasonal storm, the water supply produced in the valley is approximately the same as that in the mountains (conditions of cover and soil being similar). Given the relation of maximum seasonal storms of mountains and valley, deductions may be made from the known run-off of a mountain area to the available water supply of the adjacent valley floor.

There appears to be a more or less fixed relation between the seasonal rainfall of a water-shed and the consumptive use of its cover, which remains approximately the same for kindred water-sheds of a region. Inasmuch as the consumptive use is only the complement to the run-off, the rainfall-run-off relation of a mountain water-shed will permit of definite conclusions as to the water supply from the local rainfall of its adjacent recipient valley area, if these relations are reduced to a common basis and expressed in percentage of the mean rainfall.

Storm run-off of the valley floor is a minor factor, except for compact formations under the effect of the maximum storm of a wet year. A substantial percentage of the rainfall on the valley floor becomes available, varying with the amount of precipitation, the wetness of the preceding season, and the character of soil and cover.

The valley floor in the vicinity of San Bernardino has a mean rainfall of 16.15 in., and a modern alluvial fill of crystalline origin. Assuming a brush cover, the seasonal water supply available from rainfall over a period of years is estimated to average 4.5 to 5 in., or about 250 acre-ft. per sq. mile.

## DISCUSSION

HAROLD C. TROXELL,\* Assoc. M. Am. Soc. C. E. (by letter).—Seasonal rainfall cannot be divided into the four groups suggested by Mr. Sonderegger, unless another group, that of hold-over storage, is added. During wet years a large percentage of the rainfall might remain in storage to be discharged during the following season.

Just northwest of San Bernardino, Calif., and tributary to Cajon and Lytle Creeks is Lone Pine Creek, for which records are available since 1919. In contrast to the average Southern California stream, Lone Pine Creek passes over large sand and gravel areas and its canyon side walls are gently sloping and covered with sage-brush. The gauging station is located on an outcropping of bed-rock at the extreme lower end of the canyon. There is every reason to believe that there is practically no underflow by this station. The drainage area above the gauging station is 16.7 sq. miles.

In 1921-22 this area was visited by an unusually heavy rainfall. At a rain gauge near the mouth of the canyon 43.23 in. were registered for the season and the run-off from Lone Pine Creek was 3 810 acre-ft. Although this is the surface run-off, it does not represent the run-off from the 43 in. of rainfall. A large proportion of this rain was stored in the canyon and did not drain away for some time afterward.

During the next season of 1922-23 at least 1 440 acre-ft. of the 2 090 acre-ft. run-off for that year was from rain placed in storage during 1921-22. In 1923-24, 530 acre-ft.; in 1924-25, 195 acre-ft.; and in 1925-26, 15 acre-ft. were drawn from rainfall placed in storage during 1921-22. From this it is seen that the seasonal rainfall of 43.23 in. during 1921-22 produced, not 3 810 acre-ft., but at least 5 800 acre-ft. This figure is more likely to be an under-estimate than an over-estimate, because this storage has had to help supply the transpiration and evaporation losses for at least four years.

In Fig. 6 Mr. Sonderegger has divided the seasons into two groups—those that follow wet years and those that follow dry years. Those that follow wet years are plotted so as to show more run-off than those that follow the dry years.

The accuracy of this graph is questionable, because the entire seasonal rainfall during wet years is plotted against the seasonal run-off for that year, and not against the total run-off due to that rainfall. Likewise, during the following dry years, the run-off is plotted against a seasonal rainfall that only delivered a part of that run-off.

Furthermore, for years following wet years, the transpiration and evaporation losses are shown to be less than for those following dry years. The transpiration and evaporation losses for any season are governed primarily by the rainfall of that season. However, during years following wet years these losses would undoubtedly be greater, instead of less, due to the available storage. Ordinarily, wet years will have greater losses than dry ones irrespective of whether they follow wet or dry years.

\* Asst. Hydr. Engr., U. S. Geological Survey, Los Angeles, Calif.

For example, Fig. 6 shows that for years of mean rainfall Waterman Canyon Creek will have a transpiration and evaporation loss of 70% following a dry year and only 60% following a wet one. The transpiration and evaporation losses for the year following the wet year should be greater, due to the hold-over storage available to the plant life, and should be less for the year following dry years on account of lack of this storage.

A true division of the seasonal rainfall into transpiration, evaporation, storm run-off, and seepage run-off (penetration) can only be made when the quantity placed in storage during wet years is added to the seepage run-off for that year, and that drained from storage in the following years is subtracted from the seepage run-off for those years. Only one curve will be needed under these conditions. This curve will show the transpiration and evaporation losses irrespective of the character of the preceding years.

Curves, such as Fig. 8, showing a comparison between seasonal rainfall and storm run-off, should be used with a great deal of caution. Storm run-off depends not on seasonal rainfall, or even storm periods, but on the instantaneous rate of the rainfall and the condition of the canyon storage. Every acre of the canyon has a certain uniform rate by which it absorbs the rainfall if storage is available. If the rate for a given area is 1 in. per hour, then any storm that does not exceed that rate will be completely absorbed. If, for example, 1 in. should fall in  $\frac{1}{2}$  hour then  $\frac{1}{2}$  in. will run off. If this inch should fall in 15 min., then there would be  $\frac{2}{3}$ -in. run-off. Therefore, if a rainfall of 1 in. should occur within the hour, it would be necessary to have the instantaneous rates in order to determine the storm run-off for that rain. On the Santa Ana River the season of 1922 was a good example of this. While the first major storm of that year was as severe as those of April, 1926, and February, 1927, it did not cause any extremely high water.

Another item just as important to storm run-off as the intensity of rainfall is the condition of the canyon storage. If the voids in the canyon walls and gravels of the stream beds are completely surcharged, then the rain will run off as storm run-off irrespective of the rate of rainfall. For these reasons any comparison of seasonal rainfall and storm run-off should be avoided.

Mr. Sonderegger states that storms in mountain and valley areas of equal size will deliver equal supply, and this is undoubtedly true. Then, by drawing a curve (Fig. 11), showing the relation of the maximum storms to the seasonal rainfall, he assumes that like maximum storms will produce like seasonal run-off. The logic of this is doubtful because the seasonal run-off (or supply) depends, not so much on the maximum storm, as on the instantaneous rate of rainfall, the distribution of the storms, and the condition of the storage at the beginning of the season.

Table 13 shows the run-off from Waterman Canyon and Strawberry Creeks for the period of record, together with the seasonal rainfall and the storm periods of more than 4 in. at Squirrel Inn.

During 1925-26 and 1926-27 the seasonal rainfall at Squirrel Inn was almost the same for both years, as were also the maximum storms. On Strawberry Creek the season of 1926-27 produced a run-off almost 50% greater than that of

1925-26. This was due to several reasons, one being that the latter season was preceded by several dry years and had very little in storage at the beginning of the season. The first storm of the season, a rainfall of 4.97 in. during the early part of October, had practically no effect on the surface run-off. It was apparently used to make up the soil-moisture deficiency and storage. From then until April, the discharge of the creek varied little, except for a short period in February following a storm of 6.90 in. The maximum storm of the season was a 19.76-in. rainfall in April. The storm left the storage in the canyon fairly well filled, insuring a normal run-off for the summer months.

TABLE 13.—COMPARISON OF RAINFALL AND RUN-OFF RECORDS,  
WATERMAN CANYON AND STRAWBERRY CREEKS.

Season.	RUN-OFF.		RAINFALL (SQUIRREL INN).	
	Waterman Creek, in acre-feet.	Strawberry Creek, in acre-feet.	Seasonal, in inches.	Storm periods of 4 inches, or more, in inches.
1920-21	1 840	3 170	46.15	9.01, 8.40, 7.04
1921-22	6 420	11 000	73.58	23.79, 8.68, 6.91, 6.93, 5.71
1922-23	2 230	3 680	44.27	7.73, 5.01
1923-24	784	1 600	28.42	4.06
1924-25	555	1 430	34.81	4.00
1925-26	1 160	2 530	45.23	19.76, 6.90
1926-27	2 040	3 720	43.32	20.30
1927-28	585	1 300	16.39	5.20

At the opening of the 1926-27 season, while the storage was low, it was hardly as deficient as in 1925-26. Several storms of about 2 in. in November, followed by storms at intervals of about two weeks, kept the daily discharge about normal. In the middle of February the maximum storm of 20.30 in. occurred. This was immediately followed by several storms of more than 3 in., in March. It was these March storms that caused the run-off for 1926-27 to be greater than the run-off for 1925-26. After the heavy storm of February had filled the available storage in the canyon, the storms of March were forced to run off. Had the April storm of the 1925-26 season been followed by storms such as fell during October and February of that season, the run-off for 1925-26 season might have equalled that of 1926-27.

In 1920-21 the seasonal rainfall was greater than in both 1925-26 and 1926-27 (46.15 in. at Squirrel Inn). The season opened with a storm of 4.00 in. in the latter part of October. From then, until the end of May, followed a series of storms, the greatest of which was a 9.01-in. rain in January, a 8.40-in. rain in March, and one of 7.04 in. in May. All these storms showed a large run-off, due to the fact that the canyon storage was completely charged during most of the rainy season. Unlike both 1925-26 and 1926-27 the 1920-21 season did not have a major storm; yet the run-off from Strawberry Creek was only about 15% less than in 1926-27 and 35% greater than in 1925-26, each of which had maximum storms of about 20 in.

In 1921-22, with a maximum storm of 23.79 in. (only 3.4 in. greater than that of 1926-27), the seasonal run-off was more than three times greater.

The heavy storm of December was followed by minor storms at frequent intervals. In other words, it is not so much the size of the maximum storms that effects the seasonal run-off, but the order in which the maximum and minor storms occur. Practice in Southern California has taught hydrologists that, while a storm of 3 to 5 in. in October or November might not affect the run-off, storms of 2 to 3 in. following major storms might give considerable run-off.

In order to determine the deep penetration on the valley floor, the only comparison that can be made with the mountain area, is to assume that the evaporation and transpiration losses per unit of area are equal. It seems logical that a natural brush cover in the San Bernardino Valley should have the same transpiration and evaporation losses as the mountain area for like cover.

By drawing curves similar to those of Mr. Sonderegger, showing the transpiration and evaporation losses, and seasonal run-off corrected for storage, for Strawberry, Waterman Canyon and Lone Pine Creeks, the following conclusion might be drawn as to the deep penetration on the valley floor. If the growth was as extensive as that in Lone Pine Canyon where hold-over storage exists, then for a mean seasonal rainfall of 16.15 in. the deep penetration would be about 0.2 in. If the growth were more comparable to that found in Strawberry Creek, then for a mean seasonal rainfall the penetration would be about 0.5 in. On the other hand, there might not be any deep penetration for a season of 16.15 in., if the valley floor was assumed to have a natural brush cover, because, under these conditions, the valley would be in its native state, having large moist areas acquired during wet years. The evaporation and transpiration from such areas would greatly exceed that of the mountain areas.

HARRY F. BLANEY,\* Assoc. M. Am. Soc. C. E. (by letter).—The increasing demand for water for irrigation and domestic purposes in the semi-arid areas of the Southwest has created a need for more definite information as to what proportion of rain falling on the valley floors penetrates to the ground-water supply. Mr. Sonderegger's paper is a valuable contribution to the study of this complex subject.

Reference is made to some estimates, by the writer, of winter evapotranspiration losses and soil moisture deficiency at the beginning of the rainy season. Part of these are conclusions drawn by the author based on the writer's estimates. It should be definitely understood that these are preliminary and may be modified by subsequent information. It was necessary at that instance, to make an estimate of the contribution of the rain falling on the valley floor to the ground-water supply, for the purpose of completing the hydraulic accounting in the Santa Ana River report.†

The following is a brief description of the method used. Rainfall penetration on the valley floor below the root zone was estimated indirectly by assigning values to evaporation, transpiration, soil moisture deficiency, and surface

\* Irrig. Engr., U. S. Dept. of Agriculture, Los Angeles, Calif.

† "Santa Ana River Investigations," *Bulletin 19*, State of California, Dept. of Public Works, Div. of Eng. and Irrig., 1929.

run-off as deduced from one season's work in the Santa Ana area, and by corroborating data secured in San Diego County and San Fernando Valley. These were analyzed and deducted from each rain storm, and the remainder of the rain was considered to penetrate below the root zone and eventually reach the ground-water. Assumptions are for average soil conditions, and no attempt was made to show the effect of soil texture on the depth of penetration. Values for the factors were assigned as follows.

*Evaporation.*—Temperature, wind velocity, humidity, type of soil, kind of vegetation, transpiration, altitude, interception of rain by vegetation, period between storms, etc., are some of the many factors that affect the evaporation loss after a rain storm.

From observations it was found that the evaporation loss from a bare soil in the winter months very nearly equals the loss from a free water surface until the time the soil drains to field capacity. After that, the surface evaporation loss was readily determined by soil sampling. The best data available indicated that the average evaporation loss from the top soil is about  $\frac{1}{2}$  acre-in. per acre after each rain storm.

*Transpiration.*—After careful consideration of unpublished data from co-operative irrigation investigations\* in Northern San Diego County, covering two seasons, the total average transpiration for all active growing vegetation was taken as 6 acre-in. per acre during the six winter months, or 1 acre-in. per month. The rate of transpiration depends upon the crop. Other factors, such as temperature, air movement, humidity, available soil moisture, etc., also influence the rate of transpiration.

Investigations have shown that bare lands, vineyards, and deciduous orchards that are clean cultivated, have no material transpiration loss during the winter period.

*Soil Moisture Deficiency.*—In calculations of rainfall penetration, the deficiency of soil moisture below field capacity at the end of the summer season must be reckoned in analyzing the following rainy period. There will be no appreciable downward penetration until all the soil within the root zone has been filled to field capacity. The initial moisture content of the soil at the beginning of the rainy season will vary with the kind of crop, depth of root zone, type of soil, amount of irrigation, depth of water-table, etc.

After considering many observations made in Southern California, the values given in Table 14 were taken for the deficiency of soil moisture at the beginning of the rainy season, for average soil under various conditions.

*Run-Off.*—Hydrographers of the Santa Ana investigation determined the run-off rate per square mile on certain known areas. These rates were used also on undetermined areas.

*Calculations of Rainfall Penetration.*—In general, it was found that every season must be studied separately in order to arrive at the penetration for that season. The same seasonal rainfall may give entirely different penetration, due to varying intensity and distribution of storms. For computing the amount of rainfall penetrating below the root zone during the season,

\* "Irrigation Water Requirement Studies in San Diego County, Calif.", by S. H. Beckett, Harry F. Blaney, and C. A. Taylor, Univ. of California and U. S. Dept. of Agriculture.

1926-27, the values in Table 14 were used. Known rainfall records as near as possible, in total seasonal amount to the required average for an area, were used. An example of detail calculations for rainfall observed at the U. S. Weather Bureau Station at San Bernardino, Calif., is given in Table 15. The rainfall for the season, 1926-27, was 20.55 in. Table 16 contains a summary of estimates obtained for varying rainfall, by interpolating between calculated quantities.

At the request of the State Engineer of California a co-operative investigation is now (1929) being conducted by the Division of Agricultural Engineering, U. S. Department of Agriculture, to determine the penetration and storage of rain falling upon the valley floors of the Santa Ana River area in Southern California. This study will cover a four-year period.

\* "San Gabriel Investigation", by Harold Conkling, *Bulletin 7*, State of California, 1929.

In connection with this investigation a large number of rainfall penetration stations have been established on predominating soil types throughout the area. Measurements are being made of rainfall, evaporation, transpiration, surface run-off, and deep percolation. Soil samples are taken with standard soil tubes to depths of 12 to 18 ft., which is well below the root zone of most crop and native plants. In this way the storage of rain water in the soil and the downward percolation are determined. Ten of these stations are especially equipped for intensive work.

Shafts and tunnels have been dug at several locations along the foothill area where the ground is too rocky for soil sampling. The downward percolation of rain water is being measured at the tunnels. At one shaft near San Bernardino artificial rain has been applied during the past two seasons and the downward movement of water was observed at tunnels 12 and 20 ft. below the ground surface.

Since a large portion of the rainfall absorbed by the soil is lost by evaporation and transpiration, field plots are being intensively sampled throughout the year to determine the consumptive use of water by various crop plants and native vegetation.

Unfortunately, the rainfall in the Santa Ana River area has been below normal during 1927-28 and 1928-29 so that no final conclusions have been reached as to the amount of rainfall penetration.

Mr. Sonderegger is to be complimented on his excellent analysis of a method to determine rainfall penetration on the valley floors by comparison with mountain run-off. However, the writer is of the opinion that usually the yield of water in mountain areas is essentially different from that resulting from rainfall penetration on valley floors.

There is an initial deficiency of soil moisture within the root zone, at the beginning of each rainy season. This is a variable factor dependent on plant life, depths of root activity, soil type, and depth of soil. The soil on the valley floors is generally of such a depth that the root activity is a maximum under native conditions, while in the mountain areas, bed-rock usually is near the surface, and in all probability there is root activity throughout the entire soil cover, the depth being limited only by bed-rock.

Rainfall penetrating below the root zone on the valley floors is at once out of reach of the overlying cover, except in areas of high water-table. In the mountains where the soil is shallow the condition is different. There the water is continually within reach of plant roots until it escapes into the stream channels or deep alluvium. It is only when the rate of drainage toward and along the stream channels is greater than the rate of evaporation and plant transpiration that there is any material yield of water from a mountain area.

Another modifying factor is the steepness of the slopes of a mountain water-shed. There is a far greater actual area of plant cover than the projected area used in determining the quantity of water resulting from a given depth of rainfall in inches. Conditions then are different in mountain areas than on valley floors, even for native brush cover; but further than this, the major portion of the valley floors is cultivated and much of it is irrigated. The depth and character of root activity of cultivated crops are widely different from that of native brush cover.

C. W. SOPP,\* Assoc. M. Am. Soc. C. E. (by letter).—The author is to be commended for his outline of methods for computing a source of water supply of great importance to communities dependent on ground-water developments.

The writer believes that, where the water-table is close to the surface, the method based on the rise of water levels is the most satisfactory if used with porosity data obtained from many well logs. This method may be applied also where the water-plane is at considerable depth, because the moisture in the alluvium between the root zone and the water-table is always practically up to field capacity.

This statement is based upon an analysis of nineteen samples of sands taken from a shaft dug in recent alluvium near Pasadena, Calif. These samples were taken from depths of from 75 to 170 ft. at the end of a season in which the total precipitation was only 13.73 in. This condition permits rapid movement of moisture, penetrating below the root zone, to the water-table, and the resulting rise of water levels, even at depths of 150 ft., is noticeable within a short time. A study of the initial rise of water levels in eight wells, observing two heavy storms for each well, showed an average rate of movement downward of 10 ft. per day. This is under previously saturated conditions of top soil.

The method of comparison with run-off from adjacent mountains is the easiest to apply, but is liable to wide differences, depending on the judgment of the engineer. The extension of the measured mountain run-off data to valleys which inherently differ in slope, soil, cover, and culture, is difficult. For example, Fig. 6, using average rainfall, shows a variation in run-off of 30% for similar mountain drainage areas.

The rainfall-run-off relation illustrated by Fig. 8, agrees with a law the writer has formulated for Southern California streams; the percentage run-off is equal to the seasonal rainfall, in inches, less ten, up to an annual precipitation of 60 in. As an illustration, with a seasonal rainfall of 60 in., the run-off, and, consequently, the evapo-transpiration losses, is 50%, or 30 in. The maxi-

\* Asst. Engr., Pasadena Water Dept., Pasadena, Calif.

imum consumptive use of forest cover on Southern California water-sheds is about 30 in.

There is an additional method which the author has not mentioned, and that is, to analyze the rainfall by storms and to consider that all precipitation—after deducting run-off, evapo-transpiration losses, and moisture required to bring the soil in the root zone up to field capacity—moves downward and ultimately reaches the ground-water. This method gives conservative quantitative results. The principal criticism is that, due to collection of rainfall in depressions, some ground-water replenishment will occur even with small precipitation.

W. P. ROWE,\* Assoc. M. Am. Soc. C. E. (by letter).—The question of consumptive uses of various types of vegetation is one that is being studied by a great many investigators. These investigations, as a rule, are being made in connection with studies not directly allied with engineering but which, when finally assembled and correlated, will prove of great value to the engineer dealing with water supply.

The author has spent considerable effort in determining the consumptive use of the vegetation on various water-sheds in Southern California. Of all the water-sheds given in Fig. 6 and Table 11, Devil Canyon and Waterman Canyon are the only ones which have a brush cover similar to the valley floor area, the others, reaching to higher elevations, have considerable areas of pine and oak timber. The author states that "the Valley of San Bernardino is a sloping plain and for the purpose of this illustration is assumed to have a natural brush cover." This classification eliminates from the discussion all the water-sheds except Devil Canyon and Waterman Canyon.

Transpiration losses from these two water-sheds occur from two distinct types of vegetation. The canyon bottom with its concentration of escaping seepage water in the form of underflow and surface streams supports a water-loving growth in which alders predominate. The area above the canyon bottom supports a vegetation that is Nature's solution to the problem of a water-shed cover that will take water when it can get it and live through severe droughts. This is the true chaparral or dwarf forest. It will coppice readily after being burnt over and in a few years the cover is as thick as it was before the fire. Without this faculty of restoration, it would have been discarded by Nature thousands of years ago.

Any one familiar with the summer streams in the low altitude of Southern California, in which class Devil Canyon and Waterman Canyon belong, knows that there is a great variation between the quantity flowing in the morning and in the evening. This variation is caused almost entirely by the fluctuation in transpiration of the canyon-bottom growths, the mountain-side transpiration fluctuations being "ironed out" by the time and distance elements of percolation. In Devil Canyon the flow will fluctuate as much as 1.0 sec-ft., the morning flow being 1.5 sec-ft. and the evening flow, 0.5 sec. ft. This is not a measure of the total transpiration losses from the entire stream-bed growth because the time for the surface water in the stream to pass through this growth has a tendency to overlap the fluctuations. The writer has found that

\* Field Engr., San Bernardino; Engr., Coachella Val. County Water Dist., San Bernardino, Calif.

alders on the desert side of the San Bernardino Mountain have a consumptive use of 8 acre-ft. per acre per annum, which is probably greater than the losses from alders under the cooler climate as given by the author for the Arrowhead water-shed.

The writer fails to check the author's rainfall data, as shown on Fig. 8. The elevation of the gauging station on Devil Canyon is about 1 800 ft. above sea level. The crest of the Devil Canyon water-shed meanders for a distance of about  $4\frac{1}{2}$  miles at an average elevation of 5 000 ft. The air-line distance across the canyon between the 5 000-ft. contours on either side is about  $2\frac{1}{2}$  miles. The water-shed is a typical fan-shaped one with its narrowest part at the gauging station. In Table 8, the rainfall for Squirrel Inn, at the summit of the mountain, but easterly of Devil Canyon, is given as 73.58 in. for 1921-22 and 44.27 in. for 1922-23. The rainfall for Devore at about the same elevation as the gauging station, but westerly thereof, is given as 59.99 in. for 1921-22 and 30.76 in. for 1922-23. The author omits the Arrowhead Springs rainfall record. This station is east of the Devil Canyon gauging station and had a rainfall of 39.49 in. in 1921-22 and 19.58 in. in 1922-23. It is about the same elevation as the Devore rainfall station and the Devil Canyon gauging station. The average of the Arrowhead Springs and Devore records would give the approximate rainfall at the lowest and narrowest end of the Devil Canyon water-shed. This would make the 1921-22 and the 1922-23 rainfall at the Devil Canyon gauging station 61.66 in., and 34.72 in., respectively. If these are averaged with the Squirrel Inn record to obtain the average rainfall for the Devil Canyon water-shed, the result is 61.66 in. for 1921-22 and 34.72 in. for 1922-23. This is probably conservative as the width of the water-shed increases as it approaches the crest where the rainfall is greatest.

When these figures of average rainfall for the Devil Canyon water-shed are compared with the total run-off, the total consumptive use of the water-shed vegetation is seen to be 40 in. for the wet season of 1921-22 and 27 in. for the dry season following. There was probably some hold-over seepage water from 1921-22 which was available for plant life in 1922-23, so that the average consumptive use of 33 in. for the two seasons would be representative of what the vegetation could consume. The brush near the tops of the ridges will transpire less water than that farther down the slopes because the seepage water has a tendency to escape down hill where it becomes available for growth on the lower areas after the upper area is deficient in moisture. The brush on the northern exposures, being in the shade a longer period of time, will require less moisture than that on the hot southern exposures. It will be seen from this that the average consumptive use of the cover for the entire water-shed above the canyon bottoms is made up of brush having subnormal and abnormal transpiration losses. The maximum possible consumptive use of the brush will be more than 3.0 acre-ft.

The outwash slopes of Devil Canyon and Waterman Canyon are composed of sands, gravels, and boulders with a top soil supporting a heavy growth of chaparral, chamise predominating. This growth is neither as large nor as luxuriant as that on the northern exposures within the two water-sheds, as the southerly exposures of the outwash slopes offer maximum conditions for

transpiration losses. The writer was instrumental in having installed a set of overhead sprinklers on a test area at the mouth of Devil Canyon by means of which the moisture available for plant growth could be augmented by artificial rains. Experiments are now (1929) being conducted by the Department of Agriculture, under the direction of Henry F. Blaney, Assoc. M. Am. Soc. C. E., to determine the consumptive use of this brush.

The roots of the native chaparral extend to a depth of 18 ft. Water was applied to the test plot through the sprinklers during the night hours in the spring when the air was cool and there was no wind. The quantity falling on the plot was determined by means of rain gauges scattered over the area. An application of water at the rate of 1 in. per hour for 4 hours produced no run-off. The author has pointed out that, when comparing mountain growth chamisal with outwash slope chamisal, it must be remembered that in the mountain growths the root zone is limited by the depth to bed-rock, whereas in the outwash slopes the root zone is limited by the depth of rainfall penetration over an average of several years. The deep penetration of rainfall during a wet year will, no doubt, stimulate the root growth and encourage it to extend deeper, but the dry years with a lack of deep penetration will cause the deeper roots to become dormant. Any curtailment of chaparral growth on the porous outwash slopes will result in an additional quantity available for deep penetration to the underground water plane. After the deep-rooted native brush is removed and the area cultivated, but later abandoned, the native annuals soon overrun the area. These annuals have a depth of root zone of about 8 ft. which, when compared with the deep-rooted chaparral, should result in a lessened consumptive use by the weeds and a consequent greater supply to the underground water. In a region where at least 95% of the water supply is obtained from ground-water sources, this item becomes of great importance.

Fig. 14 shows the effect of fire on the chaparral cover in the mountain areas. Devil Canyon, with an area of 6.16 sq. miles above the gauging station, adjoins Waterman Canyon with an area of 4.55 sq. miles. These two canyons have identical exposures, and altitudes, are typically fan-shaped and probably have equal rainfall. One of the main traveled roads to the mountain resort area in the San Bernardino Mountains traverses the length of Waterman Canyon. There have been frequent fires in the Waterman Canyon area, while Devil Canyon is more isolated and, prior to 1924, had had no serious fires for at least thirty years. In 1911, the Waterman Canyon area was almost entirely burned over. The stream-bed growth, however, generally escapes these fires, either because of its position in the bottom of the canyon, or, because of a higher moisture content in the vegetation, or perhaps a combination of both. The cover in the Devil Canyon water-shed escaped burning by the fire of 1911.

Stream-flow observations were made on both canyons for a few years following the Waterman Canyon fire. A comparison between the stream flow of Devil Canyon and Waterman Canyon is shown in Fig. 14. The low flows in winter are omitted from the diagram to avoid confusion with summer flows which are important. It will be noticed that the flow from Waterman Canyon

exceeded that from Devil Canyon throughout the year. The wet season of 1913-14, three years after the fire, produced 515 acre-ft. per sq. mile more run-off than Devil Canyon, the total for Waterman Canyon being 1 322 acre-ft. per sq. mile and for Devil Canyon 807 acre-ft. per sq. mile.

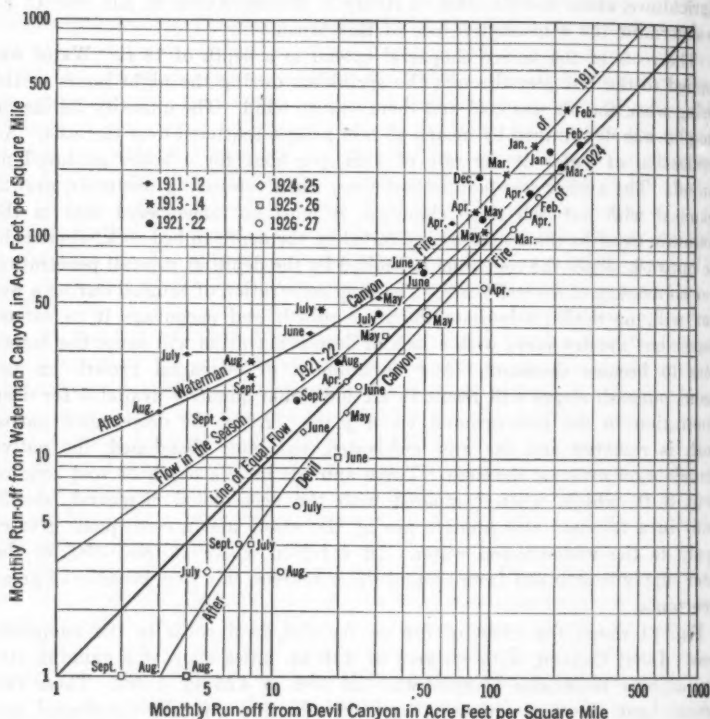

FIG. 14.—EFFECT OF FIRE ON CHAPARRAL COVER IN MOUNTAIN AREAS IN CALIFORNIA.

Inasmuch as the summer flow of Waterman Canyon was sufficient to supply the needs of canyon-bottom vegetation and yielded a surplus over the Devil Canyon flow, this excess of 515 acre-ft. per sq. mile, or 0.8 acre-ft. per acre, must be due to the decreased evapo-transpiration losses caused by the burning of the brush cover. The next season of heavy stream-flow record is 1921-22, which is also shown in the diagram. This curve approaches the line of equal run-off of both water-sheds, but is still on the Waterman Canyon side probably because of several small fires on that water-shed, which in the aggregate accounted for a considerable area of burned brush cover between 1911 and 1921.

In 1924 a fire burned over about one-half the Devil Canyon water-shed. A curve has been drawn from the stream-flow data since 1924. The Devil Canyon discharge has been corrected for diversions to the City of San Ber-

nardino. This last curve falls on the Devil Canyon side of the line of equal flow. The differences between the curves for Waterman Canyon and Devil Canyon in Figs. 6 and 10 are due to the burning of the brush on the Waterman Canyon area. In this region where water is so valuable it appears to the writer that brush fires, which are the greatest menace to the timberlands in the higher area, and which excite the professional conservationist to hysteria and furnish the local newspaper with scare-heads rivaling those of some major action in the World War, are far from being an economic waste. All that remains is to put the excess run-off into the ground. Nature, by experimenting with this problem for thousands of years, has provided the debris cones or outwash slopes below the mouths of the canyons for this purpose.

The consumptive use of the brush cover on the outwash slopes is the determining factor in deep penetration of rainfall on the valley floor. Given the rainfall on the valley floor, and the consumptive use of the cover, the difference will be deep penetration. The run-off from the brush-covered valley floor is negligible. The author, after determining the requirements of the brush cover for the Devil Canyon water-shed on Fig. 8, ignores this factor when considering the valley floor area and attempts to solve the problem by utilizing his knowledge of seepage and storm-water escape from the mountain area and by applying it to the valley floor area. Table 10 is a set-up of this comparison.

The author uses his Waterman Canyon curve to obtain rainfall-run-off relations. His Devil Canyon curve would have been better suited to conditions, as it retained its natural brush cover until the fire of 1924. Column (3) of Table 10 shows the seasonal rainfall to be expected from storms, as given in Column (2). If the author had applied his consumptive use curve as shown in Fig. 8 to this seasonal rainfall, he would have found that there would have been left for deep penetration and run-off on the valley floor an average of 3 in., instead of 16 in., for the three storms given for the San Bernardino Valley in Column (2) of Table (10).

The author does not distinguish between the effect of storms occurring in the winter months of December, January, and February, when native chaparral growth is practically dormant, and the effect of storms during the months of March, April, and May, when the chaparral is making its most active growth due to the ideal conditions of long warm days and high soil moisture content. If he had determined the relation between the consumptive use of the chaparral on the mountain areas and that of the valley chaparral this question would have been taken care of in the comparison. The greatest difficulty in the way of such a comparison would be the effect of hold-over seepage water in the mountain areas after a wet season.

When the Department of Agriculture has completed its study of the consumptive use of native plants on the San Bernardino Valley floor, it may be found that this is not such an important item as the writer believes. The author has offered the basis for a comparison between consumptive uses of mountain and valley-floor brush, which can be used in the future without

resorting to the elaborate continuous field investigations required by the Department of Agriculture. The writer is convinced that there is a very important contribution to the underground water supply in Southern California from deep penetration of rainfall on the valley floor, but he can not conceive of such a figure as 250 acre-ft. per sq. mile per year as an average for the brush-covered lands of the San Bernardino Valley. The writer believes that the greatest value of such a study was utilized when areas that were formerly brush-covered became cultivated with crops and orchards. As a result of this improvement the transpiration losses from the native growths that would draw on the rainfall were conserved and utilized for the growth of valuable crops and the creation of taxable wealth. Studies made by J. B. Lippincott, M. Am. Soc. C. E., in the Santa Ana Valley, and by Harold Conkling, M. Am. Soc. C. E., in the San Gabriel Valley, show that the substitution of cultivated crops for brush-covered areas has made very little inroad on the total water supply as it was conceived to be at the beginning of the Twentieth Century. The future benefits of any knowledge of rainfall penetration on the valley floor will be derived by increasing this quantity through removing the brush cover, or, substituting a shallower rooted growth. The brush on the mountain sides is absolutely essential and should not be destroyed, but there is the possibility of some systematic burning to remove the fire hazard and conserve excessive transpiration losses.

*Determination of Penetration from Soil Moisture Tests on North Mesa, Murrietta-Temecula Area.*—Table 4 shows the specific gravity, porosity, and probable yield of two soil samples at Test Plot No. 1, one from a depth of 2 ft., and the other from a depth of 4 ft. The increase in specific gravity, decrease in porosity, and decrease in probable yield for the sample from a depth of 4 ft. would indicate a marked change in soil structure. The author states that "the region is comparatively arid and the soil is an ancient, rather compact alluvium, a combination which would lead the casual observer to the conclusion that no deep penetration could occur." The writer made a casual observation of the region as shown on Fig. 4, and noticed a heavy hardpan underlying the top-soil wherever erosions had revealed the soil to a depth of 4 ft. The existence of hardpan is the best indication of the depth of rainfall penetration of which the writer has knowledge. The hog wallows and puddles mentioned by the author indicate that there is no free penetration of water, at least in the upper soil zone.

An examination of the data presented in Table 5 shows that the soil under Test Plot No. 1 is either very heterogeneous or that some artificial factors were introduced. Column (6) of Table 5 shows that the soil for all depths below the fifth foot was below field capacity on March 7, 1927. This fact would indicate that either the root zone of vegetation extends to a greater depth than 15 ft., or that the data given in Column (2) are not typical for the entire test plot. Any one comparing Columns (7) and (2) of Table 5, is led to believe that there was no deep penetration whatsoever, because the soil moisture at all depths to 15 ft. was less than the field capacity. The building of dikes or levees around the test plot would create a condition that would prevent the escape of moisture which otherwise might disappear as run-off.

The data presented by the fluctuations of wells given in Table 7 are far from conclusive evidence that the fluctuations were due to direct penetration of rainfall. The data for Well No. 129 shows that, despite the heavy rain in the season of 1926-27, the water level in July was lower than it was for the preceding year. There is no synchronism between the fluctuations of Well No. L8N and any of the others listed. The lack of frequency of measurements for Wells Nos. 131 and 14, which have the least depth to water, prevents any accurate study being made as to the effect of rainfall. These might be pressure fluctuations from distant sources, as both wells are near the obstruction which creates the springs and artesian wells mentioned by the author. If, as the author states, "there is corroborative testimony that the flow of the wells and springs varies little over a period of years, the inference being that the comparatively compact formation acts as a regulator of an otherwise erratic recharge," and there is no transmission of pressure, it is strange that Wells Nos. 131 and 14 should show a maximum rise of 1.21 ft. and 1.10 ft., respectively, when the maximum rises for Wells Nos. 129 and L8N were only 0.26 ft. and 0.29 ft., respectively. If these fluctuations were due to penetration of rainfall, then it must be assumed that two of the wells showed four times the penetration of the other two.

*Determination of Rainfall Penetration from Test Wells in Pauba Valley on Temecula River, Riverside County, California.*—The line of test wells used by the author in his determinations in the Pauba Valley extend from the mouth of an arroyo draining a part of the North Mesa to the Temecula River, as shown on Fig. 4. The author states that the storm of February, 1927, produced a rainfall of 14.65 in. in the Pauba Valley and, in Table 6, the same storm produced a rainfall of 9.14 in. at the test plot on the North Mesa. A rain of this intensity would certainly produce some run-off down the arroyo at the line of the test wells and add to the water supply. The author states that "in some instances the measurements indicated a rise due to run-off from adjoining mesa lands. On the other hand, there was a compensating run-off away from bottom-lands." The writer can not comprehend how run-off from the bottom-lands would compensate for water which would be absorbed in the valley from the run-off from the mesa lands. The Temecula River was undoubtedly in flood during the heavy rainfall period in February, 1927, and passing as it does, through the pervious valley fill of the Pauba Valley, would also contribute to the rise in the wells. The writer believes that the data presented by the author are far from conclusive as to the amount of contribution to the underground-water supply by deep penetration of rainfall on the valley floor.

This paper contains material some of which has been used in litigation proceedings.\* From this and other sources the writer is led to question some of the points mentioned in the paper that should be recorded.

Fig. 4 does not show correctly the drainage of Long Valley. Test Plot No. 1 is located about  $1\frac{1}{2}$  miles too far south; the location shown is in a group

\* *Rancho Santa Margarita vs. Vail, et al.*, Superior Court of San Diego (Calif.) County, Case No. 42850.

of rough, broken hills.\* The borings in the North Mesa Test Plot were made in duplicate and the samples averaged. Those portions of the samples not removed for office determinations were run back into the holes and tamped. The soil encountered in boring the holes ranged from a firm, semi-impervious soil to hardpan. The existence of the hardpan from 4 to 5 ft. below the surface shows the extreme depth to which rainfall has ever penetrated in this region. The tamping of the hardpan cuttings in refilling the test holes, a 2-min. operation, would leave a duct through which the ponded water in the test plot could percolate freely in comparison with the percolation through the undisturbed hardpan. The ponded area would prevent run-off escape. From Table 5 it appears that there were eight of these locally filled holes prior to the final determination on March 7, which would explain the presence of any excess moisture below 5 ft. under the test plot.

There is no general water-table underlying the mesas. The uncontradicted testimony in the case showed that suspended water-planes are found throughout the mesas, not by infiltration of rainfall on the surface, but by infiltration from water concentrating in gullies which cut the plain to contact with somewhat pervious lenses formed at intervals in the mesa silt.

The four wells submitted in Table 7 do not show true conditions. Near Well No. 129 is another one called Well No. 133, in which the water is usually from 65 to 75 ft. higher than in Well No. 129; near Well No. L8N is another called Well E7N, in which the water level is out of harmony with the one selected by the author and which shows a reverse slope from the river bed; near Well No. 131 is another one known as the "old Shrode Well", which has a water-plane from 40 to 50 ft. higher than Well No. 131, although down the valley where it should be lower, if in the same water-table; and near Well No. 14 are several wells and springs on the August Cantarini Ranch, which differ from it in water-plane elevation. All these facts, shown by sworn and uncontradicted testimony in Court, prove conclusively that there is no water-table under the North Mesa region and no penetration of rainfall to a water-table, but that suspended water-planes are found locally in some semi-porous lenses in the mesa silt where such lenses are cut into and fed by run-off water gathered in gullies.

Well No. L8N shows a drop by March 16, which is positive evidence that the slight rise of February 23 was caused by rain water running down outside the 2-in. pipe in this well. The well had been drilled by a rotary rig to a diameter of 5 in. in January, 1927, without casing, and a 2-in. standard lap-welded pipe inserted, the space between the outside of the 2-in. pipe and the inside of the 5-in. drill hole having been filled with loose soil. Of course, a little water would penetrate this loose fill from the heavy rains just before February 23, which would disappear before March 16. Well No. 131 had a depression in the ground around the casing which was 0.8 ft. above the bottom of this depression. There was much drainage from run-off into this depression. This caused the water to run into the well over the top of the pipe, whenever it became more than 0.8 ft. deep around the well, which did

\* Fig. 4 has been corrected, as shown in the paper, since Mr. Rowe's discussion was published.

occur during the February, 1927, heavy rainfall. Further than this, the driller had tried out his perforating tool and had cut a number of slits in the casing just below the surface of the depression around the well, through which water was seen to enter during the February, 1927, rains.

The author assumes that the flow of the springs and wells is entirely derived from deep penetration of rainfall on the mesas. He ignores entirely the fact that there is a drainage area of more than 100 sq. miles of low granite mountains, foot-hills, and plains within the drainages of Santa Gertrudes Creek, Cantarini Wash, and Shrode Wash, which all converge at the natural dam formed by the Elsinore Active Fault. In each of these drainages are sand and gravel fans deposited as modern alluvium within erosions into the Pleistocene "mesa silt" extending back from the fault line. The floods from this large back-country drainage flow over these porous fans and are absorbed in part, after which they percolate toward the Elsinore Active Fault which forces at least a part of the water up to the surface as springs.

The situation in Pauba Valley is a familiar one to those acquainted with artesian basins of the interior California valleys. There is a deeply eroded trough in the mesa silt, which is refilled to a depth of more than 500 ft. with modern alluvium. This lies between the "North Mesa" and the "South Mesa", as shown in Fig. 4. Its lower end is closed by the Elsinore uplifted fault block and into its upper end debouches the Temecula River, draining a high, mountainous area of 326 sq. miles. This stream first eroded the mesa silt and then refilled the space with porous recent alluvium. It left a coarse fan or delta at the upper end and finer deposits farther down the Pauba Valley. The flood waters of the river spread over and are absorbed in part in the fan which is called the outwash area, and rise through artesian pressure in the lower valley, which is called the artesian area. When it rains on the mountain water-shed and the resulting flow sinks and refills the outwash area, hydraulic pressure, transmitted through the saturated inclined valley fill, causes the wells in the artesian area to rise. It was this rise which the author mistook for direct penetration of rainfall.

The author cites the record of only three test holes in the Pauba Valley. There were others introduced in evidence, which, after floods in the Temecula River, showed a greater rise than would have been accounted for, if the entire quantity of rain had penetrated to the water-table.

IVAN E. HOUK,\* M. Am. Soc. C. E. (by letter).—The results of the author's hydrologic studies are both interesting and valuable, especially in view of the fact that studies of deep rainfall penetration, or percolation, as it is more often termed, have seldom been made for irrigated sections of the country. His conclusion that "the water supply resulting from deep penetration of rainfall on the valley floors is of great economic importance", is true in the more humid States as well as in the semi-arid West.

In a general consideration of the disposal of rainfall it may be permissible to include deep penetration in lieu of seepage run-off and changes in ground storage. Deep penetration would equal seepage run-off in cases where the ground-water surface has the same elevation, and the moisture stored in the

\* Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

surface soil is the same, at the beginning and end of the time interval under consideration, assuming no water to pass beyond the limits of the basin by underground flow. In many drainage areas throughout the country, including gently rolling and comparatively level topography as well as mountainous regions, ground-water, or seepage run-off, may be appreciably different from deep penetration as far as yearly, or shorter, periods of time are considered. The author shows the importance of seepage flow in mountain drainage areas in his treatment of rainfall and run-off in the Devil Canyon Basin. Because of the importance of ground-water run-off it seems better, as a general rule, to consider the disposal of rainfall, as follows: (1) Flood, or storm-water, run-off; (2) ground-water, or seepage, run-off; (3) evaporation, including interception and transpiration losses, as well as evaporation from soil, water, snow, and ice surfaces; and (4) additions to ground storage, the last being positive or negative depending on whether the quantity of water in the ground has increased or decreased during the time interval considered.

A discussion of the general conditions that affect deep penetration might well include some reference to the capillary moisture in the surface soil. Obviously, if this has been greatly depleted by evaporation and transpiration processes at the time the rain begins, a large storage reservoir will exist in the root zone of the soil, and this reservoir will absorb large quantities of water before much deep penetration takes place, even though fairly uniform wetting of the soil may not occur to the full depth of the root zone. The importance of this factor is clearly shown by the author's discussion of the soil-moisture tests made on North Mesa, in the Murrietta-Temecula Area. Furthermore, a consideration of capillary movements of soil moisture may be of some value in forming conclusions regarding the depth of uniform wetting of the soil. The author undoubtedly is correct in his conclusions† that "absorption is favored by the wedging action of roots," and that percolation tends to take place along well-defined ducts. However, it is quite likely that a fairly uniform wetting of the soil, to appreciable depths, if not to the full depth of the root zone, often takes place during the rainy season of the year, due to both capillary and gravity movements of soil moisture; and that in such cases the percolation of moisture through the minute passageways between soil particles is an important factor in conducting water to the well-defined ducts. Capillary movement of soil moisture may take place in any direction, horizontally, vertically upward, or inclined in either upward or downward directions, as well as vertically downward. Consequently, the vertical trickling streams at the ends of the suspended water-table, shown in Fig. 1, will occur only when the geologic formations below the horizontal clay layers are relatively open, as, for instance, in the case of coarse sand or gravel deposits. In the case of tighter formations the water at the ends of the clay layers will move horizontally and diagonally beneath the clay by both capillary and gravity action. However, in any case, there will undoubtedly be some deficiency of moisture immediately below the clay.

In studying percolation of rainfall it is important to know how fast water can enter different soil formations; and how the rates of absorption vary for a given soil, using the term, absorption, to include all water that enters the

ground, percolation water as well as the capillary moisture taken up in the unfilled pore spaces of the soil. A clay formation, after it becomes wet enough to close the surface cracks by swelling of the material, will absorb water at a relatively low rate, if at all.\* On the other hand a deep open gravel, or a sod surface underlaid at a comparatively shallow depth by open sand or gravel, will absorb rainfall at a relatively high rate. Experiments on a small plat in the Miami Valley of Southwestern Ohio showed that blue-grass sod, on level ground, underlaid by sand and gravel deposits at a depth of about 2 ft., would absorb water continuously at a rate of 13.0 in. per hour.† Soil deposits having rates of absorption of practically all values between these limits probably exist in various parts of the country. The maximum rate of absorption for a given soil may be somewhat lower in winter than in summer, due to the lower soil temperatures, the friction coefficients being higher for the lower temperatures. This effect is probably more pronounced in the case of relatively tight formations, than in coarse sand or open gravel deposits. However, in the colder regions, the maximum rate of absorption during the winter months is probably increased by the loosening of the surface soil, due to alternate freezing and thawing, much more than it is decreased due to the higher friction.

The experimental rainfall and run-off investigations in the Miami Valley showed that the maximum rate of absorption for soils in that vicinity, under ordinary conditions of compactness, becomes practically constant within a relatively short time after the beginning of the storm; that is, as soon as the surface storage becomes filled.‡ The surface storage includes storage space in the upper few inches of the soil; storage space formed by slight depressions in ground-surface level; and storage space on the ground surface formed by forest litter, accumulations of leaves, blades of grass, weed stems, and other forms of vegetation, both dead and alive. During the late summer and fall months, when the ground was comparatively dry, and the cultivated surface soils compacted by earlier rainfalls, from 3 to 4 in. of rain in 1 or 2 days were required to fill the surface storage. Flood run-off usually occurred sometime before the rate of soil absorption became constant, the length of time from the beginning of the storm until flood run-off began naturally being greater for the less intense rates of precipitation. Except in the case of the sod plats, underlaid at shallow depths by open sand and gravel, a rate of rainfall of 1 in. per hour caused flood run-off to begin in about 30 min., even on the driest of soils; whereas a rate of rainfall of 3.00 in. per hour invariably produced flood run-off in less than 5 min. Rates of flood run-off were directly proportional to the rates of rainfall in all cases, regardless of the quantity of moisture in the soil. However, the actual value of the relation varied with the moisture content. In other words, the relation between the rate of rainfall and the rate of run-off could be represented by a straight line equation in all cases, but the actual value of the equation varied with the moisture content. For saturated soil conditions the average rate of absorption was approximately

‡ *Loc. cit.*, p. 124.

0.30 in. per hour. For soils loosened by spading, corresponding to freshly plowed fields, the rate of absorption was found to increase somewhat as the rate of rainfall increased, the relation being represented by the equation:

$$p = 0.37 r + 0.16 \dots \dots \dots (1)$$

in which,  $r$  and  $p$  are the rates of rainfall and absorption, respectively, both in inches per hour. Apparently, the loosening of the surface soil permitted the building up of a static head which increased with the rate of rainfall. A similar effect, but not so great, was found in the experiments on a hillside where the slope of the ground was about 18 ft. per 100 ft. Incidentally, one of the principal conclusions reached as a result of the investigations was that variations in surface slope are of much less importance as affecting flood run-off than variations in vegetable cover, or in the condition of the surface soil. In the experiment on spaded soil, water was applied at a rate of 3.73 in. per hour for 22 min. before any run-off took place.

The Miami Valley experiments herein discussed were made primarily for the purpose of studying flood run-off during intense storms. Rainfall was produced artificially, by sprinkling with ordinary garden sprinkling cans, and the total depths applied during the different experiments varied from 6.00 to 17.83 in. Each experiment was made up of several separate runs and the average rates of application during the different runs varied from about 0.2 in. to about 4.0 in. per hour. Soil formations at the locations of the plates were compact yellow clay tills, alluvial deposits underlaid by glacial tills, and yellow sandy loam underlaid by open sand and gravel. Complete descriptions of plats, as well as of methods of experimentation, results, etc., are included in the reference cited.

The all-important factor as regards percolation of rainfall on a given drainage area is undoubtedly storm rainfall. However, this factor is made up of two parts: First, the rate of rainfall during the storm; and, second, the duration of the storm. For instance, a storm with a total rainfall of 6 in. in 2 days will cause much more percolation if the rain is distributed uniformly through the 48 hours than if the greater part of the total falls in a relatively short time, say, 4 or 6 hours. When the rate of rainfall exceeds the rate of absorption an increase in the rate of rainfall means a higher rate of storm run-off and a lower total depth of absorption for the same total rainfall. Of course, an increase in the duration of the storm period, with the same rate of rainfall, means an increase in the total depth of absorption regardless of whether or not the rate of rainfall exceeds the rate of absorption. If the storm occurs after the surface storage has been filled the rate of absorption may be practically constant, and, in that case, the increase in total depth of absorption is directly proportional to the increase in storm duration.

The rate of absorption as herein discussed may, or may not, be wholly a rate of percolation. In the case of deep, open, sand and gravel deposits the water entering the ground would be practically all percolation, from the beginning of the rain to the end of the storm period. Consequently, the rate of absorption would be the rate of percolation throughout the storm. However, in most soil formations, the rate of absorption at the beginning of the storm would

be definitely greater than the rate at which deep percolation would be taking place, the exact amount of the excess depending on the dryness of the surface soil. In the case of a comparatively shallow surface soil, underlaid by open sand or gravel deposits, subjected to an intense storm at the end of an extended dry period, the rate of absorption would include very little deep percolation at the beginning of the rain, but would include more and more percolation as the storm continued, approaching the maximum rate as a limit by the time the surface storage became filled, or within a comparatively short time thereafter. However, in the case of a drainage area with relatively deep soil deposits, it may, as the author states, "require a very wet year to recharge a deeply depleted soil." In such cases the rates of absorption would include but small proportions of percolation during the entire year.

The author's treatment of seepage and storm run-off in the Devil Canyon drainage area is pertinent and logical. However, the results, as shown on Fig. 8, are rather surprising inasmuch as the seepage run-off is such a large proportion of the total. The reason for the comparatively small storm run-off must be the dense surface cover of brush and trees. Similar storm rainfall on more open mountain water-sheds with similar surface slopes and similar geological formation, would probably cause much greater proportions of storm run-off. In fact, the writer is inclined to believe that the retarding effect of the dense vegetal cover is much more important than the accelerating effect of the comparatively steep ground slopes; and that, consequently, cultivated valley floors in that vicinity, subjected to the same storm rainfall, would have greater proportions of storm run-off, regardless of whether or not the underlying soil formations were clay. In this connection it may be valuable to refer again to the rainfall and run-off investigations in the Miami Valley of Southwestern Ohio, where similar studies of seepage and storm run-off were made.\*

TABLE 17.—COMPARISON OF AVERAGE ANNUAL STORM AND SEEPAGE RUN-OFF, IN MIAMI VALLEY FOR YEARS 1915 TO 1919, INCLUSIVE.

Drainage area.	Area, in square miles.	Average rainfall, in inches.	Total run-off, in inches.	STORM RUN-OFF.		SEEPAGE RUN-OFF.	
				Inches.	Per-centage of total.	Inches.	Per-centage of total.
Miami River.....	2 525	37.8	12.67	8.57	67.6	4.10	32.3
Buck Creek.....	163	38.6	10.89	4.83	44.3	6.06	55.7
Mad River.....	652	39.5	13.78	7.34	53.3	6.44	46.7
Stillwater River..	600	37.5	13.58	10.70	78.8	2.88	21.2

Table 17 gives a comparison of the average annual storm and seepage run-off for four Miami Valley drainage areas, for 1915 to 1919, inclusive. For those areas the average annual storm run-off is seen to vary from 44.3 to 78.8% of the total run-off, and the average annual seepage run-off, from 21.2 to 55.7% of the total run-off. The drainage areas are more than 90% agricultural land and may be classed as gently rolling topography with elevations

\* Miami Conservancy Dist. Technical Repts., Pt. VIII, 1921, p. 164.

varying from about 1100 ft. above mean sea level near the head-waters to about 700 ft. above mean sea level at the bottom of the river in Dayton. The reason for the lower proportions of storm run-off in the Buck Creek and Mad River drainage areas is that the surface soil in those water-sheds is relatively shallow and is underlaid by open sand and gravel deposits, thus permitting comparatively rapid rates of percolation. In the Pomperaug Basin, in Connecticut, the annual ground-water run-off, for a 3-year period, was found to be 8.76 in., or 42% of the total run-off, the remaining 58% being storm run-off.\* The Pomperaug Basin is a rural agricultural area of about 89 sq. miles, made up of rather rugged uplands and extensive valley areas, the elevations varying from a minimum of 100 ft. to a maximum of 1150 ft. above sea level. Surface soil deposits consist primarily of glacial drift, although some of the steeper slopes are practically bare bed-rock.

The author has secured some very interesting and valuable results in his exhaustive study of water supply from rainfall on valley floors. However, it is doubtful whether conclusions based thereon can be safely applied to other drainage areas, even in the immediate vicinity, without careful independent checking. This applies to conclusions regarding storm rainfall and flood run-off phenomena as well as to seepage run-off, percolation, and the resulting water supply. The geological, topographical, and meteorological conditions which affect rainfall, run-off, and percolation on different drainage areas are so many, so varied, and so variable that no intensive study of a single drainage area, or even of a group of drainage areas in the same locality, valuable as it may be in solving local problems, can furnish a satisfactory basis for general conclusions, or for the establishment of general laws universally applicable in studies of such phenomena.

CHARLES H. LEE,† M. Am. Soc. C. E. (by letter).—The author's treatment of deep penetration of rainfall is developed primarily for determination of the increment to water supply in the alluvial valleys of Southern California. The subject is one of considerable interest, however, in all semi-arid districts where growth of population has created a pressing demand for water. It may also be important in desert valleys, because the latter are usually surrounded by mountain ranges receiving more generous precipitation, a portion of which falls upon the marginal slopes of the valley. Although deep penetration from rainfall has been recognized as a source of sub-surface water, no definite methods have been generally adopted for quantitative determination on a large scale. The demand for such methods now exists, and this paper represents an initial step in filling this need.

At the outset, in the consideration of the paper, it should be recognized that the character of alluvial deposits as generally found in valleys does not conform with the author's description and illustration on Fig. 1. It is true that in many of the alluvial valleys of Southern California there are deposits which "are essentially heterogeneous in formation". These are the products of deposition from steep graded streams and result from reduced

\* "A Study of Ground Water in the Pomperaug Basin, Connecticut, with Special Reference to Intake and Discharge," by Oscar Edward Meinzer and Norah Dowell Stearns, U. S. Geological Survey, *Water Supply Paper 597-B*, p. 115.

† Cons. Hydr. Engr., San Francisco, Calif.

velocity due to flattening of slope. For these deposits the author's concept may be correct.

There are many other alluvial filled valleys and parts of valleys, however, throughout California and, in fact, generally throughout the world, in which homogeneity in formation is the ruling characteristic. Such valleys at one time or another in their history have experienced temporary flooding, or have been occupied by large lakes or arms of the sea which have had wide fluctuation in level. In these valleys, stream deposition has resulted either from the sudden checking of velocity at the edge of standing water, or from flattening of grade at the margin of an unwatered lake bed. These conditions have resulted in segregation of alluvial material into extensive sheets or beds of distinctive character. The beds consist of fine sands, silts, and clays, deposited from still water upon the lake bottom, and coarse sands and gravel derived from rehandled and segregated shore deposits which have been spread over the lake bottom by flowing water at periods of low lake stage. The occurrence of homogeneous valley formations is so general that the discussion of the paper would be incomplete if mention were not made of them.

Another concept presented by the author, which is stated without qualification, is that because of the heterogeneity of alluvial deposits the movement of absorbed water from the ground surface to the water-table is by way of "more or less defined ducts", and that it is "likely to collect into trickling streams".

Although the condition described by the author may be characteristic of the steep boulder and gravel slopes surrounding certain Southern California valleys, yet it is not a general condition. Most valleys have a soil cover which is of homogeneous texture and is underlaid by a subsoil of similar texture. In such formations the downward movement of water is generally through capillary interstices, and is more or less uniformly distributed. It frequently occurs that roots will open up a soil and, when rotted, will leave tubes which assist in the more rapid downward penetration of water; but this is merely an aid to penetration, and in no case does it extend to great depth.

The mechanics of rainfall penetration are so important to an understanding of the problems considered by the author, that the writer believes a short description would not be amiss. If rain falls upon soil, with moisture content at or exceeding field capacity, there will be an immediate gravity movement of water by way of fat capillary films to the water-table, and an observable rise of the latter. If, however, the soil has been depleted of moisture below the field capacity, penetration to the water-table does not occur unless and until complete connection has been established by capillary films extending from the surface to the water-table.

As the advance of moisture by capillarity alone is extremely slow, it frequently happens, in regions where the annual depth of rainfall is small as compared to the annual depth of water evaporation, and in areas where the depth to the water-table exceeds the capillary range, that little or no water will reach the water-table during a whole season. The reason for this is that the

losses by run-off interception, soil evaporation, and transpiration are so great that most or all water falling as rain is consumed either before or after penetrating the soil.

This point is well illustrated by observations made by the writer at twenty-four wells in the river valleys of San Diego County, California, before and after the first heavy storm of the season, 1914-15, beginning January 27, 1915.\* The formation in these valleys is of uniform textured beds of fine to coarse sand, the top stratum containing more or less silt. The soil and sand above the capillary fringe was very deficient in capillary moisture at the end of nine months' rainless period. It was found that at all wells in which the depth to the water-table, just prior to the storm, was less than the distance to which capillary water would rise (approximately 7 ft.), the effect of the storm on the water-table was pronounced and reached its maximum within from 2 to 7 days. For wells in which the depth exceeded 7 ft., no pronounced fluctuation was observed although after a short time had elapsed a gradual rise was noted culminating in from 20 to 60 days. The range of depth to water-table in the latter wells was from 7.4 to 19.4 ft. A very sharp difference was evident, and there was no difficulty in grouping the wells.

Comprehensive observations have been made by Walter E. Spear, M. Am. Soc. C. E., of the deep penetration from rainfall in rehandled glacial deposits of Long Island, New York, where the soil and subsoil are maintained more or less at field capacity throughout the year by frequent storms.† More than fifty wells were studied, with widely differing depths to water-table, which ranged from 1 ft. to 95 ft. The material through which moisture percolated consisted of 12 to 18 in. of brown loam, 18 to 24 in. of yellow subsoil, and glacial outwash made up of coarse to fine sand occasionally mixed with coarse and fine gravel, and very fine sand. For depths to water-table of 7 ft. accretions from rainfall were registered at from 1 day to 4 days, which correspond closely with the writer's results in San Diego County. For a depth of 20 ft., the time interval was from 4 to 14 days. In comparison with the latter, the time required in San Diego County wells with deficient capillary moisture was from 20 to 60 days. The effectiveness of soil moisture content at field capacity in facilitating deep rainfall penetration is thus clearly apparent.

The importance of regular sequence and magnitude of storms in producing deep penetration in regions with distinctive wet and dry periods, which has been so well brought out by the author in his discussion of general conditions, is further emphasized by the data contained in Mr. Spear's report. Depletion of soil moisture always occurs during long periods without rain, unless a permanent water-table lies within capillary distance of the surface. In an area where the water-table lies more than from 7 to 10 ft. below the surface, a certain volume of water is required to satisfy capillary demands before penetration to the water-table will occur. This volume, and the time required, increases with the depth to the water-table. In order that penetration to the

\* *Water Supply Paper 446*, U. S. Geological Survey, 1919, by A. J. Ellis and Charles H. Lee, p. 140, Table 35.

† Report of Commission on Additional Water Supply for the City of New York, 1903, Appendix VII, by Walter E. Spear, Plate VI and Table 25, pp. 798 to 805.

water-table shall occur, the rainy season must be long enough, and the storms sufficiently frequent and large to bring the moisture-depleted soil and subsoil up to field capacity from the surface to the water-table prior to the end of the season. The extent to which moisture reaches the water-table through "well-defined ducts" or "trickling streams" is under ordinary conditions extremely problematical, and the writer believes cannot be depended upon to speed up the process except in rare cases, such as that which the author seems to have encountered.

*Determination of Rainfall Penetration from Soil Moisture Tests and from Springs in the Murrietta-Temecula Area.*—The author assumes, for the purpose of reaching quantitative conclusions, that deep rainfall penetration from a certain mesa area underlaid by compact stratified alluvium is the only source of supply for a group of springs and flowing artesian wells. The latter are located at the base of a steep slope terminating the mesa. To prove that deep penetration occurs, he presents soil moisture records at test plots which are enclosed by embankments to prevent surface run-off. These records indicate that of 14.82 in. depth of rainfall and water applied to the plots between February 4 and March 7, 1927, 3.31 in. were unaccounted for within the first 9 ft. depth of soil, if evaporation loss from surface soil is assumed at 2.00 in. (see Table 5). The author concludes that this water penetrated deeply and reached a water-table approximately 200 ft. below the surface of the mesa. As proof, he presents water-level observations in four wells, three of which show a slight rise in the late spring of 1927 (see Table 7). He presents no proof, however, that there is a general water-table under the mesa, or that the springs and artesian wells have any relation to a general water-table.

The writer believes that in a few special cases this method may be useful in obtaining quantitative data of deep percolation, but that it must be used with caution. In the example presented by the author, there are several points on which the facts submitted are incomplete or not in conformity with the conclusions. For instance, assuming that percolation to a depth greater than 9 ft., occurs from a few isolated depressions on the surface of the mesa, does it occur generally over the whole area, and is all water penetrating below 9 ft. beyond the reach of capillarity and plant roots? The well observations presented in Table 7 are not conclusive on this point. Well 129, near the test plots, does not show any rise. Well L8N, farther down the slope, shows 0.25 ft. rise in 27 days; and Wells 131 and 14, still farther down the slope, show rises of 1.30 ft. in less than 90 days and 1.10 ft. in 47 days, respectively. Thus, the greatest rise occurred at the lower edge of the slope of the assumed water-table, and a profile would show a flattening of the slope during the period when the author assumes that it is being replenished by deep percolation. Such flattening is, of course, an indication of depletion rather than of replenishment.

Considering another angle, is it an entirely reasonable assumption that water would move downward in less than 90 days through 200 ft. of moisture-depleted material composed of compact stratified alluvium containing extensive clay beds? In the test made by Mr. Spear on Long Island where con-

ditions are most favorable for quick penetration, it required from 89 to 109 days for moisture to reach a depth of 80 ft. Is it not a more probable assumption that, if penetration occurred beyond the depth of capillary return, the water would move laterally as soon as it reached an impervious clay bed, and escape into some ravine or follow an old buried stream channel to the margin of the alluvium? The observed rise of water level in wells might possibly have been a rise due to pressure increase and not a water-table rise.

The author does not present the data upon which he determines the area from which the flow of the springs and wells is derived. Due to the varied structure of the alluvial formation, this would be subject to considerable uncertainty unless fairly complete geological and hydraulic facts were available. It is quite possible, for example, that the springs and wells represent the discharge from the open end of an old buried stream channel interbedded between clay strata instead of from a general water-table. If this is the case, the tributary area is impossible of determination from an examination of surface topography alone. The fact that there is not an extensive spring or seepage horizon along the base of the slope adjacent to the springs would support such an assumption.

The uncertainties, previously mentioned, indicate some of the difficulties involved in the practical application of this method, and they point to the fact that the author's quantitative result, while suggestive, is not the final answer.

*Determination of Rainfall Penetration by Comparison with Mountain Run-Off.*—The method of determining rainfall penetration by comparison with mountain run-off is based on two assumptions: First, that for mountain water-sheds underlain by impervious bed-rock which extends to the point of stream measurement, surface run-off throughout the annual cycle will correspond to the sum of surface run-off and deep percolation in adjacent valley water-sheds; and, second, that rainfall-run-off relations for adjacent mountain and valley water-sheds are so similar that necessary modifications due to differences in soil cover, etc., can readily be made.

The writer believes that this method has possibilities for general use, but that its successful application will depend upon quantitative evaluation of the various factors which govern the rainfall-run-off relation, rather than dependence on geographic proximity of water-sheds.

The factors upon which the rainfall-run-off relation depend, can be grouped as meteorological and physical. Among the important meteorological factors are: (1) Precipitation; (2) temperature; (3) evaporation from water and snow surfaces; and (4) length of the growing season.

The physical features of water-sheds, which are of importance, are: (1) Elevation; (2) topographic catchment area; (3) topography; (4) soil and sub-soil; (5) geology; (6) vegetation; and (7) cyclic storage capacity.

The precipitation falling upon a water-shed is disposed of either by: (1) Storm or seepage run-off, the latter being represented by deep percolation in valley water-sheds; (2) evaporation from water intercepted by foliage and branches of vegetation; (3) evaporation from snow or from soil moistened by

direct precipitation, melting snow, or capillary water held in the soil; (4) transpiration from growing vegetation; or (5) sub-surface leakage. Run-off curves, when prepared quantitatively in terms of depth of precipitation and run-off, as in Fig. 8, segregate these various items into two groups, as follows:

For Mountain Water-Sheds:

- 1.—Storm and seepage run-off.
- 2.—Evaporation, transpiration, sub-surface leakage (usually negligible).

For Valley Water-Sheds:

- 1.—Storm run-off.
- 2.—Evaporation, transpiration, seepage run-off, or sub-surface leakage.

If the valley occupies a closed basin, and storm run-off is measured at the outlet, sub-surface leakage will be small or negligible, represented by the underflow of the stream. For open valleys, sub-surface leakage may be large, although it does represent a definite quantity of water that can be salvaged by pumping from wells and, therefore, may be considered as potential water supply.

The quantitative rainfall run-off curve, for any water-shed, presents graphically the integrated effect of the four meteorological and seven physical factors listed previously. From this curve can be measured, for any depth of annual precipitation, the corresponding depth of evapo-transpiration loss plus sub-surface leakage; minor corrections are sometimes necessary for cyclic storage. For mountain and closed valley water-sheds this quantity represents the evapo-transpiration loss alone. Its value has one of two absolute upper limits, either the annual depth of evaporation from a large free water surface (if that is less than the annual depth of precipitation), or the annual depth of precipitation, if the latter is less than the evaporation. Actually, the evapo-transpiration loss is less than either of these quantities, being limited by the evaporation opportunity.

In order to give perspective in analyzing the weight to be assigned various factors which influence the evapo-transpiration value for mountain water-sheds, the writer has found it useful to study water-sheds with widely differing meteorological and physical characteristics. As an illustration, the rainfall run-off curves of five mountain water-sheds are presented on Fig. 15. A statement of the corresponding water-shed characteristics is given in Table 18, and the trunk stream profiles are shown on Fig. 16.

The values for Item 15 of Table 18 were determined graphically from Fig. 15, by making necessary corrections to allow for the actual slope area. The temperatures given in Table 18 (see Items 8, 9, and 10) are based on U. S. Weather Bureau records obtained at stations representative of the water-shed area. Item 16 for the different water-sheds was determined in various ways, as follows:

(a) For Coquille River an estimate was made from an incomplete 4-year record obtained by the U. S. Weather Bureau at Corvallis, Ore.

(b) The Rogue River evaporation was estimated from a 4-year floating-pan record at Klamath Falls, Ore.\* (Elevation 4100), and from an incomplete 4-year record at Fish Lake, Oregon† (Elevation 4687).

(c) The average annual precipitation for Devil's Canyon Creek was estimated as approximately 55 in.

(d) The corresponding value for the San Luis Rey River is the average of a 3-year floating-pan record at Big Lake, near Warner's Hot Springs, Calif.‡ (Elevation 2780).

(e) For the San Diego River, an average was taken from the 3-year floating-pan records at La Mesa Reservoir (Elevation 480) and Cuyamaca Reservoir§ (Elevation 4620).

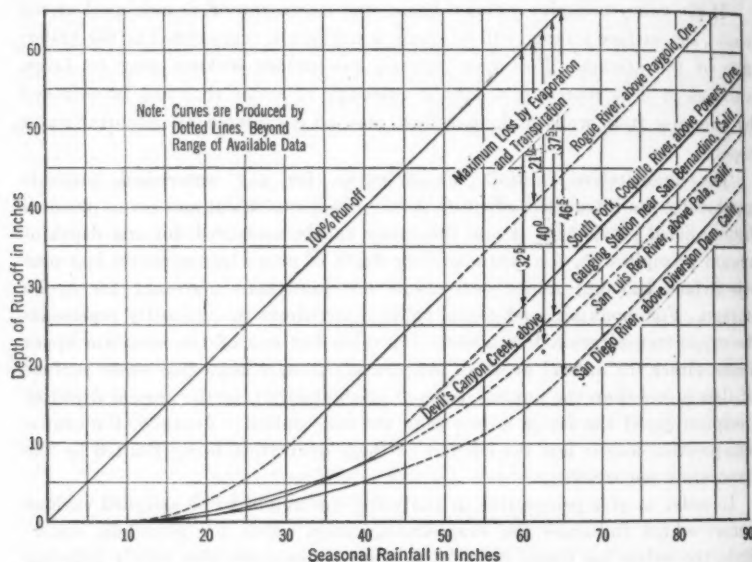

FIG. 15.—COMPARISON OF RAINFALL-RUN-OFF CURVES FOR STREAMS IN SOUTHERN OREGON AND IN SOUTHERN CALIFORNIA.

For the South Fork of Coquille River and for Rogue River in Southwestern Oregon, precipitation equals or exceeds evaporation; while for San Luis Rey and San Diego Rivers, and also for Devil's Canyon Creek in Southern California, the reverse is true. Precipitation occurs largely as snow on the Rogue River, while snow falls only upon the higher parts of the other water-sheds. The bed-rock formations also differ. Sedimentary rock underlies the Coquille, while the Rogue is largely covered by deep lava flows resting upon crystalline rock. The Southern California water-sheds are of granitic formation. Wide

\* *Transactions, Am. Soc. C. E.*, Vol. 90 (1927), p. 273.

† U. S. Weather Bureau, *Climatological Data, Oregon Section, Years 1923 to 1928*.

‡ *Transactions, Am. Soc. C. E.*, Vol. LXXX (1916), p. 1909.

§ *Water Supply Paper 446*, U. S. Geological Survey, p. 102.

differences in vegetational cover also exist. The Coquille supports a very dense forest growth, largely Port Orford cedar and Douglas fir, with alder and luxuriant shrubbery and undergrowth filling open spaces; the Rogue has open forest cover of pine and fir; and the Southern California streams have dense brush cover with alder, sycamore, and willows along stream bottoms.

Precipitation data for the preparation of all rainfall run-off curves have been obtained by planimeter measurement from detailed isohyets maps of average seasonal precipitation corrected in each year by the index of seasonal wetness as derived from five or more base precipitation stations. Most of the latter have twenty-five years or more of record. Run-off data are available for periods of 10 to 25 years on the various streams. All precipitation, run-off, and drainage-area data are from the records of the U. S. Weather Bureau and U. S. Geological Survey. The curve for Devil's Canyon Creek as thus drawn (Fig. 15), differs from that of the author (Fig. 8). The principal reason is that the writer used a greater depth of average seasonal precipitation which seems to be supported by all available records.

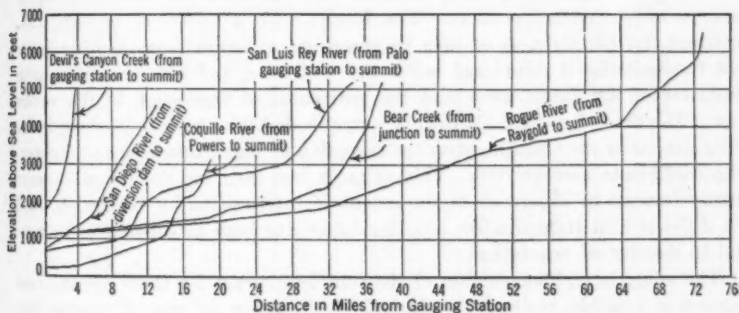

FIG. 16.—PROFILES OF DRAINAGE AREAS FOR STREAMS IN SOUTHERN OREGON AND SOUTHERN CALIFORNIA.

A striking feature of the curves for the two Oregon streams is their parallelism with the 100% run-off line within the full range of observed data, including both very wet and very dry years. (Compare the solid lines; the curves are produced by dotted lines beyond the range of available data.) This is due to the fact that even the minimum seasonal precipitation exceeds the maximum evapo-transpiration demand. For Devil's Canyon watershed the upper end of the curve is just coming parallel to the 100% run-off line at the 60-in. rainfall, indicating that the precipitation of wettest seasons is just sufficient to meet maximum demands of evaporation and transpiration. For San Luis Rey and San Diego Rivers, maximum seasonal precipitation is far too small to satisfy the demand, and the upper ends of the curves (at 45 in. of rainfall) have angles of departure with the 100% line. The condition necessary for maximum evapo-transpiration loss to occur from these water-sheds is greater annual precipitation and a regular succession of storms during the wet season at intervals just necessary to keep the soil at field capacity. On Fig. 15, the five rainfall-run-off curves have been assembled,

and with the assumption of maximum conditions, the San Luis Rey and San Diego curves have been extended in conformity with the trends of the upper ends of the supported portion of the curves and with a general shape similar to the Devil's Canyon curve. The maximum annual evapo-transpiration loss for each of the five streams as scaled from Fig. 15, together with the annual evaporation from a large free water surface and computed evaporation opportunity ratio, are listed as Items Nos. 15, 16, and 17, respectively, in Table 18.

"Evaporation opportunity" is a very useful coefficient because it represents quantitatively the ratio of maximum evapo-transpiration loss for a given combination of meteorological and physical conditions to the evaporation from a large free water surface for the same meteorological conditions. Analyzing the values in Items Nos. 15, 16, and 17 of Table 18, the Coquille, with a coefficient of 0.90, shows the combined effects of maximum interception of rainfall by dense vegetation, the maximum holding of moisture within the root zone by vegetation mat and humus soil, and unrestrained transpiration from a 100% vegetation cover. The Rogue, with a coefficient of only 0.47, registers the effectiveness of lava in absorbing moisture from melting snow and transmitting it downward below the root zone, and also the more open character of the forest cover and the sparseness of vegetation in the valley area. The three Southern California water-sheds have physical characteristics quite similar to the Coquille, with the exception of vegetation type and density. The coefficients average 0.66. This value is less than for the Coquille principally because of difference in the extent of interception by vegetation, and the difference in transpiration loss, the latter due both to differences in rate and in density of vegetation.

The analysis and comparison of the complete curves for these five streams suggest a possible method for logical construction of run-off curves for mountain water-sheds for which run-off data are incomplete. The control for constructing such curves is comprised largely in determining values for: (1) The minimum rainfall necessary to produce run-off from the water-shed; (2) evaporation opportunity; (3) annual evaporation from large free water surface for the meteorological conditions of the water-shed; (4) the vegetational tolerance with respect to variations in water supply; and (5) the storm distribution of seasonal rainfall.

(1) The minimum rainfall necessary to produce run-off from the water-shed determines the point of beginning of the curve, and for mountain water-sheds it varies from 5 to 10 in., depending upon water-shed characteristics and the index of wetness.

(2) The ratio, evaporation opportunity, varies for different water-sheds from 0.40 to slightly more than 1.0, depending largely upon the physical conditions and vegetation cover. If the annual evaporation from a large free water surface and the evaporation opportunity are known, the maximum evapo-transpiration loss can be computed. This, in turn, makes it possible to establish the position of the straight-line section of the run-off curve with respect to the 100% run-off line.

TABLE 18.—WATER-SHED CHARACTERISTICS FOR TWO OREGON AND THREE SOUTHERN CALIFORNIA STREAMS.

Item No.	Name.	South Fork, Coquille River, above Fowers, Ore.	Rogue River, above Raygold, Ore.	Devil's Canyon Creek, above gauging station, near San Bernardino, Calif.	San Luis Rey River, above Pala, Calif.	San Diego River, above "Divide" Dam, Calif.
15	Maximum evapo-transpiration, in inches.....	32.5	21.0	37.6	40.0±	46.5±
1	Elevation, in feet.....	3 200	6 500	3 600	5 250	4 500
2	Mean level, in feet {	220	1 100	1 750	650	750
3	Minimum level, in feet {	168	2 020	6.16	322	90
4	Area, in square miles.....					
5	Average seasonal precipitation:					
	Character.....	Rain with occasional snow at higher levels.	Snow with rain at lower levels.	Rain with occasional snow at higher levels.	Rain with occasional snow at higher levels.	Rain with occasional snow at higher levels.
6	Amount, in inches.....	96.0	43.6	34.3	25.6	27.3
7	Seasonal distribution: 75% occurs in the period.....	November 1 to March 31.	November 1 to April 20.	December 1 to March 31.	November 1 to March 31.	November 1 to March 31.
8	Temperature, in degrees Fahrenheit:					
9	Mean annual.....	52.0	48.0	.....	58.6	56.2
10	Minimum monthly.....	32.9	66.6	.....	73.7	69.3
11	Maximum monthly.....	41.4	31.4	.....	44.2	44.2
12	Average annual evaporation from large free water surface, in inches.....	36±	46±	55±	62.2	71.0
13	Topography.....	Mostly steep slopes, low relief in flats, and ridge at head of drainage.	Moderate slopes in mountainous portions; hills and ridges in valleys (8 per cent.).	Steep slopes.	Largely steep slopes with some low relief valley (15 per cent.).	Mostly steep slopes, some low relief valley at head of drainage.
14	Soil.....	Shallow residual with much humus and forest litter.	Decomposed lava and pumice in mountains; shallow residual in foothills; alluvial in valley.	Shallow residual with decomposed granite subsoil.	Shallow residual with decomposed granite subsoil, clayey soils in valley.	Shallow residual with decomposed granite subsoil.
15	Geological formation.....	Early tertiary sandstone, shale, and conglomerate.	Mostly lava with crystalline rocks and shallow valley fill in lower portion.	Granitic with some old alluvium (flats and detrital slopes).	Granitic with lacustral deposits occupying valley portion.	Granitic.
16	Vegetation: Character and density during the growing season.....	Dense forest cover of coniferous and deciduous trees with leafy underbrush.	Coniferous forest cover in mountainous portion, foothills and valley, mostly or bare.	Dense brush cover with alder and sycamore in stream beds.	Dense to thin cover on slopes with oak and pine at higher levels, valley margin and floor bare.	Dense brush cover with sycamore and willows in stream bed.
17	Evaporation opportunity.....	0.30	0.47	0.68	0.64	0.66

(3) Annual evaporation should be as observed in a floating submerged pan exposed on a large free water surface, such as a lake or reservoir. Its ordinary range of variation is from 30 to 72 in.

(4) Vegetational tolerance with respect to variations in water supply, has considerable influence on the shape and location of the point of tangency of the straight line and the curved part of the run-off curve. The more tolerant the vegetation, the flatter the curve and the greater the depth of run-off at which the change from curve to straight line occurs. Deciduous and coniferous trees are normally very exacting in their water requirements. Brush cover is quite tolerant. The most flexible types of vegetation are the annuals, such as flowers, weeds, grasses, tules, etc.

(5) The storm distribution of seasonal rainfall has a direct bearing on total loss by interception and soil evaporation. Maximum conditions occur for a regular sequence of storms throughout the wet season at intervals of proper length to keep soil moisture at field capacity. Its relation to the run-off curve corresponds with that of vegetational tolerance.

The principles which govern valley run-off plus deep percolation are essentially the same as for mountain water-sheds, and it would appear that the foregoing method could be extended to valley water-sheds with appropriate modifications. The item of greatest uncertainty, because of the many factors influencing it and the lack of digested data, is the evaporation opportunity. Factors which would tend to make this ratio larger for valley than for mountain water-sheds are:

- (a) The usual absence of shallow sloping bed-rock in valleys, which in mountain water-sheds tends to hold percolating water within the root zone of vegetation.
- (b) The greater intensity of storms in the valley, at least in Southern California.
- (c) Lower density of natural vegetation cover in a valley, which affects both interception of rainfall and the transpiration aggregate. The effect of Factor (c) may be somewhat offset by increased exposure of the soil to evaporation.

Factors that tend to make the ratio larger are: (1) Flat topography in valleys instead of broken, as on water-sheds; (2) cultivation of valley lands; and (3) in the valley, greater depth below the ground surface to which moisture depletion less than field capacity may occur.

Referring to Factor (1), the actual land area of a mountain water-shed may exceed the projected map area by from 10 to 20 per cent. If the conversion of measured run-off from volume to depth is made on the basis of actual land area, the result will be correspondingly reduced. This may result in an increase of evaporation opportunity for valley water-sheds of from 5 to 10 per cent. Cultivation of valley lands (Factor (2)) offers greater opportunity for absorption by the soil during storms and thus greater loss by soil evaporation between storms.

In the absence of actual data for the evaporation opportunity ratio for valley water-sheds, assumptions can be made based upon the ratio in adjacent mountain water-sheds with modification as comparison of influencing factors

suggests. A run-off curve may then be constructed following the outline described herein and using values for other items which ordinarily are available. The resulting run-off curve includes deep percolation and storm run-off. The former can then be segregated by constructing a storm-water run-off curve from measurements of valley run-off, and taking off of differences.

The writer has applied this method to the determination of penetration in mountain water-sheds, and because of its practical usefulness in constructing mountain run-off curves, he believes that its use may be extended as future determinations of evaporation opportunity for type valley water-sheds are made.

*Determination of Rainfall Penetration from Test Wells in Pauba Valley.—*

The method of determining rainfall penetration from test wells in Pauba Valley, as described by the author, has distinct possibilities where it can be applied free from influences other than precipitation. During the winters of 1913-14 and 1914-15 the writer had under observation more than 120 wells and test holes in various valleys of San Diego County, California, many of which were located in valleys of a character similar to the Pauba Valley. This experience led to caution in the interpretation of water-level observations under the conditions such as exist in the Pauba Valley. One of the sources of difficulty was the influence of flood run-off in an adjacent stream upon water level in test holes in the same alluvial formation. This interference may occur either as a water-table "wave" traveling slowly outward from the stream channel, or as a quick transfer of pressure through a stratum of coarse sand. The former would not produce sudden rises, such as are indicated on Fig. 5, unless test wells were located close to the channel. It is possible, however, that such rises were the result of pressure transfer not reflected in the water-table. In the case of the three wells shown on Fig. 5, the possibility of a pressure effect could be easily determined by ascertaining whether flood run-off in Temecula River occurred during the storm of December 3 to 10, 1927. During this storm nearly 9 in. of rain fell and there was no sudden rise in water level in the wells, due to the moisture deficiency of the sand.

The author omits to state his method of determining the factor used in converting observed rise of water-table to equivalent depth of water. He states that "a porosity factor of 25% was allowed". The writer has frequently had occasion to make this evaluation, and has developed a graphical method which takes into account existing capillary moisture above the water-table before rise commences. Apparently, the author has not given attention to this phase.

The method is based on the fact that the volume of water in a soil column of given depth and unit area is equal to the average percentage of moisture by volume in the column multiplied by the depth. Hence, on a moisture percentage-depth graph (see Fig. 17), the volume of moisture in any column is represented graphically by the area between the moisture curve and the line of zero moisture. The volume of water represented by a given rise in the water-table, is equal to the difference of the water in the soil between the original water level and the surface of the ground, after and before the rise occurred. This volume is graphically represented by the area between the moisture

percentage curves before and after the rise. For ordinary conditions these curves are similar. The following is the development of a simple equation for computing the volume. Since a soil column of unit area is assumed, volume and depth have the same value. For a soil column 1 sq. ft. in cross-section, extending from the ground surface to the lowest level of the water-table (Fig. 17):

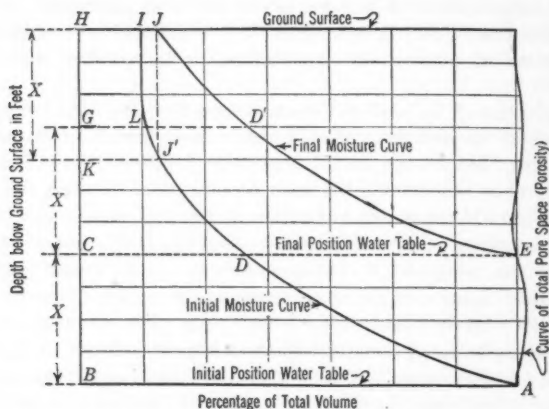

FIG. 17.—DEVELOPMENT OF FORMULA FOR CONVERTING OBSERVED RISE OF WATER-TABLE INTO EQUIVALENT DEPTH OF WATER.

Let  $v$  = volume or depth of water represented by a rise,  $X$ , of water-table;

$r$  = volume or depth of water represented by the total pore space of soil through which water-table rises; and

$c$  = volume or depth of water in the soil between the ground surface and a level,  $X$  ft. below the ground surface.

Then, because of geometric relations,

$$v = \text{Area } ADE + \text{Area } EDLIJD'$$

$$r = \text{Area } ADE + \text{Area } ABCD = \text{Area } ADE + \text{Area } ECGD'$$

$$c = \text{Area } J'KHI = \text{Area } HILG + \text{Area } GLJ'K = \text{Area } HILG + \text{Area } DCGL - \text{Area } DCKJ'$$

Hence,

$$v = r - \text{Area } ECGD' + \text{Area } EDLIJD'$$

but,

$$\text{Area } EDLIJD' = \text{Area } ECGD' - \text{Area } DCGL + \text{Area } D'GHJ - \text{Area } HILG$$

Substituting,

$$v = r - \text{Area } DCGL + \text{Area } D'GHJ - \text{Area } HILG$$

and since,

$$\text{Area } D'GHJ = DCKJ'$$

therefore,

$$v = r - c \dots \dots \dots (2)$$

In other words, the volume of water represented by a rise of  $X$  ft. in the water-table equals the total pore space in the soil column through which the water-table rises, minus the moisture in the soil column between the ground surface and a level  $X$  ft. below the ground surface.

In the use of Fig. 17, the average percentages for total porosity in the column  $X$  ft. above the initial position of the water-table, minus the average percentage of moisture on the column  $X$  ft. below the ground surface, multiplied by the rise in the water-table, in feet, gives the equivalent depth of actual water, in feet.

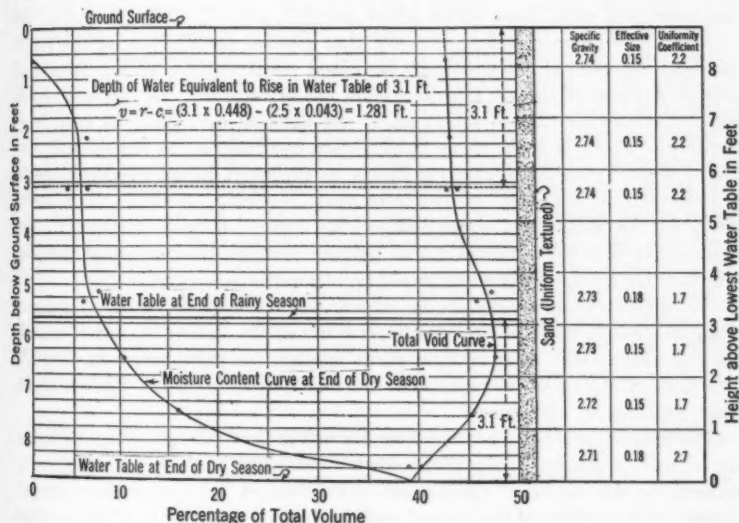

FIG. 18.—APPLICATION OF FORMULA FOR CONVERTING OBSERVED RISE OF WATER-TABLE INTO EQUIVALENT DEPTH OF WATER.

In applying the method, type areas are selected such that the character of the soil and subsoil is more or less uniform. In each area a pit is dug to the water-table at the end of the dry season. Samples are cut from the exposed face, at intervals of 1 ft., or more, so as to be representative of the gradations of material in the column, and initial moisture and total porosity are determined. If desired, a mechanical analysis of each sample may also be run, although this is not necessary. The data are then prepared in graphical form, as illustrated by Fig. 18, which represents the condition where the depth to water-table exceeds the capillary limit of the material. This diagram represents a typical material for similar valleys in this region, including Pauba Valley. It is to be noted that the computed depth of equivalent water represents percentage by volume of 39.4 for a material with an average porosity of 45 per cent. It is probable that the author's assumption of 25% for net porosity is too low.

A. L. SONDEREGGER,\* M. Am. Soc. C. E. (by letter).—The extensive discussion of this paper is proof of the interest which the subject has aroused of late years in the semi-arid West. It has been fruitful of many new and interesting ideas and facts and not a few contradictory statements; also, some criticism. A discussion of natural phenomena, such as rainfall penetration and run-off, and particularly of the methods for their determination which the paper was intended to bring out, must, of necessity, make reference to specific cases.

Mr. Houk, in the closing paragraph of his discussion, summarizes the general conclusion reached, namely, that the geological, topographical, and meteorological conditions which affect rainfall, run-off, and percolation, are so many, so different, and so variable that general conclusions, or the establishment of general laws, cannot be based upon studies of an individual area or a group of areas. The discussion has brought out that present knowledge of the many factors which affect the disposal of rainfall is only fragmentary. There is little or no information available as to the consumptive use of water by native vegetation except as expressed in the general rainfall-run-off relation. The latter indicates that, generally speaking, from 40 to 100% of the rainfall is consumed by the cover. It goes without further explanation that the conservation of rainfall through the control of the consumptive use in the water-sheds would be of unestimable value.

To further such results, it is imperative that country-wide, systematic investigations be made of the consumptive use of the water-shed cover, including the water needs of individual plant species, the distribution of rainfall, the effect of over-year storage, and the multiplicity of other factors which affect penetration and run-off.

The idea is repeatedly advanced by discussers that rainfall, after it reaches the ground, remains evenly distributed, practically, and that absorption is uniform to the depth of plant roots, regardless of the ever-present irregularities of the surface of the ground and the lack of uniformity of the residual soils of the mountain water-sheds or of alluvial deposits in the foothill areas and steep valleys adjacent to mountain ranges. Hence, the discussers have repeatedly asserted that no deep penetration can occur unless the field capacity of the soil down to the root limit is first satisfied over the entire area under consideration.

Doubt has been expressed by some of the discussers as to the comparatively large quantities of deep penetration in the valley floor which the writer believes become available. In this connection, the study of water supply from closed basins should furnish conclusive evidence. Such studies are available for the San Bernardino Basin in the water-shed of the Santa Ana River, above Prado, in Southern California. Reference is here made to two independent investigations of the water supply of this basin, one by the Engineering Offices of J. B. Lippincott, M. Am. Soc. C. E., in Los Angeles, Calif.,† and one by the State Engineer's Office of California.‡

\* Cons. Engr., Los Angeles, Calif.

† Report on Water Conservation and Flood Control on the Santa Ana River for Orange County, July, 1925, Table 16.

‡ "Santa Ana River Investigation." *Bulletin No. 19*, State of California, Dept. of Public Works, Div. of Eng. and Irrig., 1929.

The water-shed of the Santa Ana River above Prado is a closed basin; it is bordered on all sides by mountain ranges embracing a valley area, which is a sunken basin many hundred feet in depth, filled with alluvial materials. This area is capable of absorbing a considerable percentage of water. A large portion of the tributary mountain water-shed enjoys a prolific rainfall and run-off. The latter has been measured by the U. S. Geological Survey in the Santa Ana River and numerous creeks, for a sufficient period of time to permit of accurate estimates of total run-off reaching the valley. The principal stream is the Santa Ana River (water-shed, 203 sq. miles). The river, after traversing the basin and intercepting its tributaries, enters the gorge of Lower Santa Ana Canyon where a gauging station has been maintained near Prado since 1919-20. There is also available a large number of current-meter measurements at this point, made at more or less frequent intervals, since the early Nineties. The cross-sectional area of the underflow at this point is known. Surveys as to the use of water for domestic purposes and irrigation within the basin are available; surveys also are available of the moist areas from which water evaporates. Furthermore, there are rainfall records, covering long periods, of a number of stations in the valley floor and fluctuations of the water level in wells. In short, there are available comparatively complete data to establish the water supply, use, and waste in this closed basin.

In the Lippincott report previously mentioned, the possible sources of water supply, mountain water-sheds, foothill areas, and valley floor, were credited with the quantities listed in Table 19. These data are the averages for the 29-year period from 1895-96 to 1923-24.

TABLE 19.—TOTAL SEASONAL WATER CROP OF SANTA ANA RIVER  
ABOVE PRADO, CALIF.

Region.	Area, in square miles.	WATER CROP, 29-YEAR MEAN.	
		Total, in acre-feet.	Acre-feet per square mile.
Mountain water-shed, north and east.....	547.01	193 142	353.08
Temescal Creek.....	200.74	1 509	7.52
Foothill areas, north and northeast.....	68.26	22 328	327.10
Foothill areas, northwest.....	48.16	27 168	564.12
Foothill areas, south.....	40.73	2 748	67.46
Valley floor, north and northeast.....	245.88	46 644	189.70

Valley floor, south.....	84.89	13 428	158.18
Total.....	1 485.19	360 991	243.
Santa Ana River, at Prado.....		153 102	

The water crop attributed to the valley floor, 580 sq. miles in area, is nearly all deep penetration and amounts to 114 000 acre-ft. per annum, or more than 30% of that of the entire water-shed.

For the purpose of comparison with Table 19, estimates of rainfall penetration in the valley floor of San Bernardino for the seasons 1926-27 and 1927-28 are presented in Tables 20 and 21.\* These statements are based upon penetration experiments and studies by Mr. Blaney, and discussed by him in connection with the paper.

The water supply characteristics of the two seasons are expressed in the index of wetness (percentage of long-period mean rainfall) and index of run-off (percentage of long-period mean run-off of the mountain streams), to wit:

	1926-27.	1927-28.
Index of wetness (City of San Bernardino)....	128	87
Run-off index .....	147	34

Tables 20 and 21 indicate that under certain conditions the water supply from rainfall penetration in the valley may assume substantial proportions and may become a factor of economic importance.

Mr. Blaney has contributed a valuable discussion and much useful data on evaporation and transpiration losses obtained in Southern California by the method of systematic soil moisture determinations. For areas with various types of soil, cover, and culture, this in many cases may be the only method available for the determination of the percentage of deep penetration. As stated in the paper, the method is subject to the errors resulting from the assumption that rainfall remains uniformly distributed after it reaches the ground and that there is no erratic variation of soil texture. The method is not so successful with very gravelly soils, because it is difficult to obtain samples except by digging shafts.

TABLE 20.—SAN BERNARDINO BASIN: SUMMARY OF ESTIMATES OF PENETRATION WITHIN VALLEY FLOOR FOR 1926-27 AND 1927-28.

Basin.	Area, in square miles.	Mean rainfall, in inches.	MEAN PENETRATION.		Total penetration, in acre-feet.
			Inches.	Acre-feet per square mile.	
Upper:					
1926-27.....	124.1	21.9	7.62	407	50 700
1927-28.....	124.1	17.6	1.68	86	10 700
Jurupa:					
1926-27.....	99.1	18.4	4.17	223	22 000
1927-28.....	99.1	16.1	.77	41	4 100
Cucamonga:					
1926-27.....	268.9	22.9	8.85	472	126 700
1927-28.....	268.9	15.2	2.93	156	41 700
Temescal:					
1926-27.....	55.9	16.0	3.02	161	9 900

Lower (Coastal Plain):					
1926-27.....	305.6	16.1	4.87	260	79 200
1927-28.....	305.6	15.3	4.70	251	76 900

The extensive and thorough investigations now being carried on by the Division of Agricultural Engineering, U. S. Department of Agriculture, some

\* Bulletin No. 19, State Dept. of Eng., California, Tables 22-A and 22-B.

of which are under the immediate direction of Mr. Blaney, will throw light on many phases concerning the problem of rainfall penetration. Comparison between penetration resulting from protracted storms and sprinkling experiments carried on in dry weather should lead to conclusions regarding the effects of atmospheric conditions, which are difficult of analysis.

TABLE 21.—SAN BERNARDINO BASIN: ESTIMATE OF MEAN PENETRATION VALUES WITHIN VALLEY FLOOR, IN ACRE-FeET PER SQUARE MILE, FOR VARYING MEAN RAINFALL.

Mean rainfall, in inches.	MEAN PENETRATION, IN ACRE-FeET PER SQUARE MILE.				
	Upper Basin.	Jurupa Basin.	Cucamonga Basin.	Temescal Basin.	Lower Basin (Coastal Plain)

15	0	0	150	124	224
18	118	187	272	250	360
21	336	336	390	390	490
24	500	470	520	520	620

Mr. Sopp's statement as to the results of soil sampling in a shaft 170 ft. deep is in confirmation of the writer's views and experience, and contradicts the theory advanced by many engineers that rainfall of the intensity characteristic of Southern California would not, and could not, penetrate a soil prism 170 ft. What most water supply engineers did not expect, however, and some still dispute, is that the percentage of rainfall reaching the water-table is as large as the writer's investigations have led him to conclude.

Mr. Troxell takes issue with the analysis of mountain run-off as shown in Fig. 8 and with the determination of the consumptive use of the cover from the "total run-off" curve. The values obtained by the writer's method represent averages over a period of years in which the effects of individual years are ironed out. For larger water-sheds with perennial flow, this method is probably the only one that is practicable, since it becomes difficult to trace the effect of individual years on account of the long-period storage which takes place. For a small water-shed like that of Devil Canyon, the following considerations will apply:

- For a dry year, preceded by a wet year, the curve gives values of consumptive use that are too large because of a draft on over-year storage (see year 1923, on Fig. 8);
- For a wet year, preceded by a dry year, the curve gives values of consumptive use that are too low, because a part of the rainfall remains in storage (see year 1922, on Fig. 8); and
- For the second and third years of a series of years of the same wetness, the curve gives correct values (see years 1920 and 1921 and years 1924 and 1925).

The larger the water-shed the more complex becomes the effect of hold-over storage. Considering further that, as a rule, data relative to the distribution of rainfall over large water-sheds are fragmentary, that no two seasonal rains fall in the same manner, and that moisture conditions and

conditions of the cover of a water-shed are likely to vary from year to year, practical results can be obtained only by methods which iron out the irregularities of individual years.

Just why Mr. Troxell criticizes the storm run-off curve of Fig. 8 is not clear. The curve speaks for itself; it deviates very little from the construction points. The discussor states that "storm run-off depends not on seasonal rainfall, or even storm periods, but on the instantaneous rate of rainfall and the condition of the canyon storage". A determination of the storm run-off of a mountain water-shed from the instantaneous rate of rainfall is too impractical to deserve serious consideration. The method is used to estimate peak flows in urban areas, where the instantaneous rate of rainfall is known. In mountain water-sheds rainfall stations, as a rule, are few and far between, and daily or weekly rainfall records are the best to be expected.

Mr. Troxell's application of the run-off curves of Strawberry and Waterman Canyons to Lone Pine Creek is hardly fair. The first two water-sheds are short, steep slopes on the south side of the San Bernardino Mountains, exposed directly to the moisture-laden clouds drifting in from the ocean and receiving a very prolific rainfall. Lone Pine Creek, on the other hand, is on the lee or desert side of the highest peak of the Sierra Madre; its northerly slopes are formed by a low range of desert hills. The creek bed runs along the San Andreas fault rift for a distance of 10 miles; climatic conditions are those of a desert valley. No wonder the results of Mr. Troxell's comparison were disappointing.

Mr. Rowe's discussion divides itself into two distinct sections. The first refers to the consumptive use of water-sheds near San Bernardino, with which Mr. Rowe is very familiar. His data as to the effect of a denudation of the brush cover by fire are very instructive. The quantity of deep penetration from rainfall of 250 acre-ft. per sq. mile as determined by the writer for the brush-covered part of the San Bernardino area, is questioned by Mr. Rowe.

The second section of Mr. Rowe's discussion refers to the determination of rainfall penetration in Pauba Valley and on the Big Mesa of Temecula River. A casual trip over the Big Mesa is hardly enough to enable a person to become familiar with this water-shed or with the writer's investigations.

Relative to the penetration experiments on the Big Mesa, Mr. Rowe refers to the existence of hardpan at 4 ft. below the surface and states that this is the greatest depth to which rainfall ever penetrated. The writer made borings on the Big Mesa after the great storm of February, 1927. Some of the samples taken from approximately 16-ft. depths were wet and plastic. This moisture must have found some way to get below the so-called impervious layer of hardpan.

Mr. Rowe attributes special significance to the fact that on the Big Mesa there are two wells in which water stands higher by more than 40 ft. and 65 ft., respectively, than in adjoining wells. In reply, it may be stated that it is conceivable that a well would terminate in a thick clay stratum which is above the general water-table. Such a well, naturally, would drain the suspended water-table produced by the clay stratum in accordance with Fig. 1.

The well, therefore, would hold water, but its level would be above that of the general water-table.

Engineers interested in rainfall penetration are indebted to Mr. Lee for an instructive discussion which has brought to light many new and important points. The discussion relative to mountain run-off and "evaporation opportunity" is particularly useful.

Referring to the discussion of the computation of rainfall penetration from test wells in Pauba Valley, Mr. Lee's method of determining the factor to convert the observed rise of a water-table to the equivalent depth of water, is a decided improvement over the assumption of a flat percentage; but the elements which enter into such computations are more in detail than would ordinarily be available to the engineer in making a water-supply study, except for small areas. The writer's percentage of porosity of 25% was the result of the study of a number of well logs.

The following remarks relative to the Pauba Valley test wells are applicable to the discussions by both Messrs. Lee and Rowe.

Approximately sixty-four wells were used in making the study of rainfall penetration in the Pauba Valley. Practically all these wells were shallow; many of them penetrated only 2 or 3 ft. into the water-plane. Most of the wells were located in, or adjacent to, fields which were irrigated approximately once a month during the summer season. These wells within the irrigated area showed a rise following the application of irrigation water very similar to the rise which followed rainstorms. The deduction was made that if an application of irrigation water of 5 to 6 in., at a time when no storm run-off was present in the river, produced a rise in the wells, a similar rise would occur after a rainfall of 5 or 6-in. intensity to, roughly, the same amount, and it would be logical to conclude that this rise had been produced by the rainfall rather than by transmitted pressure.

Some of these irrigation rises, from May to September, are shown in Fig. 5, but they are much clearer in corresponding graphs of many of the other wells. It was impossible to present all the data upon which the deductions were based.

The conclusion was advanced by the discussers that transmission of pressure, rather than local rainfall, is responsible for the rise in the test wells. This is a question which may be of general interest. In explanation of any such theory, it should be stated that Pauba Valley is a closed basin; the river enters by way of Nigger Canyon Gorge and leaves by way of Temecula Gorge (see Fig. 4), with bed-rock outcropping in the river bed in both gorges. The gradient of the river averages about 38 ft. per mile. Below the upper gorge the river spreads over a wide outwash area, or *débris* cone, covered by deposits of sand and gravel. It is in this region that effective absorption occurs, because the entire summer flow, as a rule, seeps away. Pauba Valley is several hundred feet in depth and is filled with alluvial materials capable of absorbing about 25% of water as disclosed by the well logs. As the underflow approaches the lower gorge it is obstructed by the bed-rock formation and is forced to the surface, producing a rising stream which begins as a trickle about 6 miles above the lower gorge and increases to about 10 sec.-ft. as the river approaches

the gorge. The combined effect of the bed-rock and the resistance to percolation by the valley fill produces a pressure in the ground-water strata, responsible for the rising stream and for the flow in artesian wells. This is a phenomenon quite common with Southern California streams.

The water-table of the outwash area presents the fountain-head of this pressure. The process of ground-water movement, however, is believed to be a combination of pressure and percolation, the latter being the predominant factor for the reason that this basin, although only 9 miles in length between gorges, has the effect of long-period regulation of stream flow, with a summer flow varying from 8.5 to 12.5 sec-ft. In 1900, after a period of seven predominantly dry years, there was still a perennial flow at the lower gorge of about 10 sec-ft. during the summer months.

If the rise in the test wells was due to transmission of pressure, it would have had to occur either simultaneously with, or after, the appearance of the flood flow in the stream. As a matter of fact, a flood would naturally lag behind the downpour. It should also be noted that the flood channel in the outwash area may occupy only a fraction of the total width of the latter, unless the flood were to assume extraordinary proportions; that under ordinary flood conditions a certain lateral percolation must take place in the outwash area; and that a rise of the water-table over a considerable region before a transmission of pressure would affect the entire valley below. The lateral percolation observed, occurred under an oblique angle to the axis of the stream bed, and at rates varying from 16 to 33 ft. per day.

On certain of the test wells continuous records were kept which indicated that the rise preceded the flood flow at the outwash area. Many of the graphs also show that the test wells reached a peak before the wells in the outwash area above them and which, of necessity, would be the origin of any transmitted pressure. In most cases, after the occurrence of these peaks the test wells declined rapidly, while the wells in the outwash area were still approaching their high point. It would be logical to conclude that if the fluctuations in the test wells were dependent upon transmitted pressure, both the rise and the decline would follow the corresponding rise and decline of the levels in the wells in the outwash area rather than precede it.

Any conclusion that the rise in a test well might be due to a rise in the river opposite that well cannot be reached because the elevation of the water-table was higher than the river. It also appears that both Mr. Lee and Mr. Rowe expect a uniform manifestation of rainfall percolation, regardless of the unevenness of the ground and lack of uniformity of soil formation. Collection of rain water in depressions may readily account for a rise in some test well, greater than the rainfall would warrant.

Relative to the matter of rainfall penetration on the Big Mesa, which is doubted by Mr. Lee and Mr. Rowe, the question resolves itself ultimately as to the existence of a general water-table beneath the Mesa. A pumping test made from May 18 to June 15, 1928, on Well No. 131, located on the Mesa about  $1\frac{1}{2}$  miles east of Temecula (after the paper had been written), tends to support the writer's conclusions. The well is 12 in. in diameter and

604 ft. in depth. Its log shows 61 ft. of aquifer, 18 ft. of undetermined water-bearing capacity, and 525 ft. of impervious strata. The general features of the test are shown in Table 22.

TABLE 22.—PUMPING TEST AT WELL NO. 131.

Date.	Time.	Depth to water, in feet.	Output, in second-feet.	Remarks.
May 18, 1928.....	11:09 A. M.	63.04	.....	.....
May 23, 1928.....	10:00 A. M.	62.70	.....	.....
May 23, 1928.....	11:00 A. M.	82.40	0.941	Pumping at intervals; many interruptions.
May 24, 1928.....	7:00 A. M.	88.77	0.351	
May 25, 1928.....	7:00 A. M.	85.65	0.382	
		Changing casing		
May 25, 1928.....	9:00 P. M.	111.58	0.789	.....
May 29, 1928.....	12:00 M.	105.10	0.837	{ Constant pumping for 20 hours 40 min.
May 30, 1928.....	5:40 P. M.	115.70	0.799	
				{ Stopped pumping
May 30, 1928.....	5:48 P. M.	78.69	.....	Not pumping.
May 30, 1928.....	6:40 P. M.	71.63	.....	Not pumping.
May 30, 1928.....	7:40 P. M.	70.49	.....	Not pumping.
May 31, 1928.....	7:00 A. M.	67.66	.....	Not pumping.
June 1, 1928.....	7:10 A. M.	66.10	.....	Not pumping.
June 10, 1928.....	9:35 A. M.	68.70	.....	Not pumping.
June 15, 1928.....	4:00 P. M.	63.41	.....	Not pumping.

The total quantity of water pumped was 3.63 acre-ft. The volume of water pumped and the rate of recovery of the water-shed would seem to warrant the conclusion that a general water-table underlies the Big Mesa.

Paper No. 1757

### THE PLANNING OF CAPITAL CITIES: DENVER, COLORADO\*

By S. R. DeBoer,† Esq.

WITH DISCUSSION BY MESSRS. MORRIS KNOWLES, RICHARD R. LYMAN, WILLIAM  
T. LYLE, GEORGE H. HERROLD, AND S. R. DeBoer.

#### SYNOPSIS

As this is the first of an intended series of papers on the "Planning of Capital Cities", some general remarks may serve to define their scope.

Capital cities dot the map of the United States from ocean to ocean and from Mexico to Canada. They include varying conditions of climate, commerce, and physical characteristics; but they are alike in that each is the seat of government of a Sovereign State. Some are old, others are relatively new and are still developing "growing pains". Some are located on ocean, lake, or river, some enjoy the clear vision of mountain slope or range. A few are located on outstretching plains, and many are favored with an eminence on which to place their significant building which is the emblem of State authority.

It is always of interest in studying the origin and development of an important city to know who made the first street plan; how this has been enlarged from time to time; and whether the city has a planning commission and has been zoned. Because of the many lessons that can be drawn, and the older history of development which can be studied, reference is made in the paper to several of the better known European capitals. The City Planning Engineer can find much of interest to study in foreign capitals.

After noting the general characteristics of capital cities, the paper presents a description of Denver, the capital of Colorado, and outlines its early development and transitions in stages of growth. Attention is called to the various

\* Presented at the Technical Session, Denver, Colo., July 13, 1927.

attempts in city planning; to the fact that the location of the Capitol has acted as a nucleus and, to some extent, has dominated the street system.

Considerable attention is given to the recreational system of Denver and its environs, as well as to the application of principles in the development of the Denver plan, and the unique features of zoning which are applied thereto.

#### GENERAL CHARACTERISTICS OF CAPITAL CITIES

A city may be termed the "service station" of its district. It performs the work which the surrounding region requires. Thus, based on their means of existence, cities can be classified as factory, mining, agricultural, commercial, residential, or tourist cities; health resorts or educational centers; and military or capital—that is, governmental—cities. It is true that most urban communities include more than one of these classifications, and large cities often cover all of them; but in the life of each, except the metropolitan center, some one feature is predominant. In the United States, few capital cities have a metropolitan character. In planning for their future, it is proper, therefore, that major emphasis be placed on those features which will focus attention on the seat of the Government.

It should be remembered that, not only are the reins of government centered in a capital city, but also the pride of a State or of a Nation. Modern civilization is not as yet far enough removed from the feudal days, but that the pomp and splendor attending governmental functions are still objects of admiration. This interest, however, is shifting from individuals to buildings and cities. Democracy has taken the diamond-studded uniform and sword from the rulers of this country, but its citizens still want to point with pride to their Government, and this pride is more and more becoming embodied in buildings and cities.

These fundamental facts determine the character of the plan according to which a government city should be built. It must be laid out on liberal lines, with wide boulevards and attractive parks. It must have large, open plazas, around which imposing governmental buildings can be grouped, and the main group with its plaza should be developed into a civic center.

#### FOREIGN CAPITALS

The civic-center idea reaches far back into the history of Rome when the Emperors beautified large areas for the city, mostly for their own glorification; but the idea of beautifying capital cities and planning them from the outset had its origin with Louis XIV, the self-styled "King of the Sun", of France. He hired Le Notre to plan the gardens and city of Versailles on a scale of magnificence which the world, at that date, had not witnessed. Jealous of his fame, other princes began to build similar cities, or to beautify their existing ones. A German prince immediately began the building of Karlsruhe. Czar Peter the First built St. Petersburg, and then other cities—Vienna, Berlin, and Paris—adopted extensive improvements.

The City of Paris had corrective and beautifying plans as far back as 1664. It seems that the Royal House of France retarded the development of these plans, fearing the City would become too powerful. The first basic plan was

developed after the Revolution, and it was partly carried out by the First Napoleon as a military necessity in controlling the city. The Third Napoleon, with the assistance of Haussmann, completed more of the work, also for military purposes. In spite of the military influence, Paris has developed a plan that is following the general lines characteristic of a capital city, with the exception of the location of railroad stations, which have no particular relation to the center of the city.

The City of Vienna is an interesting illustration of a capital developed around an existing old city. The "Ring Street", built on the old fortifications, has become the location of the Government buildings and the royal palaces. The outer streets radiate from this circle boulevard. The inner part of Berlin is carefully planned with radiating traffic lines and circular boulevards, which are placed mainly on the old fortifications. The newer parts of Berlin are not as well planned as the older part.

The City of London has no apparent design. It has been built on the principle of expediency of the moment rather than by following a comprehensive idea. In spite of this, the Houses of Parliament, Buckingham Palace, and the Administrative Offices along Whitehall are more or less connected. The remainder of the city seems to follow the lines of cowpaths rather than planned city streets. Through the conglomeration of blocks, major streets wind their more or less indirect ways. The proposal of the great Christopher Wren would have made London a well-planned city after the fire in 1666; but it was never adopted. The reason London can exist and grow, in spite of this street handicap, is the fact that its underground transit system supplies the need for arterial and circular lines.

Karlsruhe, Germany, represents a good illustration of a city built along radiating lines. All streets are focused on the governmental center—in this case, the palace of the ruling prince. Two-thirds of the circle is occupied by the Royal Park placed back of the palace. The city in front is well planned, with open plazas in various places. Triangular plots, caused by the intersection of radiating lines, are carefully avoided.

All the plans thus far discussed were designed before modern means of transportation affected the city plan. The plan of Canberra, Capital City of Australia, takes into consideration not only this, but also the still newer ideas of zoning. Each of several centers is laid out as an independent city, connected with the other units by broad and direct lines of traffic. Canberra has a main civic center—the group of Government Buildings. Around it are grouped secondary centers, such as the municipal, business, residential, industrial, and the suburban districts.

#### THE CAPITAL OF COLORADO

All these cities are capitals of large nations, in which the Government center is dominant. In the forty-eight State capital cities of this country, the governmental feature is of less consequence. Many of them, however, are typically administrative cities, and would not be what they are to-day were it not for this activity.

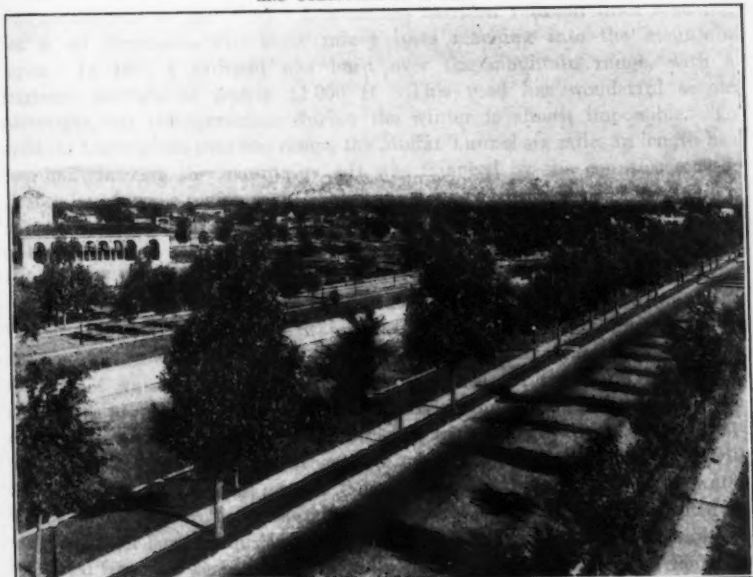

FIG. 2.—VIEW OF SPEER BOULEVARD, DENVER, COLO.

Fig. 1. View of the landscape from the station.

The City of Denver is an outstanding example of a capital city in America. It is third in population among State capital cities. Built at the foot of the Rockies (Fig. 1), it has as its background 200 miles of the Rocky Mountain range, towering up to peaks more than 14 000 ft. high. As seen from the city, this affords one of the most magnificent vistas any capital ever had, but, at the same time, it has been one of the most serious barriers to commerce. Denver had its beginning as a mining town in 1858, and immediately became the leading city of a large district. Many of the mountain valleys open into the plains near the city, and it soon became the distributing point to the mining cities in the mountains.

When the first transcontinental railroad was built by the Union Pacific Company, the proposed line over Berthoud Pass was abandoned as impractical, and the line was built through Southern Wyoming, with Cheyenne as a division point. It was a hard blow to the small city of Denver, and it is said that its population decreased to one-half. Many cities are aided rather than harmed by serious calamities; the fight and co-operation necessary to overcome them may carry the city to far greater success than it would have reached otherwise. The citizens of Denver were jarred into action by this location of a railroad that ignored their city. They built a connecting line from Denver to Cheyenne. When they realized that they actually could do such things, it took but a few years for them to build other lines, and, thus, at the time Colorado was admitted to Statehood, the city was the center of eight railroads.

The Rocky Mountains have always been a barrier against the city's railroad connections to the West. Denver has thirteen railroad lines reaching out in all directions, with three minor lines reaching into the mountain region. In 1907 a railroad was built over the mountain range, with a maximum altitude of nearly 11 000 ft. This road has wonderful scenic advantages, but transportation during the winter is almost impossible. To avoid the heavy grade over the range, the Moffat Tunnel six miles in length has been built through the mountains. It was financed by the counties served, Denver carrying the major part. This tunnel will eventually put Denver on a major transcontinental line. Connecting lines west of the tunnel are still to be built, but once this main line is in operation, the distance to the Pacific Coast and to Salt Lake City, Utah, will be reduced by 250 miles.

Being located in the arid region, its water supply is another problem of the City of Denver. It has ample water for domestic use at present, but, with the expected growth, the city is laying plans for a far greater supply. The quantity of water contained in the drainage areas of the State is limited, and a large part of it must be used for the irrigation of farm lands. The city cannot utilize this irrigation water because, with the growth of the municipality, the watering of a larger acreage of farm land around the city will become as essential as the greater domestic supply. Scientific use of water will be one of the problems the city must face. Plans have been effected to use the pioneer bore of the Moffat Tunnel for an additional supply of water to be carried from the western slope of the mountains to within reach of the city.

A bluff overlooking the city was selected for the site of the State Capitol. Three blocks of ground were acquired, sloping up from the city's main

thoroughfare to the top of this hill on which the Capitol was built. The building was placed in such a way that it commands a beautiful view of the Rockies (Fig. 1). The tower is located on the axis of the city's main shopping street, but the building is shut off from this street by one block of stores. In the early days, the city failed to open this shopping street to the Capitol grounds, and since that time such efforts have been unsuccessful.

Fifteen years after the completion of the State Capitol, the city prepared plans for the development of a civic center, as a continuation of the Capitol grounds, and on the same axis. Two and one-half blocks of ground were acquired, on which the Library, an open-air theatre, a fountain, and an ornamental colonnade now stand (Fig. 1). In 1924, the city acquired another block for the erection of a new City Hall and Court House. Denver is fortunate in having a definite civic square on which, in the future, all its major public buildings can be made to face. Tentative plans for the continuation of this State and Civic Center have been made, and there is no doubt but that, eventually, this park will be more than  $\frac{3}{4}$  mile in length. The Federal Mint is already located on this extension, and an art gallery will very likely follow.

Denver is still an infant among cities. It is scarcely more than three-score years old, but it may be stated that it has sensed its calling as a capital better than many an historical city. At a considerable expense, it has acquired this civic center in front of the State Capitol, and has begun laying it out in one of the best known, if not the most attractive, municipal centers of the world. This has proved to be a good investment. The actual return is an indirect one, and is difficult to estimate, but it is said that the city's added income pays for the cost of its Civic Center every two years.

Regardless of the accuracy of these figures, the value of this Civic Center is shown in the attitude of the citizens themselves. From active opposition during the period of construction, this viewpoint has changed to one of impatience for any delays in continuing the work, and of anxiously guarding the treasure against mistakes of design or vandalism.

Denver is planning another Government center. The Federal Building and Post Office was in a remote corner of the commercial section. For many years the location has seemed unfortunate, from a business standpoint and because it does not tie in to the State and municipal group. There was a time when the Civic Center needed this extra building. Time, however, healed this, also. Down-town Denver is growing to its Post Office, and the added confidence in its Civic Center has made the Federal Building unnecessary to the municipal and State group. Other Federal Buildings are needed, however, and now the City contemplates a special plaza for this purpose. The people of Denver would not think of a second center had its main Civic Center not been a success.

The population curve of Denver shows a steady growth of 2.1% annually. At the present rate, the city will have a population of 520 000 in 1950, and plans are being completed for a major street layout based on this estimate. Traffic studies in the down-town district have shown conclusively the need of a belt boulevard for traffic around the business district. This line will consist

of wide boulevards that will tie the municipal and State centers to the Government center, to the hotel district, to the Union Station, and to the major arterial lines. It will encircle the business district, and traffic can enter from all four sides. This belt boulevard will take on very much the character of the Ringstrasse of Vienna or Cologne and, when completed, will be monumental in appearance. From it radiate all the arteries of the city.

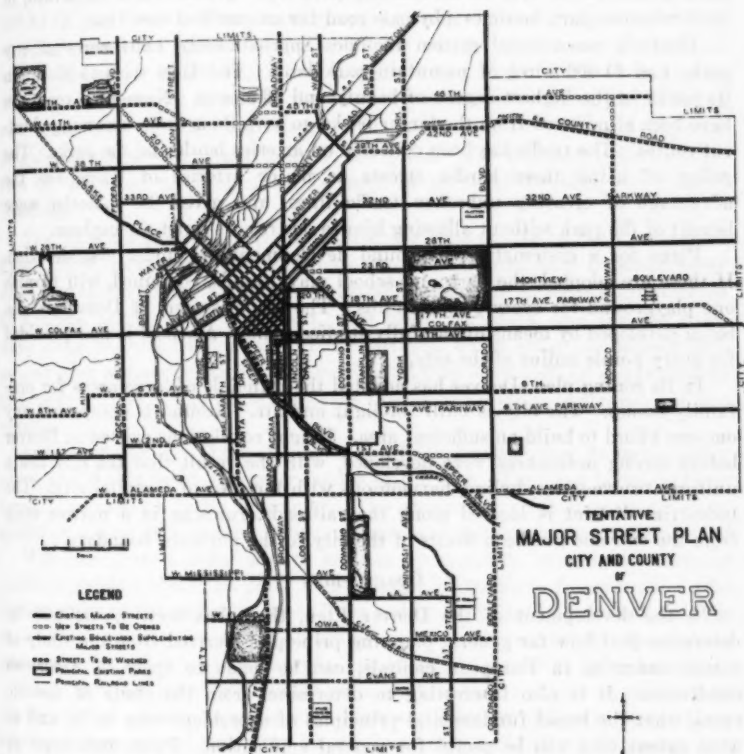

FIG. 3.—DENVER'S MAJOR STREET PLAN—STATUS AS OF DECEMBER, 1927.

The main radial line of the city is Speer Boulevard (see Fig. 2), built on the borders of Cherry Creek. At the time of its construction, the creek bottoms were the dumping grounds for the city. The Boulevard was much opposed, but its value is now shown in the 26 000 cars that pass over it daily. As an attractive feature in the Denver plan, it is just as important. The continuation of the Boulevard north and south is one of the proposed lines of the present plan of Denver (see Fig. 3). The other major traffic boulevard that will become part of the belt is the present 20th Street. Its widening and extension will carry it to the northern entrance of the city, and south to a line that reaches to the southern limits.

Broadway is one of the major traffic streets of Denver. It was extended in 1919, and it is now (1929) contemplated to continue it to the city limits north. Many other radial lines are being considered, some of which will necessitate the building of viaducts over the Platte River. The main belt boulevard will be followed by other lines that reach out in large ellipses around the city. One of the boulevards follows the railroad lines, and ties together in the eastern part of the city on an existing parkway. This circular boulevard, in its down-town part, becomes a by-pass road for an east and west line.

Denver's recreational system includes approximately 1 664 acres of city parks and 11 006 acres of mountain park land. The City tries to maintain its parks in the highest degree of beauty and efficiency. Numerous roadways have been eliminated from the larger parks, to save them from becoming short-cut routes. The traffic has been collected on arteries bordering the parks. The policy of using these border streets as major arteries of traffic has the advantage of creating unbroken traffic lines, and gives the motorist some benefit of the park without allowing him to destroy its quiet atmosphere.

Plans for a systematic playground development are under consideration. If these are adopted, the park and school playgrounds, combined, will furnish one playground for every  $\frac{1}{2}$ -mile radius. The school system of Denver is also being developed by means of carefully studied plans. A school is now provided for every  $\frac{1}{2}$ -mile radius of the city.

In its zoning plan, Denver has adopted the principle of large areas for one-family homes. The city is built for light and air. Ground is cheap, and any one can afford to build on sufficient area. Height regulations existed in Denver before zoning ordinances were developed, with the result that the city has a uniform twelve-story skyline, harmonious with the idea of a capital city. The industrial district is located along the railroads, running in a narrow strip from the extreme southern limits of the city to the northern boundary.

#### CONCLUSIONS

In the development of the Denver Plan, there has been opportunity to determine just how far general planning principles, derived from the study of classic examples in European capitals, can be made to apply to American conditions. It is also interesting to determine, from the study of specific cases, what the broad fundamental principles of a problem seem to be, and to what extent they will be useful for general application. From experience at Denver and general studies made in conjunction therewith, it appears that the theoretical plan of a capital city can be divided into four major zones: The zone of Government buildings; the central business district; the residential zone; and industrial zones.

*The Zone of Government Buildings.*—This is an area not usually found on city zoning plans. The City of Washington, D. C., has this zone, divided into two focal points—the Houses of Congress in one, the Executive Buildings in the other. For a smaller State capital, it will not be possible to plan on such a large scale. The State Governmental group will usually consist of Capitol buildings, additional office buildings, Historical Museums, State Armory, and often a Federal Building. These buildings should be grouped around a large

and attractive square. A second open square should contain all the buildings serving the municipality, including the City Hall, City Auditorium, Post Office, Library, Chamber of Commerce Building, etc. This second square should be also well designed and proportioned, but may be slightly less imposing than the former.

*The Central Business District.*—The two squares should be directly connected by one, two, or three broad shopping streets. In the planning of this shopping zone, the governmental character of the city must be kept in mind. The people of a Commonwealth want to be proud of their State House, of the grounds around it, and of the city surrounding all. Thus, the shopping zone must answer this requirement. Streets should be wide and building heights should be well proportioned to the width. The building height limitation of the office buildings must be such as to avoid dwarfing the Capitol buildings.

*The Residential Zone.*—The residential districts should be built on similar lines. Here, more than anywhere else, must the capital city outshine every other city in the State. It must have attractive residential streets, ornamented by unusual horticultural treatment, with broad parkways, and curving roadways around creek and river beds. The apartment house zones should be placed around open squares of park. The residential district should be so inviting as to give every one of the State's citizens the desire to move to the capital city eventually.

*Industrial Zones.*—These should be carefully located away from the other zones, and should be on the outer border of the city. They can be made large enough to sustain a fairly large city. The residential areas essential to them should be placed between the industrial zone and the governmental area.

With the governmental square and the civic center located, the railroad station should be the third point of a triangle. The three features should be connected by direct and wide street lines and, possibly, by a boulevard running in a circle around the city's shopping center and connecting these three features. The station square must be attractive and set off by hotel buildings.

From each of these three center points, major traffic streets should run in all directions. Every point should have at least six different street lines radiating from it, and centering on the important building of its group—the State House, the City Hall, and the Railroad Station. The radiating street lines should be tied together by a circular boulevard surrounding the whole city.

This theoretical plan is naturally subject to the topography of the site. In case of the governmental group, it may be possible to select a high promontory, as was the case in Salt Lake City, where the State House towers over the Utah plains as the Acropolis once dominated Ancient Greece. Such an arrangement lends itself to great beauty, and a city should not fail to make use of it. The city center must bear a close relation to the shopping district, but there is no reason—if it were possible—why this square might not be on a second and lower hill, leaving the shopping center in between in a slightly lower area.

The time for low and relatively small governmental buildings will soon be passed. Capital cities must plan along bigger lines than they have dared to dream of thus far. The country has not reached its maximum growth, or population, by any means. At the rate of density of the population of present-day Germany, this country may eventually hold a population of 800 000 000 people. This means a sixfold increase, which is not only possible, but very probable. It will mean a proportionate growth in the cities, especially in the capital cities.

Denver is absolutely self-conscious in regard to its needs and its destiny. To be the capital city of a proud Commonwealth, it must be attractive for visitors; it must be good enough to live in; it must be clean and hospitable; and, even more, it must have the imposing character that the people can idolize.

## DISCUSSION

MORRIS KNOWLES,\* M. AM. SOC. C. E.—The City of Denver is one of the newer capitals of the West—one that has many rare combinations of outdoor expanse, scenery, and other attractions, the value of which is so well recognized that plans are being made not only for the city interior, but for all the surroundings.

The author properly calls attention to the fact that most cities of reasonable size, even if characterized by one particular line of activity, are, to a certain extent, cosmopolitan in nature. Few cities, like few persons, can well succeed in, nor are they destined for, a single-track existence. There are not many capital cities that claim to be devoted wholly to Governmental functions. Even in the National Capital, a well organized committee is having a survey made to discover whether or not more business can be attracted to the Federal City; and, also whether perhaps industry of a light, unobjectionable nature cannot well be conducted—not too near Governmental buildings.

Is it not true, then, that all cities, even capitals, must have a threefold purpose: (1) To provide homes—places in which to live; (2) to provide means of livelihood—facilities for working, doing, creating; and (3), finally, to provide for education, enjoyment, and recreation?

It may be worth while to pause for just a moment on the second stated object of cities, because there has been some change of feeling in the United States in regard to the strenuous competition between cities; there is some doubt as to the wisdom of the chambers of commerce, and of the people, in striving to enlarge and increase their cities, as if size alone were the desired object.

Much is heard as to how the city shall be made greater industrially or more important as a business market. There is discussion of a new activity called the "industrial survey"; an important and desirable review. Frequently, however, such survey has been confined to factories, types of industries (good and bad), market conditions, transportation conditions, etc. In consequence, it sometimes has become so concentrated upon these subjects of industrial supremacy, important as they are, that there has been a complete neglect of reckoning of the amenities, vital statistics, social values, community health, educational opportunities, governmental operations and effect of taxation system, the closeness of adherence to a good city plan and zoning; recreational opportunities, etc.

Thus, there has dawned on some a feeling that such communities are becoming unbalanced. That they are forgetting the complete development of which the author has written, and are devoting themselves to one thing. The Chamber of Commerce of the United States has called attention to the fact that there is danger in this kind of ambition and in this kind of survey when it attempts only to picture one's community as an aggressive, wise, thorough organization, seeking for industry and nothing further.

Study has been given, by the Civic Development Department of the Chamber, to the subject of what has been called a "Master Survey" Such a study

\* Pres. and Chf. Engr., Morris Knowles, Inc., Pittsburgh, Pa.

would review the community in a large and comprehensive way and would consider all municipal functions. After thus learning about itself and what it must do to make itself attractive to industry—and to the people and their families who will engage in such pursuits—the city will be ready for the more detailed analysis of what it should do to care for the manufacturing and the business which it hopes to secure.

The author has called attention to the subject of utilities. One often forgets that public utility planning is city planning. The city engineer may be said to have been the original city planner of America, because if he were "on the job", he never did anything without considering, as far as was humanly possible, what the future was going to be for that particular function, and how it was going to affect the growth and development of the city. As the author has wisely stated, one of the most important things for a city, particularly for a capital city, if it desires to proclaim itself as an attraction for tourists, is the water supply. This, in fact, is true of all forms of public utility service, but the Eastern cities never have been so seriously concerned with the question of water supply as those in the West because seemingly, but not absolutely, they are affected by less arid conditions. Nevertheless, their very prodigality has brought them trouble. In New York, N. Y., and Boston, Mass., for instance, it is becoming necessary to go farther and farther away for new supplies, because near-by sources have either become contaminated or polluted, or industrial wastes have made their use undesirable.

There is a Biblical truth which may be applied in such cases: "What is a man profited, if he shall gain the whole world, and lose his own soul?" To paraphrase, it might be said concerning some Eastern cities, "What does it profit a city to plan for wonderful industrial growth and allow the streams to become so polluted that the people working in the industries have no suitable drinking water?" And, conversely, "Where is the benefit if some large city of the arid West must provide its own needs by taking life itself from the very crops which are themselves needed for sustenance for the people of the city?" These things are by no means minor or insignificant phases of city planning. Cities must give way to the least important in all these problems if they are to have the well-rounded development necessary for people to live and exist as they should.

Mention has been made of the planning of Washington, D. C., and the creation, after some years of discussion and controversy, of the Capital Park and Planning Commission. This promises a new study and a new development commensurate with the dignity of the National Capital. In passing, it may be well to call attention to the rather important part which the Society has taken in the counsel and discussion, and in the decision, for wise legislation and the appointment of civilians to aid those in the official life of Washington, in providing that kind of planning which will insure a National Capital of which the whole country will be proud.

Recently, some interesting historical data have been brought to life in Western Pennsylvania, concerning the planning of what was intended to be a model community on the bank of the Ohio River, about eighteen miles below Pittsburgh. The plan itself antedates by several years the L'Enfant plan of

Washington. For information concerning this notable early bit of planning, credit is due to the Historical Association that has carefully preserved the records of what was known as the Harmony Society of Economites, a German religious sect whose followers came to this country in the early part of the Nineteenth Century. First, they settled at Harmony, Pa., on the Conoquenessing Creek. Later, they moved to New Harmony, Ind., an American hobby of Owen, the English mill owner. Finally, they abandoned this city because of an epidemic of malaria and, in 1824, moved to Economy, now Ambridge, Pa.

They were a frugal, careful, substantial people; they gained much of the world's goods and generally were considered to have a far-seeing wisdom. What is not generally known, however, is that they settled upon a site already laid out, which they bought from the heirs of one, Col. Isaac Melcher.

In 1786, Colonel Melcher and his associates secured from the Colonial Office a grant of 1000 acres and laid out what he and his friends thought would be the capital city of Westmoreland County, which at that time was practically all of Western Pennsylvania. Some streets were laid out to be 99 ft. wide and others, 66 ft. The locations of the important buildings and churches were indicated. The town lots were 44 ft. wide and 221 ft. deep. A square of ample size was provided for a large public building and this site, later, was utilized by the Economites, for what they called "the great meeting house". This structure still exists. The land now is under the control of a Board of Trustees appointed for the preservation of the early town and building. The old plan follows the rectangular plan originated by William Penn, and shows an early appreciation of the design of a capital city. This example truly represents that old-time phrase that "there is nothing new under the sun."

RICHARD R. LYMAN,\* M. AM. Soc. C. E.—This paper on the planning of Denver, Colo., prompts the speaker to add his thoughts, especially with respect to street numbering. In Salt Lake City, Utah, the streets extend north and south, east and west. Most of them are 8 rods (132 ft.) wide.

For one who has been brought up on this system to be required to find his way in a city with streets so named that they do not indicate their location or their relation to one another, is an exasperating experience. People endure these conditions without complaint chiefly because they are accustomed to them, and do not really comprehend the great inconvenience.

Beginning at the Temple Block, the streets in Salt Lake City are numbered and named as follows: First South Street, Second South Street, Third South Street, etc.; First North Street, Second North Street, Third North Street, etc.; First East Street, Second East Street, Third East Street, etc.; and, First West Street, Second West Street, Third West Street, etc.

The houses are numbered east and west from Main Street and north and south from South Temple Street. Thus, there is no limit to the area over which such a system of naming and numbering streets and houses can be carried.

\* Civ. and Cons. Engr. (Lyman & Pack), Salt Lake City, Utah.

To each block there are one hundred numbers; therefore, the house number and the name of the street give at once the location of the house and its distance from the southeast corner of the Temple Block—the initial point. For example, No. 728 East on Seventh South Street is located 7 blocks south from the place of beginning and 7.28 blocks east of East Temple Street. After examining the maps of several American cities, it seems to the speaker that the streets can be given numbers, and that the numbers can run north and south and also east and west from the two streets selected as the initial streets.

A stranger needs no map of Salt Lake City. In a few moments he can learn how to find his way to any address.

Some have objected to this method of numbering streets and houses on the ground that it would be like putting a man in a filing case with a number on him. Is not that the best method of putting away anything that is to be found again?

For purely business reasons it will be to the credit and advantage of any city to have its streets and houses so numbered that any one in any city can find easily the place he is seeking. The speaker has examined the maps of numerous cities with the thought of solving this problem in this way, and he is convinced that such re-numbering would be a comparatively simple matter.

WILLIAM T. LYLE,\* M. AM. SOC. C. E. (by letter).—The selection of "The Queen of the Plains" as the first of American capital cities to receive the attention of the Society is an appropriate one. Denver stands unique in many respects and should embody in external characteristics the civic consciousness of an extensive region.

The engineer in his conception of city planning is apt to drift into materialism. In the design of capital cities, even more than in others, the planner must avoid an emphasis which might be characterized as materialistic. Of course, the city must be a comfortable and healthy place in which to live, with every consideration given to those matters which facilitate trade, promote industry, and simplify transportation; but it must be much more than this. It must be a concrete expression of noble civic ideals.

Denver has unquestionably sensed several of these ideals and is bringing them out in the new city plan. The capital of Colorado is fortunately situated, as those who have seen the Rockies from the Capitol Building and have viewed from Inspiration Point, a glorious mountain panorama extending from Long's Peak in the north to Pike's Peak in the distant south, can testify. In addition to parks, boulevards, and a civic center within the city limits, advantage has been taken of splendid opportunities for the acquisition and development of mountain parks. In her civic center the majesty of the law and the universal dispensation of justice are held up to view.

There are other ideas and ideals that should be emphasized, some or all of which may be in the minds of the planners. Denver eventually will become an historic center and should perpetuate in visible expression the early life of

\* Prof. of Civ. Eng., Washington and Lee Univ., Lexington, Va.

what was at one time a frontier, and, later, became a great mining center in the rush for gold.

The writer would suggest an emphasis on humanitarianism, charity, and morality without which civilization cannot survive. It would seem proper, especially in a city which has featured moral reform among the young, to bring out the idea of civic righteousness. Instead of zoning eleemosynary institutions practically off the map, they should be featured properly in the city plan. In medieval times, before the separation of Church and State, the Dom was featured prominently and was often the center of an attractive "street picture". To-day, the location of the city's churches should receive due consideration by the city planner in order to emphasize the religious idea in the life of the American people.

GEORGE H. HERROLD,\* M. AM. SOC. C. E. (by letter).—The planning of a capital city requires a different conception of functions than that of the ordinary commercial or manufacturing city, although the plan must provide for those necessary adjuncts to city life—banking, retail business, industry, transportation, and housing. In considering a capital city there must be a clear thought of its political character. It is the State's city; the seat of Government; the home of certain elected officials representing the Commonwealth; and the people of the State have an interest centered in this city that is dominant and must be recognized.

The State Capitol Building is and should be of fine architecture. Its satellite office buildings for housing the various State activities should be placed to form an architectural grouping, a State Civic Center, noted for the nobility of its structures. Here is located the Governor, the State Supreme Court, and certain Constitutional officers, such as the Secretary of State, State Treasurer, and State Auditor. The members of the Legislature (and these members are of no small number) must be properly housed during the Legislative session, which may be for one-third of the year. All these people must be provided with offices of a type and character consistent with the dignity of a great State.

In addition to the business of Constitutional officers, there are many activities carried on by the State Government and under State supervision which are not found in any other city. In general, there are the following departments which require buildings to house officials, their technical and clerical forces and equipment: The State Automobile Department; the State Department of Agriculture; the Bacteriological Laboratories of the State Department of Health; the Adjutant General's Department; the State Highway Department with its locating, construction, and maintenance engineering departments, drafting rooms, testing laboratory, and purchasing department; the Department of Conservation; Drainage Department; Geological Survey; Forestry Department; the State Dairy and Food Department, with chemical laboratories; the State Department of Education; the Grain Inspection Department; the State Department of Health, Division of Preventable Diseases; and the State Department of Health, Division of Sanitation, includ-

\* Managing Director and Engr., The City Planning Board, St. Paul, Minn.

ing the engineering forces for inspection and supervision of construction of sanitary work, such as sewage disposal.

There are also the State Immigration Department; State Department of Insurance; Labor and Industrial Commission; the Livestock Sanitary Board; the Nursery and Orchard Inspection Service; the State Nurses Examining Board; the Professional Engineers Licensing Board; the Department of the Public Examiner; the Department of Public Property; the Department of State Parks; the Railroad and Warehouse Commission with its technical staff; the State Securities Commission; the Surveyor General's Office; the State Tax Commission; the Game and Fish Department; the Reforestation Service; the Department of Weights and Measures; the Division of Banking; the State Sanitorium Advisory Commission; U. S. Department of Commerce Office; Board of Control; Feed Inspection; State Humane Society; State Inspection of Hotels; State Board of Investments; State Boiler Inspector's Office; the Board of Pardons; Department of Rural Credit; State Weed Inspector; and the State Law Library.

To add still further to the political atmosphere of a capital city, the Federal Government is here represented by the U. S. District Attorney and the Federal Court, the U. S. Marshal, Customs Office and Internal Revenue Officials, the Prohibition Administration Service, the U. S. Bureau of Animal Industry, the U. S. Agricultural Bureau of Markets, the Army and Navy Recruiting Offices, the U. S. Civil Service, U. S. Veterans Bureau and Veterans Hospital, the U. S. Weather Bureau, the Meteorological Station at the Airport, the U. S. Engineer's Office, the U. S. Bureau of Public Roads, the Secret Service, Public Health Service, Feed and Grain Inspection, Food, Meat, and Drug Inspection, Banks of the Federal Reserve and Land Bank System, and the U. S. Forest Experiment Station.

All the people in these departments have a governmental or political complex. They are interested in Government, its personnel and its method of doing business. Their engineering and architectural conceptions are based on governmental practices. They are a group who think along different lines and who have a different viewpoint from those engaged solely in trade and commerce.

A proper consideration of the housing of these departments leads to important and rare possibilities in the matter of location and design. All have distinct functions and require a definite type of office space. They should be located for the convenience of the citizens of the State who transact business in these departments and for the convenience of the officers themselves for inter-communication. In fact, a large number of the people going and coming by train, bus, automobile, and air have some business with the State or Federal Government, or its various governmental departments, and they travel to and from the capital city on Government business; their secondary interests are social, other interests and business being incidental.

The streets leading to the Capitol and Capitol grounds should be of special design. They should have a cross-section for two or three roadways, separated by park strips, two wide one-way pavements, wide sidewalks, ample boulevards—all carefully landscaped; or three roadways, one major traffic

lane, with side service roadways to serve abutting buildings. This requires a way of considerable width which is necessary in a Capitol group. The buildings will be of a monumental character, the streets must be wide and spacious, the street appurtenances must be designed in a generous way, and the public utilities such as sewage, water, message, heat, light, and transportation require special engineering treatment. The natural development along such an esplanade would be buildings of public and semi-public character, such as club houses, churches, lodge temples, hotels, theaters, and small shops of a high-class character. Retail business, however, should be on parallel and cross streets, in order that it may carry on the same as in any city and develop its own characteristics and spirit of business, separate and distinct from the State Capitol development. These things are controlled by proper zoning.

To carry out the idea of a State Civic Center there must be whole-hearted co-operation between the State Department in charge of grounds and development for the State and the City Planning Department of the city. The thoroughfare plan of the city should be co-ordinated with the Capitol approaches and so designed as to create fine vistas. The zoning of traffic is also necessary so that heavy trucking and commercial vehicles may have streets of their own on which to travel, and not be required or permitted to move over the esplanades and semi-parkways designed for approaches to the State group.

The State Civic Center is a unique and interesting development, superimposed upon the commercial district of the city and so placed that it will not interfere with its commercial expansion. At the same time, it should be the show place within the business center or adjoining it.

Capital cities are peculiarly political regardless of their commercial or manufacturing interests. The social life is a political social life and the State's activities will more or less dominate the character of the city despite other conditions.

As pointed out by Mr. DeBoer, the people of a Republican Commonwealth are no longer interested in diamond-studded uniforms or decorations for their officials. They have transferred their admiration and allegiance to fine architecture as depicting the spirit, culture, vision, and economic importance of the State. They demand architecture of rare distinction in a pleasing setting. They are style conscious in architectural motifs and the design and placement of State edifices. The buildings must have beauty both inside and outside, and the grounds must give an air of spaciousness brought about by fine landscaping and the proper spacing of buildings, forming a major development of the city. The people of a capital city are beginning to recognize these things, and the people of a State are impressing it upon the people of the capital city that there must be full co-operation in the development of the Capital Civic Center, which will place both the city and the State before the world as built by a people of vision and engineering intelligence.

St. Paul is the capital city of Minnesota. It is a metropolitan city, and the fourth or fifth largest capital city in the United States. It has

one of the finest Capitol plans of any city in the United States, except the Nation's capital—Washington. When Mr. Cass Gilbert was supervising the construction of the Capitol in 1903, he made tentative sketches of the possibilities of the approaches to Capitol Hill. In 1907 he was definitely employed by the City of St. Paul to prepare the State Civic Center Plan, so that the city itself in all its proposed street widenings, in the acquirement of down-town parks or public squares, and in the construction of public buildings, could co-ordinate them with the Capitol Plan. During the years intervening the State Historical Building was constructed and grounds have been acquired from time to time in accordance with this plan. Nothing has been done by the City of St. Paul which would interfere in any way with the complete development of the State Civic Center.

A State Office Building Commission authorized to expend \$1 500 000 for housing State offices has referred back to the Legislature the question of location and number of buildings. This was brought about by State-wide protest against proceeding without first adopting a State Capital City Plan.

The question of the State's interest in a State Civic Center has been settled in Minnesota, and the future development of Minnesota's capital city will be made in accordance with a plan.

S. R. DEBOER,\* Esq. (by letter).—The discussion by Mr. Knowles points out very correctly that, after all, a capital city is, in the first place, a city in which places to live, to make a livelihood, and to enjoy education and recreation must be provided. The presence of Government offices in a city is secondary to these general problems of municipalities at large, and in essence the question comes to this, that they form one of the many sources of livelihood that a city must have. The importance of the Government center decides whether or not its influence on the life of the city is an important one. There are in the United States a great number of small cities—State capitals—to which the State offices form one of the major single items. In the city's business life this must be fully acknowledged and to a certain degree the city should be built toward it. The average citizen of a Commonwealth may be ever so much opposed to taxation, but to have a capital city of which he must be ashamed is beyond his conception. In other words, it must perforce become a "dress-up" city that equals or surpasses others in the State in attractiveness and compares well with other capital cities.

Whether a capital city should not encourage industry and commerce must depend on the relative importance the Government offices hold in its business life. Nearly every capital city will find it to advantage to have some industry and commerce, and to such large cities as Boston, Mass., these overshadow the Government business to such an extent that the latter becomes of minor importance. Even in a small capital city, where the State offices are extremely important, industry can be safely encouraged if it is located in a carefully selected district. Any city is much better equipped by having many sources of livelihood rather than just one, but if the Government offices play the important rôle of being the main resource, the city authorities should fully recognize the fact and build to it.

\* City Planning Consultant, City of Denver, Denver, Colo.

Denver is to a great extent a governmental city and the administrative offices play an important part in its business life. It is not only the Capital of the State of Colorado, but its citizens consider it more or less a Western Capital of the Nation. It has a very large number of Federal offices and a tremendous territory is administered to from this center. In Denver's business life the Government offices have become of unusual importance through the fact that climate and mountain scenery have made it a National recreation center as well, in a sense similar to Washington, D. C. Tourists form a good adjunct to the business life of Colorado's Capital City.

Mr. Knowles' reference to the industrial survey is timely. Too many cities have concentrated on getting industries at the expense of neglecting the building of a desirable city. The aim must be, in the first place, contented, healthy, and educated citizens. If for this purpose more industry and business are necessary, well and good, but to encourage the latter for the mere sake of greater population and higher real estate values is as absurd as it is frequent. In generations to come many cities which have overdone industrial efforts may have to demolish what has been built now, in order to create better living conditions. The writer agrees fully with Mr. Knowles that the city engineer was the first city planner. Many cities owe their conditions, good or bad, to the city engineer. He has considered every improvement in its value to the city as a whole, and he has done this work with a loyalty and earnestness that characterizes the profession. His main handicap has been the lack of a study treating the whole city as one entity, rather than many separate parts and in such a way that fundamental lines of development are laid down for a long period to come. The few engineers who did follow these lines must have realized the difficulty of getting elected councils to follow their imagination. The present age with its highly specialized work is more inclined to relieve the city engineer of the burden of city planning and leave this to specialists, and thus allow the engineer more time for his already complicated work.

In many respects Denver has problems that are the very opposite of those of other communities. Many cities on lake or ocean fronts are battling the problem of drainage. Denver is a mile above sea level and is the heart of the greatest semi-arid region in the country. Farm lands must be irrigated in order to yield heavy crops. The city is surrounded by large areas of these irrigated farms and they stabilize its growth and real estate values. Great care is exercised by the water authorities to see that in the growth of the city this farm water is not used for domestic supply. The domestic supply returns to the river bed several miles below the city limits; a use of the water from farms above would mean the shifting of irrigated land with a possible shifting in the growth of the city. Arrangements are being made to bring water through the Moffat Tunnel from the western slope of the Rocky Mountains for use in Denver. This water will not be needed for many years, however, and the additional storage now being planned will provide water from the eastern slope sufficient for probably 25 to 50 years' growth.

In Mr. Lyman's discussion the very interesting numbering system of Salt Lake City, Utah, is described. This system is undoubtedly of great practical

value. Many cities have followed the plan of naming streets after their leading men. There is a more human factor in this practice than in mere numbering. It has often seemed to the writer that the names of streets should indicate to what they lead, such as Capitol Avenue, University Avenue, etc. This would not be practical for large numbers of streets, but would well be possible for the more important avenues.

The plan of Salt Lake City, with its blocks 660 ft. square and its streets 132 ft. wide, presents an unusual problem in city planning. The wide streets are of great value in present-day traffic. Just how far the interior of the large blocks will prove to be practical the future must tell.

In his discussion, Mr. Herrold confirms the thought that the writer tried to express, namely, that the people in a capital city must clearly understand its function; they must realize its position in the eyes of the citizens of the State, and they must strive to build to attain that position. A State Civic Center with broad parkways leading to it embodies considerable of this thought. Denver has undertaken this in its Civic Center, which is a continuation of the Capitol grounds. The two have been developed in such a way that a harmony exists, which makes a general State center out of them.

The suggestion embodied in Mr. Herrold's discussion of broad parkways leading to the capital buildings and fronting them with buildings, such as lodges, churches, etc., is a very attractive one. The time will come, perhaps sooner than can now be predicted, that such semi-public buildings can be forced to a location of this kind by zoning provisions. Some zoning men frown at this statement, but the step to a definite regulation of this character, with many more of its kind, is much shorter than the original step to zoning.

The City of Cheyenne, Wyo., is working more or less in this direction. It is constructing all its lodge buildings and some of its churches on Capitol Avenue; it has plans for a State center. Some of it is a conscious effort and some perhaps subconscious, but the results are very promising.

In closing this discussion on capital cities it may be of value to recapitulate the governing ideas brought out:

- First.*—A capital city must recognize its position in the State and Nation and try to express the pride of the citizens of its political entity.
- Second.*—It must carry out this idea with, and not in spite of, its following the usual building program of any city.
- Third.*—It can encourage industries and commerce, but must be careful in their location on the plan of the city.
- Fourth.*—It must lead its State or Nation, not only in beauty of civic buildings, but also in beauty of residential and business sections.
- Fifth.*—It must lead where others can be contented to follow.

Paper No. 1758

### GOVERNMENT RECLAMATION POLICY IN BRITISH INDIA\*

By E. S. LINDLEY,† M. Am. Soc. C. E.

WITH DISCUSSION BY E. R. FOY, Esq.

#### SYNOPSIS

This paper describes the British Indian land-holding and revenue system based on ancient custom; how, in the Punjab, water is given, and charged for; what land is reclaimed, and how. Without attempting a comparison with America, attention is drawn to points that seem to be of value. Data are given which show the magnitude of irrigation and reclamation works which seems not to be realized in America.

Efforts of the British Government in the Punjab cover nearly all the reclamation work of India. In a pamphlet, "Federal Reclamation, What It Should Include", Elwood Mead, M. Am. Soc. C. E., devotes a section to "What Other Countries are Doing". In this, facts and even mention of India and Egypt are conspicuously absent. This is not an omission that is unimportant, for it is believed that the 27 500 000 acres annually irrigated in India are more than one-half the irrigation of the whole world. Of that in India, more than 40% is in the Punjab; the 5 000 000 acres of desert Crown Waste populated by canals constitute more than 20% of the area served by existing canals in the Province, and schemes under execution or projected will double that area of reclamation. Moreover, these data do not include privately owned desert land. In what follows, costs have been translated into terms of American money, for convenience.

\* Presented at the meeting of the Irrigation Division, San Diego, Calif., October 4, 1928.

† Superintending Engr., Indian Public Works Dept., Punjab Irrig. Branch (Retired), Wotton-under-Edge, Gloucester, England.

## THE ECONOMIC PROBLEM AND ITS SOLUTION

The reclamation policy of the Punjab Government has grown up from experience, starting from certain points of fiscal custom which must be described for proper understanding. Immemorial custom handed down from previous administrations prescribes that private "ownership" of land is subject to payment of the Government Land Revenue, or rent, as a first charge; in fact, in the last resort land may be sold to recover unpaid revenue. The owner may cultivate the land himself, or may let it to tenants. Such tenancies may be as firm as the ownership itself, subject only to payment of the agreed rent to the owner; or they may be ordinarily terminable at will.

Certain large desert tracts that were uncultivable because of their aridity were "Crown Waste", subject to no rights of ownership. Questions of "reclamation", called "colonization" in the Punjab, arise only where such Crown Waste is brought under irrigation.

The Punjab covers 65 000 000 acres, inclusive of mountains and areas with sufficient rainfall, of which, 21 753 000 acres are within the irrigation limits of Government canals already completed. Of this area, 4 726 000 acres were formerly Crown Waste; 11 160 000 acres was the average annual irrigated area (measured field by field) in 1922; and the tendency of growth is still upward apart from the opening of new canals. Canals now under construction in the Sutlej Valley Project provide for covering 8 878 000 acres, of which, 3 821 000 acres are Crown Waste; other canal projects which have been framed for successive execution will bring the area covered to a total of 35 327 000 acres, of which 9 674 000 acres in all are, or were, Crown Waste. The largest single block of Crown Waste was on the Lower Chenab Canal—2 300 000 acres out of a total of 3 391 000 acres covered; this canal irrigates more than 2 500 000 acres annually.

The customary revenue taken by pre-British Administrations was "in kind", by division on the threshing floor; the fraction taken varied, but was most commonly one-sixth of the gross produce, at least in theory. The British Administration soon based its demand on the net produce, and substituted cash rents; the fraction applied to this smaller amount was soon fixed in theory at one-half. The British claim may be described as one-half the economic rent in theory, but actually only from one-third to one-quarter is charged. The change to cash rents based on net produce obviously involved a system of assessment of agricultural profits. Such assessment, called a "settlement", is repeated at intervals, generally of twenty years.

Where the conditions affecting agriculture are relatively stable, the revenue to be levied is fixed and distributed over all the cultivable land; in bad years, its collection may be postponed, or even remitted. Where the conditions are less stable, the revenue is reduced to acreage rates to be levied season by season on the fields actually cropped; and in bad years the revenue may be reduced or remitted.

Proprietary lands to which irrigation is extended are generally under the latter ("fluctuating") form of assessment, because rainfall is uncertain. For land that can be given water, the "dry assessment" is then increased by a

"water advantage rate", this being the revenue on the increase of rental value due to irrigation facilities. The total "wet" assessment for such land is now about \$1.70 per acre in the year when cropped.

Water is also charged for at acreage rates per crop season, levied only when water is actually used; these average about \$1.70, varying from \$1.00 to \$4.00 according to the crop grown. These rates are fixed partly on the value of the crop and partly on its water requirements. They are deliberately fixed very much below the commercial value of the water, which must approximate what it would cost a cultivator to water his land from a well with bullocks, say, \$9.00 per acre per crop. On a small group of private inundation canals, instead of the water rate, the proprietors take "chauharimi", one-quarter of the divisible produce on the threshing floor.

There are no water rights enforceable at law, on the supplies delivered by Government canals. It is the policy of the Government to supply water to all whose land is so situated as to be able to take it, to such extent as water is available. This policy is followed impartially. Occasional proposals to penalize villages or individuals by withholding water, have invariably been disallowed, and frequent discontent is caused by refusals to reward loyalty or services by extra water. A project now under execution provides largely for irrigation in States under Indian Princes. Apart from the duty incumbent on any civilized administration, its interests are to exploit resources to the greatest benefit of the community as a whole. The degree of these interests can be judged from the fact that the net revenue derived from the construction of canals, a return of nearly 20% on the capital invested, constitutes more than 40% of the total revenue of the Punjab.\*

When irrigation is extended to a tract, it is divided into zones according to the depth from the surface to ground-water. For each zone a percentage of the total area is fixed for which water shall be provided; it is lower for proprietary land (which can be cultivated to some extent without canals) than for Crown Waste to be reclaimed (which it has not been possible to populate at all without a canal). These percentages range from 25 for proprietary land with ground-water within 20 ft. of the surface, to 75 for Crown Waste with ground-water more than 40 ft. from the surface. The ratio of irrigation proposed in the summer and winter seasons is also fixed, as well as the summer and winter discharges at heads of farmers' ditches, per acre of proposed irrigation. Higher rates of discharges are given to some poor lands which need more water. These quantities, applied to the area to be served by each farmer's ditch, give the discharge to be delivered there; the outlets at the heads of farmers' ditches are designed to deliver these discharges. If the summer rate is higher than the winter rate, the outlet is designed for that, and in winter the time of delivery is reduced according to the supplies actually available. That the designed rates of supply are liberal is shown by the irrigation accomplished; this is 1.21 times the proposed irrigation for the entire

\* The Lower Chenab Canal, which brings in two-fifths of this revenue, pays more than 50%; but this is not profit calculated in a commercial way. Water rates alone minus working expenses are 10% for the whole Province and 22.5% for the Lower Chenab Canal. The remainder is accounted for partly by enhancement of land revenue for irrigation facilities, and partly by land sales; it is not clear whether the last is interest on total realizations to date, or instalments received during the year.

system of canals in the Punjab for which supplies are secured by weirs (85% of the whole).

Before the recent introduction of "semi-modules" for outlets, it was impossible to determine the average discharge—the criterion in judging complaints of insufficient supply was then the area actually irrigated. If an outlet were found to be irrigating less ground than proposed, and this was not accounted for by waste or by intentional limitation to support the complaint, the size of the outlet would be increased (after approval by competent authority, and not merely by the local assistant engineer). Some engineers would even admit as the criterion not merely the proposed irrigation, but the ratio actually achieved in the neighborhood. With the introduction of "semi-modules" the criterion is becoming the discharge actually delivered, as it should be; this has the advantage of simplicity, and of no longer penalizing care and efficiency in irrigation.

When a new canal is opened, it is at first possible and necessary to give more than the designed supply to the land; this is gradually reduced as more land is developed. Under the conditions described, the originally designed area does not form the limit of development that is possible with a given supply of water. In some areas the ground-water level rises sufficiently to limit the supply that can be applied without harm, or even to water-log the land. In some cases actual irrigation has risen so far above what was proposed, as the result of improved distribution by the Government engineers (and, probably to a lesser degree, better irrigation by the farmers), that supplies can also be reduced. There is nothing to limit such reductions of present supplies, beyond the need to give fair and equitable treatment to present irrigators.

#### EXPERIENCE WITH THE LOWER CHENAB CANAL

The Lower Chenab Canal Colony is a good example of Punjab reclamation. It had 2 250 000 acres of Crown Waste, and serious inaccessability. The small blocks that were colonized previously in other places had afforded some valuable experience, although reclamation problems can hardly be said to have arisen. Since then, other areas have been colonized, some of them considerable, but principally after the Lower Chenab Canal had become an assured success; these will be referred to in noting points of difference.

The Province was predominantly agricultural, about 90% of the population being occupied with farming, and the inhabited parts were sufficiently crowded to cause land hunger. Peasants, however, are conservative—where the margin between earnings and needs is narrow and precarious, an Oriental feels less the impulse to rely on his powers and try to better himself, than the fear of losing even what he has. "A bird in the hand is worth two in the bush". Canals had not then achieved the conspicuous success they now have, and a serious failure might have stranded the whole population nearly a week's march even from drinking water. However, the Administration did not need to go beyond its own borders to find settlers.

The total of settlers required was divided into quotas for each district, for which the Deputy Commissioners in charge of the Civil Administration were

asked to nominate candidates. These quotas were presumably determined by relative degrees of crowding, and the quality of the peasantry. In some districts more difficulty was experienced in finding settlers than in others; in fact, it is often claimed that some districts made this an opportunity to export some of their undesirable characters; thus, the original quotas were not rigidly exacted.

In previous schemes settlers had also not been taken from the adjacent surroundings; in one case because of local opposition to the scheme; in the other because it was found that the attempt injured the proprietors by drawing off their tenants. In later schemes, it has gradually become a matter of selection from the crowd of eager applicants.

Settlers were sought for land grants of three orders of size: Peasants, to receive from one-half to two unit "squares" of 28 acres each; yeomen, to receive from three to five squares, which they would cultivate themselves with the assistance of hired labor; and capitalists, who were to receive larger grants to lease to tenants, and were intended to become the gentry and natural leaders of the new community. A small proportion of the area was sold by auction. In the first blocks, 67.5% of the area was granted to peasant colonists, 15% to yeomen, and 10% to capitalists. In later blocks, the first class was increased at the expense of the two latter, as these were found to be less satisfactory colonists.

The terms of course included payment of water rates, then about 80% of the present rates (but on a new canal water is always given free for the first few harvests); also land revenue, although this seems to have been only about \$0.50 for the first years. In addition to this revenue, corresponding to the revenue in proprietary lands, there was a payment to the Government as the proprietor. Yeomen had to pay \$2.00 per acre in two instalments, and capitalists from \$3.30 to \$6.60 on entrance; and both had the option to acquire proprietary rights after 5 years for \$6.90 per acre. Peasants were given tenancies for 20 years, with the option of acquiring permanent tenancy rights within 5 years and without payment; they were charged an annual royalty, apparently only \$0.125 at the start, in lieu of the rent they would have had to pay to a proprietor. About 20 years afterward, these peasants were given the option of acquiring proprietary rights for \$4.20 per acre, payable in instalments.

In addition, peasant grantees were from the beginning required to reside on their grants. Very soon the same condition was laid also on yeomen grantees, and the building of a house was further explicitly enjoined. All were required to join in digging a village well, in keeping the village less unsanitary than is customary in the country, in protecting the common land (roads, farmers' ditches, grazing grounds, etc.) from encroachment, and in planting a few trees. To protect them from their own improvidence, rights of alienation were restricted; and to keep control of the type of settler the customary rules of inheritance were limited.

In effect, the settlers were given the bare ground to start on. Boundaries had been demarcated, a village site and roads were located, and canals and farmers' ditches had been made ready to bring water to a point in each

holding. All else, from clearance of brush to the building of houses, was left to them.

In addition to the Deputy Commissioner appointed to ordinary civil charge of the new area, and the Canal Staff for technical duties and canal administration, a Colonization Officer of the Indian Civil Service was appointed for work in connection with selecting the settlers, allotting them their grants, seeing that they fulfilled their conditions, and all the work incidental to establishing the new population.

The writer has not ascertained the prices at which land was sold in the early colonization of this area. In 1896, when this colony was just beginning a rapid increase of irrigation, an average price of \$17 per acre was realized in another small and fairly accessible colony; while in 1904 the average price of a further small auction in the same colony was \$89 per acre. Now (1928), the average rent commanded by land on the Lower Chenab Colony is about \$6.60 per acre, while good land favorably situated commands three times as much. About 1916 land in the Lower Bari Doab Colony was sold during a land boom, and on occasion more than \$200 per acre was paid, for new unbroken land. The fee for which peasants were allowed to acquire proprietary rights had gradually been raised, and was then \$33.30.

To a proportion of grants on the Lower Chenab Canal special conditions were attached; some grantees were required to maintain a small area planted in trees; some were required to maintain a suitable mare for breeding remount horses or transport mules, and to give the Army the first right of purchase. Many of the "Janglis", the former nomad grazing tribes who were the only inhabitants of the desert, were required to continue to maintain camels, and supply transport for Army use when needed. In the Lower Jhelum Colony the bulk of the grants were made on horse-breeding conditions. An effect of this has been that the settlers are, on the average, a less satisfactory type of farmer.

In the earlier schemes, a proportion of the grants was earmarked for ex-soldiers and the races with traditions of military service. The colonization of the Lower Bari Doab Canal was still proceeding when the main recruiting effort for the European War was made, and to assist this the area earmarked for military grants was considerably increased. Including the scheme now under execution, a total of 387 000 acres has thus been specially set aside or given in military grants. This area does not include the grants mentioned previously, or special good service rewards of land given free of revenue demands.

In the earlier schemes only small areas were auctioned. As colonization of the Lower Bari Doab Canal was still proceeding when the period of difficult war, and early post-war, finance was entered, land sales were increased to meet the difficulty. In the scheme now under execution, land sales are providing an appreciable proportion of the capital needed for construction, thus decreasing the amount that has to be raised in loans.

The experience and now assured success of the older colonies make a modern colonization simple when compared with earlier efforts. Some of the

more obvious difficulties can easily be imagined. Before the colonists on the Lower Chenab Canal had settled down at all, a severe epidemic of cholera swept over them, and the Lower Jhelum colonization was interrupted by plague. If allowance is made for picturesque description, some of Kipling's stories convey an idea of such situations, with a handful of Englishmen and their womenfolk heading a staff of Indians to manage a scared crowd. The Janglis did their best to wreck the scheme; they claimed ownership of the tracts they had roamed and grazed over, and the earlier administrators too lightly ignored the question of what to do with them, although the nomads of other deserts naturally would not admit them. One of their standing occupations was cattle theft, and by this and in many other ways they persecuted the settlers. This drove many away, and others frankly declared their intention of leaving as soon as free water ceased. However, the scales were turned when some years of good rainfall up to 1894 were succeeded by lean years from which the canal protected the tract; relatives and labor flocked in, and the settlers began to make good profits. Soon afterward a railway into the colony was opened and this improved the marketing of produce.

An internal question in this work of colonization and canal administration has been the fairness of the terms charged. The first colonization was so experimental that it was necessary to offer extremely liberal terms at the start, and to think more of the point of view of the settler than that of the taxpayer. As success was achieved, it became possible to take a wider view, and terms have gradually been raised. The question is debated from two points of view: The settlers' party asserts that the high rate of profit from these works means that they are being called upon to bear an undue burden; the opposite point of view is that these profits are really a measure of the extraordinarily favorable conditions for canal development, and that the charges are only a fraction of the true value of what is given. The settlers are drawn from the agricultural population of the whole Province, which is the bulk of the whole population; and, much of the Province being under canal irrigation, the bulk of the agriculturists are equally interested in low water rates. Opposition should come from those who are not in a position to enjoy cheap water and colony land—those whose taxation would be lightened if the charges were raised. Actually, this opposition is hardly vocal, and the Government has at the same time to voice the opposition and to judge the issue fairly. As a retired official of that Government, the writer simply presents these statistics without personal comment.

#### LESSONS LEARNED FROM INDIAN RECLAMATION

Without attempting comparisons with American conditions, it seems worth while to draw attention to some points that appear of value.

India has the obvious advantage, in its agricultural population, of a reservoir of settlers of the right stamp. Success has been greatly facilitated by the liberal terms given them; but these were made possible only by favorable natural conditions—ample supplies of water which could be brought cheaply to large blocks of flat fertile country.

By comparison with provinces in which canal engineers were restricted to the technical maintenance of channels, it has been found advantageous to make the engineers responsible also for revenue work, as that brings them into intimate touch with the results of their technical labors.

Instead of the canal management being in the hands of the farmers, who need consider only their own interests, it is in the hands of the Administration which is impartial. The branch of the Administration immediately concerned is often accused of bias, of considering too much the showing of profits to mark its efficiency; but it has not the sole voice in the Administration, and the data quoted make it possible to judge whether there is bias shown. Impartial management is an advantage toward securing efficiency.

Given an impartial administration, it is an advantage to have water rights in such a form that fair development is not checked. The system of water rights described is advantageous in permitting the exploiting of supplies greatly in excess of the minima.

It is disadvantageous that irrigation receipts go straight into the general revenue, and that funds for improvements depend on the general budget situation. This disadvantage in the case of Indian State Railways has recently been admitted and removed.

## DISCUSSION

E. R. Foy,\* Esq. (by letter).—The author gives a clear and interesting exposition of "colonization" as carried out by Government agency in British India. The problem of installing settlers on new lands in that country is shown to be a State function. The chief interest of this paper, therefore, lies in comparing methods used in India with those in the United States.†

In India, the control of all water rights is vested in the Supreme Government. Due regard, however, is being paid to the rights of the Native States which are governed by Indian Princes. If there is any clash of interests the matter is adjusted by arbitration. The projects for supplying irrigation water, either to old proprietary lands, or to new areas that are being colonized, are financed by the Government. An adequate income is obtained by means of water rates levied on each crop-acre irrigated, and by the sale of new lands to settlers. These projects are generally remunerative, but there are a few areas in which canals are "non-productive" and in such places irrigation projects are undertaken as protective measures to guard against periodic famines. In years of good rainfall, irrigation water is not needed, but there are years in which failure of the seasonal monsoon rains causes failure of all husbandry operations, thereby inducing heavy demands for canal water and thus increasing the income of these otherwise unfavorable projects. It must be realized, however, that no colonization programs are undertaken in areas where cultivation with natural rainfall is possible. Protective works are only provided for occupied or proprietary villages subject to periodic famines.

In America, it appears that at first there was no settled policy, and the earlier irrigation projects were the result of private enterprise. Some of these were for the mutual benefit of the local landholders and settlers, and others were purely speculative ventures. In some cases speculators disappeared as soon as they "had made their pile," leaving those unfortunates who had invested their money to carry on as best they could. Now, however, the Federal Government seems to be assuming complete control; but even on State irrigation projects the procedure does not appear uniform, and varying conditions prevail. Some settlers are required to pay full charges and costs, while others have special privileges as subsidies, remission of interest dues, etc. Assumption of complete control by the State, however, is a forward step and no doubt a uniform policy will be developed in due time.

When the writer was, in 1897, first posted to the Lower Chenab Canal Colony in the Punjab, "colonization" methods were just emerging from the experimental stage. Water was then plentiful, while land was available on absurdly liberal terms; but the difficulty lay in inducing settlers to break ground under adverse conditions in new surroundings, even when it held

\* Cons. Engr., Ilchester, England.

† "A National Reclamation Policy: Explanatory Statement, Regarding Report of the Committee of the Irrigation Division," by J. B. Lippincott, M. Am. Soc. C. E., and "A National Reclamation Policy: Economic Aspects of Federal Reclamation," by Elwood Mead, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., May, 1929, Papers and Discussions, pp. 1193 and 1207.

promises of wealth as an alternative to starvation in their old homes. After some years of slow progress, the Administration was just beginning to gain the confidence of the settlers. Since that time two other projects involving several millions of acres have also been completed and are now fully matured. There is now (1929) a fourth irrigation project being brought to completion, and there is a wild scramble for land at any cost. In the Sutlej Valley Project, 9 000 000 acres of new and old lands are being developed to expand irrigation in British India and in the two Indian States of Bahawalpore and Bikaner. Water was turned into one of the series of these canals on this project in 1926. Ultimately, this part of the project alone will develop 1 000 000 acres of new land in British India, and more than that in the State of Bahawalpore. It will also insure an adequate supply to a large area of old village lands in both territories. The settlers of to-day find it hard to understand the hesitancy of their predecessors thirty-five years ago in accepting the first farm lands offered on these projects.

Mr. Lindley refers to the political side of the question concerning high *versus* low rates. Fortunately, irrigation is not what is known as a "transferred" subject under India's "reform" administration. The ultimate decision on matters of policy rests with the Government and not with the Legislative Council; therefore, the danger of interference by political parties is not yet present.

Apparently, political influence is a factor in America. An eminent member of the U. S. Reclamation Service once made a short tour through the Punjab. In the course of conversation with the Governor of the Province the visitor said, "Keep irrigation out of politics. Do not give the farmers a vote." Coming as this did from a prominent citizen of democratic America, the Governor was rather surprised. The visitor then went on to explain that some rather good and financially sound irrigation projects in America had been either wrecked or quite severely hampered by candidates for election to Congress, who secured the settler's vote by promising either cancellation of the unpaid balance or postponement of payment if elected. This condition is verified by J. B. Lippincott, M. Am. Soc. C. E.,\* although he further explains that the State is beginning to adopt a more rigid attitude toward those who fail to pay.

An important detail not mentioned by Mr. Lindley is the absolute necessity of providing an ample communication system on irrigation projects before the arrival of the first settler. Of primary importance is the construction of a railroad. Next, all the main arterial roads and highways; and, third, the "feeder" roads to connect the main highways, the railway stations, and the near-by markets. These obvious conveniences were neglected forty years ago when the Lower Chenab Colony was first being developed, and no doubt that factor contributed greatly to the lack of enthusiasm for the new lands. In the latest of the developments (the Sutlej Valley Project) an existing railway was re-aligned so as to pass through the middle of the new colony, while a complete and carefully designed system of roads and main highways is being provided, and special marketing towns have been located at suitable points along the rail-

\* *Proceedings*, Am. Soc. C. E., May, 1929, Papers and Discussions, p. 1193.

road. In these towns the competition to secure building sites is particularly active and splendid prices are being realized. The extra cost of these conveniences is being recouped by the higher prices that the settlers willingly pay for the service, because they are no longer harassed by the difficulties of produce transportation, and isolation from their old homes.

The writer is fully in accord with the lessons with which Mr. Lindley concludes his paper.

Paper No. 1759

### REFLECTIONS ON THE STATUS OF THE ENGINEER

ADDRESS AT THE ANNUAL CONVENTION AT  
CLEVELAND, OHIO, JULY 9, 1930

By J. F. COLEMAN,\* PRESIDENT, AM. SOC. C. E.

For years there was a constant cry to the effect that the engineer did not receive the recognition which he deserved. Lately, the same cry is heard although less frequently. In the past there was much to justify such complaint, and even now there is some excuse for it.

It seems probable, however, that the engineer himself is in great degree responsible for such a state of affairs in that he has been until recent times almost inarticulate in the councils of men; and, at this date, while by no means silent, is heard far less frequently than he should be. It is astonishing how few laymen know what an engineer is and how he accomplishes the tasks allotted to him. For that situation, the engineer is more to blame than the layman; and it would be distinctly to his advantage to have others know more of him and his work than they now do. It may therefore profit the engineer to analyze the matter and to take steps to overcome this disability.

#### IN THE PUBLIC LIGHT

Leaders of the profession have preached for years on the desirability of its members taking part in civic and other public affairs, and as time has passed, these preachings have borne some fruit. The engineer is to-day more prominently in the public eye than he has ever been before, and without doubt this improved position has been brought about at least in part by those engineers who have given of their time and their talents to public affairs.

It has been stated that in the 1929 edition of "Who's Who in America", there are 2858 engineers and architects, among which number there are or have been 10 Governors, 13 Members of Congress, 2 Members of the Cabinet, and the President of the United States. There are also engineer presidents and a number of other engineer executives in large and important

\* (J. F. Coleman Eng. Co.), New Orleans, La.

corporations. The profession is represented in chambers of commerce and other similar organizations and, on the whole, enjoys a better position than it formerly did.

#### ADVERTISING THE PROFESSION

Notwithstanding these facts, there appears to be an almost abysmal ignorance on the part of the layman as to what an engineer is and does. He knows that the engineer builds bridges, but he has no conception as to the designing of such structures, which must precede the construction. He knows that the engineer builds subway systems, railways, manufacturing plants, and water-works, but his information does not extend to any conception of what the engineer must know and do to plan such works in an orderly and intelligent manner before the actual construction may begin.

From his contacts with the doctor in the sick room or with the lawyer in the court room, he has some idea as to how the members of those honorable professions function. He is practically never present, however, at any stage of the work of the engineer, except that in which the construction is in progress and manned almost wholly by laborers skilled and unskilled, and, therefore, he has no visual evidence of the guiding hand and brain of the engineer who planned the structure and who directs the details of its execution.

It is a fact that in his daily life the layman is in more frequent contact with the products of the brain and skill of the engineer than with those of any other calling, but he takes these things as much for granted as he does the sunshine and the rain. The water in which he takes his bath; the electricity and gas which furnish light and fuel; the transportation agencies which bring his food to his door; the street railway, the automobile, or the railroad, which conveys him to his office; the office building itself, with its equipment of elevators, heating system, etc. All these are the products of engineering achievement as are countless other items of daily use, such as the telephone, the telegraph, the radio, and the airplane; but so far as conscious thought goes, to the average layman they "just happened", and he uses them without thought as to how they happened.

#### PLAGIARIZING OF A GOOD NAME

The World War was often spoken of and written about as an "Engineers' War", although it would be hard to find in any such spoken or written statement any information as to what made it such. As engineers, we have knowledge of those factors which caused it to be so designated. The various agencies whereby large bodies of men and large volumes of supplies were transported and handled; the various means of rapid communication, such as the telephone, the telegraph, and the radio; the submarine and the airplane; guns both large and small; and explosives of all classes and for all purposes. All these and countless other items important in war represent engineering achievement.

By reason of the prominence given to the name, "Engineer", during the World War, this designation attracted the favorable attention of people of

all classes, some of whom showed a desire to capitalize on the public favor by calling themselves engineers or by attaching the word, engineer, to the name of their trade or calling. We thus had Forgery Prevention Engineers, Milk Engineers, Feed Plant Engineers, Socio-Religious Engineers, Display Engineers, etc., *ad infinitum*.

While the profession may have suffered to some extent from such practice on the part of these unauthorized persons, it is certain that it was extensively advertised, and it seems fair to presume that it gained as much as it lost.

#### HANDICAP OF THE MODEST TEMPERAMENT

Without doubt, each profession suffers from some disadvantage by comparison with others. Among those from which the Engineering Profession suffers and must continue to suffer is the fact that so large a percentage of its members are salaried employees. Whatever his capacity, the salaried employee must attain a position of some importance in the organization to which he is attached before he can expect to receive much consideration outside that organization. In his contacts with other men, he is handicapped by being a subordinate. He cannot be the master of his own time, nor can he be as free and independent in the expression of his views as are those who both work and speak for themselves. Under such circumstances, he is far less likely to seek or to accept opportunity for public expression of his views than is the man of any calling who is not on anybody's payroll.

In the performance of his professional work, the engineer is far more accustomed to the quietude of his office, his drafting room, or his home, where he analyzes data, studies reports, and the like, than he is to making public talks or speeches. His whole training and experience makes him somewhat hesitant in presenting his ideas until he feels that he has fully matured them and is in possession of all available facts.

These considerations being understood, it is easy to see why the engineer has been more or less inarticulate, and it is surprising that he has progressed as far as he has into the public consciousness. No man or set of men will ever get very far or make much progress if satisfied with the *status quo*. A healthy state of dissatisfaction is necessary to progress in any branch of human endeavor. The somewhat remarkable progress of the Art of Engineering bears testimony to the fact that the engineer has that healthy state of dissatisfaction.

While no such progress has been made in the status of the engineer as in the state of the art, it does not indicate a satisfied state of mind with respect to the status. It is rather an indication that the engineer has a more lively interest in his work than in himself.

#### DUTY OF IMPROVING THE STATUS

In an attempt to bring about some improvement in the status of the engineer, the American Society of Civil Engineers has within the past few months adopted a program for the broadening of its activities so as to reach into fields not hitherto covered by it. Committees have been appointed and have begun to attack the problems assigned to them, so that work is now in progress in a

number of ways looking toward the desired end. The task is not an easy one, nor is it so definite in its nature as are many of the more technical ones which the engineer must approach. Also, it is a task which cannot wholly be accomplished by any number of committees. The task of the committees is rather one of determining upon the best means to be adopted to achieve results.

Each individual member of the profession has a duty to perform to attain the hoped-for ends. Each man may be and should be a "focus of infection" to his friends and neighbors and to others with whom he comes in contact. He should avail himself of reasonable opportunities to convey to the minds of others those things which the layman should know of the work of the engineer. To be most effective, there should be avoidance of anything like boosting or advertising of individuals in the interesting bits of information presented.

There are many most interesting facts which could be conveyed to laymen in ordinary conversation, or in brief talks, which would tend to create in the minds of the hearers a better understanding of the mental equipment necessary to the engineer, and opportunities for so doing are plentiful without the necessity for creating them.

#### PERSONAL AND PROFESSIONAL REWARDS

Those who avail themselves of such opportunities are almost certain to reap individual reward even though they do not seem to seek it. Every man who conveys an interesting bit of knowledge to a fellow man attracts some measure of attention and respect from that fellow man, and such respect and recognition by one's fellows in sufficient number will assuredly result to advantage in a material way.

The engineer is as anxious for opportunity to improve his earning capacity as any other man. He is as ready appreciatively to accept added income and better surroundings as the next one. It has been charged that he is not as ready and willing to assume civic duties which do not carry financial returns. It is more likely, however, that he is not tendered such duties so frequently as are the representatives of other fields of endeavor, and this for reasons which have hereinbefore been noted. Such assignments are not infrequently the means whereby a man may disclose his capacities, and they sometimes result in his advancement.

The engineer is apparently often overlooked in the community in which he resides, and he has always seemed less ready to push himself forward and to express his thoughts than are men in other avenues of life. It is only when a man has achieved some degree of prominence that his words are likely to be heard with respect and attention; and the engineer being in the mass modest, or one might say super-modest, appears to hesitate about taking issue on general subjects with other men who either have or assume positions of greater prominence.

#### THE SOCIETY'S OPPORTUNITY

Possibly local sections of the National Engineering Societies and local engineering societies may aid in bettering things. They may be able to foster

a proper public spirit among their members, and no doubt there are opportunities for them to put forward men for civic and other public work who will reflect credit upon themselves and upon the profession. The engineering societies and individual engineers should hold themselves in readiness to grasp opportunities of this nature as may come to them.

The American Society of Civil Engineers has now definitely set its feet in this direction and without doubt will continue in that course. With a reasonable amount of well-directed aid on the part of the individual members, it seems safe to predict good results. It is to be hoped, however, that as a profession and as a Society, we shall never become wholly "satisfied", as in that would lie inertia, atrophy, and, ultimately, dissolution.

Paper No. 1760

### CONSUMPTIVE USE OF WATER IN IRRIGATION

#### PROGRESS REPORT OF THE DUTY OF WATER COMMITTEE OF THE IRRIGATION DIVISION\*

WITH DISCUSSION BY MESSRS. HAROLD CONKLING, CHARLES H. LEE,  
AND M. R. LEWIS.

#### SYNOPSIS

This report proposes detailed definitions of the consumptive use of water in irrigation. It also calls attention to differences between the basic meaning of consumptive use and its application to the farm, the project, and the valley. Common difficulties in making a dependable determination of consumptive use are enumerated and briefly discussed. Experimental observations of consumptive use of water in typical irrigated valleys of the West are reported.

#### INTRODUCTORY

The rapid growth of American irrigation during the first quarter of the Twentieth Century has developed a keen public interest in a study of the disposal of irrigation water. The pioneers in irrigation had little opportunity

\* Presented at the meeting of the Irrigation Division, Denver, Colo., July 14, 1927. This report represents a part of the results of the work undertaken by the Duty of Water Committee of the Irrigation Division. A progress report on this subject was presented at the meeting of the Irrigation Division at Salt Lake City, Utah, July 9, 1925, by O. W. Israelsen, Assoc. M. Am. Soc. C. E. The present report has been prepared by Prof. Israelsen and includes, in addition to the material previously presented, further experimental data on consumptive use in different areas and analysis of the results.

Results of the work of the Committee on the "Determination of Duty of Water in Water-Right Adjudications" were published as Paper No. 1620, in *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 1074.

The membership of the Committee on Duty of Water is as follows: S. T. Harding, Chairman, Harry Barnes, Lynn Crandall, Augustus Griffin, Charles R. Hedke, O. W. Israelsen, R. I. Meeker, H. M. Murdock, R. L. Parshall, W. L. Powers, G. E. P. Smith, and O. L. Waller.

fully to ascertain what became of the water which they applied to their lands. That they lost some water by surface run-off was obvious; that some water was absorbed by the crops they grew was likewise apparent; but that large quantities of water percolated deeply into the dry soil was to them merely speculation, if, indeed, such losses were suspected at all. However, the gradual rise of water-tables, with resulting enlargement of natural springs and the development of new springs, and the seepage return to flood-water channels, to small creeks, and, finally, to rivers, gave increasing evidence concerning the magnitude of losses of water through deep percolation. Moreover, it was found through experience that much less water need be applied to the farms to produce profitable crops than was formerly believed necessary, and the areas of land successfully irrigated by the water from a given stream were greatly increased without any apparent increase in the water supply. Obviously, such increase in area of irrigated land could not continue without limit, some water being actually consumed by the growing crops.

#### DEFINITIONS AND ANALYSIS

Gross duty of water, head-gate diversions, and net duty are familiar terms concerning water uses, but "consumptive use" is a term of recent origin, and should not be confused with the net duty on land and other terms used in discussions of duty of water.

Some engineers have used the term, consumptive use, as restricted to "valley consumption", or net depletion of river flow, whereas others have used it to include water used from all sources, or total water consumption, irrespective of whether it was from river water, rainfall, carry-over soil moisture, or absorption from ground-water. It is believed that the use of the definitions given in this report will avoid confusion in the study of consumptive use of water, and comparisons of engineering data will thus be placed more nearly on a common basis.

The term, consumptive use of water, was used in Colorado nearly two decades ago by John E. Field, M. Am. Soc. C. E., then State Engineer. It has since been used in Court testimony concerning water supply studies in the Laramie River inter-state water litigation between Wyoming and Colorado; in the North Platte River Co-Operative Report between the U. S. Reclamation Service and the State of Wyoming; in the Rio Grande Basin water supply studies of the U. S. Reclamation Service; and in the Colorado River Compact deliberations in the several Western States. It has heretofore been defined by R. I. Meeker, M. Am. Soc. C. E., of this Committee, as:

"The permanent water loss incident to irrigation of large tracts of land. Generally speaking, consumptive use is the difference between the inflow and the outflow below any specific area under consideration, or the difference between the amount of water diverted and the amount returning to a stream. With respect to an entire river system, it is the net amount after deducting the outflow from the inflow."

To add convenience and brevity to the following definitions and analysis of consumptive use proposed by the Committee, mathematical symbols are employed and mathematical methods are followed, despite the fact that the equations are of a comparatively simple form.

*Symbols Used.*—The meaning of each of the more important symbols is fully given subsequently. For convenience of reference, the meaning of these symbols is briefly as follows:

Let  $U$  = consumptive use.

$U_f$  = farm consumptive use.

$U_p$  = project consumptive use.

$U_v$  = valley consumptive use.

$Q_h$  = quantity of available heat, in day-degrees, during crop year.

$e$  = evaporation from water surfaces.

$m$  = mean seasonal soil moisture content.

$s$  = the soil with all its influencing factors, notably potash, phosphorus, lime, humus, and nitrifying power.

$c$  = the kind of crop.

$y$  = the yield of crop.

$D_f$  = deep percolation losses from the farm.

$H_f$  = the total quantity of water supplied the farm.

$R_f$  = surface run-off from the farm.

$D_p, H_p,$  and  $R_p$  = project deep percolation, project water supply, and project run-off, respectively.

$E_p$  = project evaporation losses.

$E_v$  = valley evaporation losses.

$D_v, H_v,$  and  $R_v$  = valley deep percolation, valley water supply, and valley outflow, respectively.

*Consumptive Use in a Basic Sense.*—The consumptive use,  $U$ , is here defined as the quantity of water, in acre-feet per cropped acre per year, absorbed by the crop and transpired or used directly in the building of plant tissue, together with that evaporated from the crop-producing land.\*

The direct source of "consumed" water is the water in the soil in any form that crops can absorb it. The indirect sources of "consumed water" are those parts of the precipitation and of irrigation water which are stored in the soil in such depths and for such time as to permit direct absorption by crop roots, together with such water as may be obtained by the crop roots from the ground-water after such water is raised to the plant root zone by capillary action. The consumptive use as herein defined is, therefore, equal to the total evapo-transpiration plus the water used in the building of plant tissue.

It is natural to inquire concerning the factors which determine the magnitude of  $U$ . A statement of the major influencing factors is made in the following equation:

$$U = \int (Q_h, e, m, s, c, y)^\dagger \dots \dots \dots (1)$$

\* The consumptive use, as here defined, is not rigorously a correct application of the term, "consumptive," since the water which passes out of the crop leaves is not truly consumed. It is merely converted by the plant and the energy of the sun from the liquid to the gaseous phase. However, for the purposes of this report, water vapor in the atmosphere is considered beyond direct recovery by practical means, and hence the conversion of liquid water into water vapor is considered herein as consumptive use.

† Plant diseases and insect pests may reduce the crop yield,  $y$ , without proportionately reducing the consumptive use,  $U$ . Likewise, inefficient farm practices may change the relation between  $U$  and  $y$ .

It is apparent that most of the factors which influence the magnitude of  $U$  are themselves variable. The number of variables may be reduced somewhat under specified conditions; for example, if the soil of a farm is liberally supplied with organic matter and all the essential plant-food elements, so that the yield of a particular crop will be limited by the quantity of heat available and not by lack of moisture or plant food, it is possible to eliminate the last four factors in Equation (1) and write:

$$U = \int (Q_h \cdot e) \dots \dots \dots (1a)$$

In the light of the foregoing statements, it is unreasonable to expect that a precise experimental determination of  $U$  will give a definite magnitude that can always be considered rigorously correct. Engineers must use dependable approximations of the magnitude of  $U$ .

Knowledge concerning the magnitude of  $U$  is dependent on further analysis. Does  $U$  indicate consumptive use per acre on a particular farm, an irrigation project, or in an irrigated valley? Further definitions are clearly necessary.

Let  $U_f$  = "farm consumptive use";

$U_p$  = "project consumptive use"; and

$U_v$  = "valley consumptive use".

Definitions of each of these three modifications of consumptive use are considered desirable and are, therefore, proposed herewith.

It seems reasonable to assume that the public may expect the individual irrigator to account for all the water which goes on to his farm. With respect to a particular farm, the water applied is disposed of by consumptive use, plus surface run-off, plus losses from the farm by deep percolation.

*Farm Consumptive Use.*—Let  $D_f$  = deep percolation farm loss, in acre-feet per cropped acre per crop year. This loss usually cannot be measured with precision by direct means. Then, by definition, as used in this report,

$$U_f = U + D_f \dots \dots \dots (2)$$

It is important to distinguish between  $U_f$  and a related quantity,  $H_f$ , which is defined as follows:

Let  $H_f$  = the sum of: (a) The quantity of water delivered at the farm plus (b) the water taken from moisture stored in the capillary form before planting, or during the non-growing season plus (c) the crop-year rainfall plus (d) the amount absorbed from the ground-water—all in terms of acre-feet per cropped acre per crop year.

Let  $R_f$  = surface run-off from a farm, in acre-feet per cropped acre per crop year. Then, by equating the water going on to the farm plus rainfall and draft on soil moisture plus the quantity absorbed from the ground-water, ( $H_f$ ), to farm consumptive use, ( $U_f$ ) plus farm run-off, ( $R_f$ ):

$$U_f = H_f - R_f \dots \dots \dots (3)$$

Equation (3) gives an indirect means of arriving at the farm consumptive use.

*Project Consumptive Use.*—In order to define  $U_p$  and indicate an indirect means of measuring it, the following quantities are introduced:

Let  $D_p$  = the non-measurable deep-soil percolation and capillary losses, in acre-feet per project acre per crop year, from any project.

Let  $H_p$  = the sum of: (a) The area of measurable surface water which flows into the project plus (b) the crop seasonal draft on soil moisture plus (c) the depletion of ground-water plus (d) the crop-season rainfall, also in acre-feet per project acre per crop year. Items (b) and (c) may be positive or negative.

Let  $R_p$  = the sum of: (a) The surface run-off losses, in acre-feet per project acre per crop year plus (b) such deep-soil percolation losses as contribute directly to a measurable rise in the height of the water-table plus (c) the deep-soil percolation losses as may re-appear in natural or artificial channels at the boundaries of a project.

Let  $E_p$  = the evaporation losses, in acre-feet per project acre during the crop year, from the non-cropped area within the boundaries of the project, such as roadways, barnyards, towns, etc., together with the transpiration from natural non-crop vegetation within the project boundaries.

Then, by definition,

$$U_p = U + D_p + E_p \dots \dots \dots (4)^*$$

By equating inflow to outflow plus change in moisture content:

$$H_p = (U + D_p + E_p) + R_p = U_p + R_p$$

and, therefore,

$$U_p = H_p - R_p \dots \dots \dots (5)$$

Equation (5) gives an indirect means of determining the project consumptive use. It is important to note from Equation (4) that the project consumptive use includes two factors which are difficult to determine directly, namely,  $D_p$  and  $E_p$ . With poorly prepared land, porous soil, small irrigation streams, and great distances between the head ditches,  $D_p$  is likely to become excessive, possibly greater than  $U$ . It is not probably extravagant to state that, in general, project managers should endeavor to reduce ( $D_p + E_p$ ) to a minimum and thus decrease  $U_p$  until it closely approaches  $U$ . On some high land projects,  $D_p$  may be recovered and used on lower neighboring land. On such projects it is less objectionable to have  $D_p$  large although excessive deep percolation losses on high land usually decreases the productivity of lower areas.

*Valley Consumptive Use.*—In order to define  $U_v$  and indicate an indirect means of measuring it, some further quantities are needed.

\* Provided a relatively small area of the land within the boundaries of an irrigation project or valley is irrigated, the common practice of determining project or valley consumptive use by dividing the difference between the inflow above and outflow below the tract in question by the area of the tract is misleading even if the corrections for contribution of rainfall, draft on soil moisture, and absorption from ground-water are properly made. To illustrate:

Let  $W$  = the total water diminution on the tract, in acre-feet;

$A_c$  = the cropped area, in acres; and,

$A_p$  = the area within the project boundaries, in acres.

From Equation (4),

$$W = U A_c + (D_p + E_p) A_p \dots \dots \dots (a)$$

Dividing Equation (a) by  $A_p$ ,

$$\frac{W}{A_p} = \frac{A_c}{A_p} U + (D_p + E_p) \dots \dots \dots (b)$$

If the ratio,  $\frac{A_c}{A_p}$ , is small, approaching, say, one-half, then  $\frac{W}{A_p}$  is not equal to  $U_p$ , as here defined.

Equation (b) shows the importance of measuring  $A_c$  with a fair degree of precision.

Let  $D_v$  = the non-recoverable deep-soil percolation losses during the crop year recorded, in acre-feet per acre, based on the total area of irrigated land in the valley, that is, on the sum of the gross areas of projects within the valley.

Let  $E_v$  = the evaporation and transpiration losses from the non-cropped area of the valley per crop year, in acre-feet, divided by the gross area of irrigated land in the valley.

By definition as here used:

$$U_v = U + D_v + E_v \dots \dots \dots (6)$$

However, as in the case of a project, it is very difficult to measure  $D_v$  and  $E_v$  by direct means. This is particularly true of  $D_v$ , and, hence, other more easily measured quantities are introduced.

Let  $H_v$  = the sum of the following: (a) The acre-feet of water entering the valley in measurable channels during the crop year; (b) the crop-year draft on soil moisture; (c) the crop-year rainfall; and (d) the water derived from the ground-water divided by the irrigated valley area, as defined under  $D_v$  and  $E_v$ .

Let  $R_v$  = the measurable outflow, in acre-feet, divided by the irrigated valley area, as defined for  $D_v$  and  $E_v$ .

By equating inflow plus rainfall plus draft on soil moisture and ground-water ( $H_v$ ) to valley consumptive use ( $U_v$ ) plus outflow ( $R_v$ ):

$$H_v = (U + D_v + E_v) + R_v - R_v + U_v$$

therefore,

$$U_v = H_v - R_v \dots \dots \dots (7)$$

It is very important that consumptive use as here defined, either in its basic sense or as measured on a farm, a project, or in a valley, should not be considered as representing the quantity of water which the farmer, the project manager, or the valley community should be permitted to divert for irrigation purposes. In localities of very low crop-year rainfall, deep loam soils, favorable topography, reservoir storage for water when not needed, and other favorable conditions, it is possible that the quantities,  $R_f$ ,  $R_p$ , and  $R_v$ , will be reduced to a minimum, thus making  $H_f$ ,  $H_p$ , and  $H_v$  approach  $U_f$ ,  $U_p$ , and  $U_v$ , respectively, as Equations (3), (5), and (7) indicate would be the case. In general, however, such favorable conditions do not exist, and, consequently, there is no simple relation between the quantity of water necessary properly to irrigate a farm, a project, or a valley, and the respective consumptive uses.

#### COMMON DIFFICULTIES

Some of the more common difficulties in measuring consumptive uses under the cases considered, together with notes concerning their variability, are briefly given, after which some actual measurements are reported. The factors which cause variability in  $U$  at a particular place have been given in Equation (1). It is obvious that all the factors in the right-hand member of Equation (1) vary greatly from place to place. Based on elaborate experiments in Nebraska, Kiesselbach (10)\* concluded that "there is no such thing as a definite water requirement which is constant for any kind of crop";

\* Reference is made by number to literature cited at the end of the report.

and, similarly, there is no definite consumptive use. In Equation (2),  $D_f$  depends on:

- (a) The quantity of irrigation water applied in each irrigation;
- (b) The uniformity of distribution;
- (c) The frequency of irrigation;
- (d) The length of land irrigated in a single run and the size of stream used;
- (e) The texture of the soil and subsoil;
- (f) The depth to the water-table;
- (g) The dryness of soil between the water-table and the zone of root action, provided the water-table is very deep;
- (h) The kind of crop and depth of root zone; and,
- (i) The moisture conductivity of the soil and other less important factors.

In many localities,  $D_f$  was large during the early years of irrigation, but it is now relatively small because: (1) The dry desert soil to great depths has been fully moistened through the years of irrigation; (2) the land is better prepared for applying water; and (3) general improvement in irrigation methods has been made. The quantity,  $D_p$ , of Equation (4) is likely to be larger than  $D_f$  of Equation (2) since it includes deep percolation from canals, ditches, streets, yards, ponds, borrow-pits, and sloughs. It may be high on one project and negligible on a neighboring lower project.

To measure the evaporation and transpiration losses from non-cropped areas by direct means the engineer can measure the areas for which such losses occur and make an approximation. Relative to the  $(U + D)$ -quantities, such quantities are usually very small.

It seems advantageous, however, to endeavor to approximate the consumptive use on the farm, project, and valley areas by indirect means as indicated in Equations (3), (5), and (7). More detailed consideration of the difficulties of measurement and sources of error in the elements of moisture supply and run-off are, therefore, desirable.

Provided the farm, project, or valley considered has a deep uniform soil and deep water-table, the elements of supply may be measured with fair precision, but on gravelly or greatly variable soils the draft on soil moisture cannot be effectively measured. Moreover, moisture loss cannot be precisely measured on large projects or in large valleys without prohibitive expense; it can only be estimated. The rainfall may vary greatly from point to point; and it is, therefore, essential carefully to estimate percentage inaccuracy in the elements of supply which may result from rainfall variation, provided the rainfall factor is comparatively large. Possibly a still greater source of error is inflowing ground-water from neighboring high land, measurements of which are sometimes impractical.

In some of the larger valleys of the West, of which many in California, Colorado, and Arizona are typical, the inflowing ground-water is of great importance. Water from melting snows and rains in the mountain ranges may sink into the coarse textured soil of the valley rim immediately after leaving the canyons. These waters gradually move underground toward the middle or lower areas of the valley and may here form high water-tables,

thus supplying water for crop production. Under such conditions, this factor may make it impractical to obtain dependable measurements of the project or valley water supply.

In general, the measurement of surface run-off from the farm is neither difficult nor very expensive. Likewise, the measurement of project run-off depends on the particular project. On some projects situated as long strips of side-hill land, it is difficult to measure run-off. The measurement of run-off from valleys, in general, is not so difficult as it is from projects. Some valleys have deep canyon drainage outlets over impervious floors, and in such cases the run-off can be measured without serious difficulty. Some valleys have surface-flow and ground-water flow outlet drainage, but if it is evident that the surface flow greatly predominates, the measurement may permit a close approximation of valley consumptive use.

That the dependability of measurement of the consumptive use rests on a complete analysis of all these factors is not likely to be over-emphasized. Moreover, reports of consumptive use, for the farm, for the project, or for the valley, or, indeed, for any other area, should not be given great weight, unless they are accompanied by complete and detailed descriptions of the conditions under which they were made. Doubtless, in some localities, the relative magnitudes of the inaccessible inflow and outflow below the ground surface, or those under other conditions which render measurements impracticable, are so great as to make computations of project or valley consumptive use of little value if not really dangerous. On the contrary, the need for economic utilization of water from all sources and the urgency of being able to predict with a fair degree of accuracy the areas that may be adequately served by a given water supply seem fully to justify extraordinary efforts toward increasing the ability to measure consumptive use under specified conditions.

#### EXPERIMENTAL MEASUREMENTS

The literature on duty of water is voluminous. The Federal Department of Agriculture, through its Bureaus of Public Roads and of Plant Industry; the Department of the Interior, through the Bureau of Reclamation and the Geological Survey; the State Agricultural Experiment Stations; the State Engineers' Offices; and some private agencies are annually contributing substantial amounts of time and energy to a solution of the duty-of-water problem. In Canada, also, very careful study is being made of duty of water by public and private agencies. Some of the experiments thus conducted give a fair basis for determinations of the consumptive use and the farm consumptive use. Many duty-of-water studies have been conducted without measuring the water obtained from capillary soil moisture, and, indeed, some have failed to report the crop-year rainfall. Consequently, reference is here made only to those experiments which seem most directly to contribute toward a determination of consumptive use both in its basic sense,  $U$ , and in its modified meanings, for the farm, the project, and the valley, respectively.

#### CONSUMPTIVE USE, $U$ , AS DETERMINED FROM TANK OR POT EXPERIMENTS

Hammatt (2) and Stevens (19) have endeavored to determine the consumptive use from the crop yield on a given area and estimates of the evapo-

transpiration ratio. Most of the evapo-transpiration studies have been conducted in tanks or potometers. Kiesselbach (10) found that the limitation of the amount of soil used, because of the small capacity of the potometer, may be a great source of error in pot experiments. It seriously affects not only the transpiration relationships, but the entire development of the plant.

Other difficulties in determination of consumptive use by means of potometers are:

- (a) Obtaining the same atmospheric environmental conditions around pots as exist in ordinary cropped land.
- (b) Obtaining the same number of plants per unit area of land as occur under field conditions.
- (c) Getting the soil into tanks in the same physical conditions as exist in the field, thus permitting the same aeration and water movement.

The influence of these factors on the consumptive use is great enough to render the pot method of determining such use of questionable value.

#### CONSUMPTIVE USE AS DETERMINED ON FIELD EXPERIMENTAL PLOTS

Direct measurements of consumptive use in field plots are believed to be more dependable than measurements with pots or tanks. In order to permit measurements in the field, it is clearly necessary to use land in which the water-table is at a considerable distance below the surface, because when working with small field plots it is usually impractical to measure the quantity of water absorbed by the crop from the ground-water. It is also necessary that the irrigation water be applied in small units not to exceed a depth of 5 in. in a single irrigation on ordinary soils. Even a smaller quantity will often result in percolation beyond the depth of feeding roots in coarse-textured soils. Either very large unit applications of water at ordinary time intervals, or excessively frequent irrigations resulting in the maintenance of a high moisture content, is likely to cause an appreciable downward movement of moisture in the gravitational or capillary form, and thus give apparent values for the consumptive use higher than the true values. It is impracticable, by direct means, to measure the amount of such downward movement, and hence an attempt to measure the consumptive use under these conditions may give, in reality, the farm consumptive use.

When the percolate equals zero, the farm consumptive use equals the consumptive use; therefore, it follows that the consumptive use equals the supply less the surface run-off. In most of the field determinations of net duty of water, the run-off has been either carefully measured or reduced to zero by the proper preparation of the experimental plots. The supply factors, in general, have not been measured with precision even on plots where the great depth of the water-table has precluded the possibility of the crop receiving any ground-water. This is due to the fact that precise measurements of the quantity of water taken from capillary soil-moisture storage is practical only in comparatively homogeneous soils free from gravel, and that even under the most favorable soil conditions dependable soil moisture tests add greatly to

the cost of duty-of-water studies. There is, however, a growing need for more thorough duty-of-water studies in which the consumptive use will be determined for different conditions. In some such studies the consumptive use has been either determined or closely approximated, and of these the following are typical.

*Widtsoe's Utah Work.*—Widtsoe (23, 24) pioneered the measurement of consumptive use in field plots at the Utah Agricultural Experiment Station, beginning in 1902. This work was done on land having a water-table about 75 ft. below the surface; and, hence, it is reasonably safe to conclude that the crops obtained no ground-water and that the crop-season rainfall, the draft on stored capillary soil moisture, and the irrigation water furnished all the water to which the crops had access. There was no run-off from the experimental plots used by Widtsoe,  $R_f = 0$ . The deep percolation losses,  $D_f$ , were not measured. If these losses are assumed to be negligible, then,  $U = H_f$ , that is, the sum of the quantities, (a), (b), and (c), of  $H_f$  as used in Equation (3). Widtsoe measured these sources of water for 14 crops during the 10-year period, 1902-11, inclusive. Results for the 7 crops on which most of the work was done, are given herein. The crop-season rainfall used by Widtsoe was 0.42 ft. and the seasonal draft on capillary moisture in the upper 8 ft. of soil, varied from 0.10 ft. for corn to 0.83 ft. for alfalfa. Quantities of irrigation water were applied, varying from 0.42 ft. to 5.00 ft., and wide variations in crop yields were obtained. In the studies by the Committee the yields obtained by Widtsoe were plotted against the total water used, and, as a basis for arriving at the consumptive use, those yields were selected which appear to be most profitable. With nearly every crop, the yield increased rapidly to a certain point with increase of total water used, and then either decreased with further increase in water or increased very slowly, and at this "break in the curve", the value of  $U$  was taken. The results are given in Table 1.

TABLE 1.—CONSUMPTIVE USE AS DETERMINED ON FIELD PLOTS BY WIDTSOE AT THE UTAH AGRICULTURAL EXPERIMENT STATION, IN CACHE VALLEY, UTAH.

Crop.	Number of single trials.	Yield, in bushels, or tons per acre.*	Consumptive use, in acre-feet per acre.
Sugar-beets.....	152	21.3	2.5
Potatoes.....	124	267.0	2.2
Alfalfa.....	49	4.7	3.3
Corn.....	31	99.2	2.5
Wheat.....	142	45.7	2.4
Oats.....	29	80.7	2.5

\* Yields are given in tons per acre for sugar-beets and alfalfa and bushels per acre for the remainder of the crops.

Widtsoe's work indicates the importance of yield in determining the consumptive use. It is also important to keep in mind the fact that deep percolation losses from the plots on which Widtsoe worked would result in observed magnitudes of  $U$  higher than the true ones. It is far more probable that the given values of  $U$  are too high rather than too low.

*Snelson's Alberta Work.*—Working on field plots in Brooks, Alberta, Canada, Snelson (18) used moderate quantities of water in single applications and made careful measurements of soil moisture to a depth of 6 ft. at the beginning and the end of the growing season. Under his methods percolation loss in all probability was very small if not zero, and hence it seems safe to assume that  $U$  is equal to  $U_f$ . If percolation losses were zero, then according to Snelson's experiments with wheat on the more fertile soil the consumptive use varied from 0.85 ft. to 1.82 ft. as the crop yield varied from 10 to 50 bushels per acre. For oats on the more fertile plots the consumptive use ranged from 0.72 ft. to 1.75 ft. as the yield varied from 40 to 135 bushels per acre. Barley required a consumptive use from 1.25 to 1.60 ft. for yields ranging from 40 to 51 bushels per acre, and for alfalfa the use varied from 1.00 to 2.62 ft. for yields ranging from 1.0 to 5.7 tons per acre.

*Powers' Oregon Work.*—Powers (16, 17) has made many field plot measurements of consumptive use in Oregon. Experimenting with alfalfa in the Willamette Valley during 1911, using moderate irrigation he found values from 1.4 to 2.0 ft., accompanying yields of 4.1 to 5.2 tons per acre. The consumptive use for clover was approximately the same as that for alfalfa. Moisture determinations were made to a depth of 6 ft. at the outset in the Willamette Valley work, but as most of the borings showed a water penetration to only 4 ft., the later borings were not made below this depth except in connection with a few very heavy irrigations. Powers was convinced that there was "practically no loss by percolation" apparently because dry soil was frequently encountered in the lower depths and also because these lower depths in many instances gained in moisture content during the period following one irrigation and preceding the next following. It is doubtful whether this is conclusive since the increase in the lower depths may have been caused by a movement of capillary water downward from the moist surface to the dryer sections below. If such were the case, some percolation probably occurred and Powers' measurements would represent  $U_f$  instead of  $U$ . If, on the other hand, the moisture did rise in significant quantities from below the zone of soil sampling, then the value of the consumptive use as measured by Powers is too small as there was an unmeasured source of water. In reporting the Western Oregon work, Powers is silent concerning the depth of the water-table.

Further measurements were made in Eastern Oregon by Powers (17), but it is beyond the scope of this report to give them in detail.

*Utah Work by Harris.*—Further field plot work at the Utah Agricultural Experiment Station by Harris (6) and associates from 1911 to 1919 gives additional information concerning consumptive use. The results of this work, together with the work done by Widtsoe, have been reported in detail in fifteen *Station Bulletins* which were published as the work progressed. Finally, in one paper (6), Harris has brought together the results of seventeen years' work. This *Bulletin* contains six charts, each representing a different crop, which show the relation between the yield and the quantity of water applied. Two curves are plotted on each chart, the actual average yields for

the different irrigations being shown by dotted lines, and the average found by weighting the results according to the number of tests is shown by heavy lines. Harris did not report the seasonal draft of each crop on the soil moisture. For purposes of comparison, this has been assumed to be the same as that found by Widtsoe. Moreover, to make the results still further comparable, the depths of water applied, according to the heavy lines of the charts prepared by Harris, have been selected corresponding to the respective crop yields used in connection with Widtsoe's data, that is, for 21.3 tons of sugar-beets, 267.0 bushels of potatoes, etc. On these bases, Table 2 has been prepared.

The values given in this table show fair agreement with those obtained from Widtsoe's work, except for the alfalfa and oats. According to Fig. 5 of Utah Station *Bulletin 173*, a yield of alfalfa of 4.3 tons per acre would require the same consumptive use as found by Widtsoe for 4.7 tons, namely, 3.3 ft. The maximum yield of oats according to the 17 years' work reported by Harris is slightly less than the 80.7 bushels per acre used in Widtsoe's work. A yield of 74 bushels per acre, according to the curves by Harris, would have been produced by a consumptive use of 2.5 ft., the quantity required to produce 80.7 bushels in Widtsoe's work.

TABLE 2.—CONSUMPTIVE USE APPROXIMATIONS BASED ON THE FIELD PLOT WORK OF WIDTSOE AND HARRIS AT THE UTAH AGRICULTURAL EXPERIMENT STATION.

Crops.	Yield, in tons or bushels per acre.	Depth of water applied, in feet.	Depth of soil moisture and rainfall used, in feet.	Consumptive use, in acre-feet per acre.
Sugar-beets.....	21.3	1.50	0.86	2.4
Potatoes.....	267.0	1.67	0.52	2.2
Alfalfa.....	4.7	3.33	1.25	4.6
Corn.....	99.2	1.67	0.52	2.2
Wheat.....	45.7	1.33	1.15	2.5
Oats.....	80.7	2.33	0.81	3.1

#### FARM CONSUMPTIVE USE

*Lewis' Idaho Work.*—Lewis (11) measured the quantity of water used by nine important crops in the Snake River Valley, near Twin Falls, Idaho. He divided his observations into two groups: (1) Those on the better plots that produced high yields; and (2) those on which average yields were produced. His data are summarized in Table 3. It will be noted that in the better plots the seven grain crops and also the potatoes consumed less than 2 acre-ft. per acre. The alfalfa consumed the largest quantity and the clover the next largest, the average for all the crops being 1.75 ft. on the better plots and 1.53 ft. on the average plots. It is probable that these magnitudes represent the farm consumptive use,  $U_f$ , for the Twin Falls area more nearly than the consumptive use,  $U$ , since the experimental conditions very likely permitted some deep percolation.

*Hemphill's Colorado Work.*—Working in the Cache la Poudre Valley, Colorado, during 1916 and 1917, Hemphill (8) measured the water applied

to twenty-five farms. The run-off,  $R_f$ , is not given for each farm, but the average,  $R_f$ , was 6% of the quantity applied. Deducting 6% of the quantity for maximum crops to arrive at the quantity of irrigation water held on each farm and adding arbitrarily an allowance of 0.3 ft. for moisture absorbed from the stored winter precipitation and adding, further, 0.92 ft. for rainfall from April 1 to September 30, there results the farm consumptive use as given in Table 4. How closely this use, as given in the table, approaches the consumptive use is conjectural, as the magnitude of the percolation losses is not known and as it is subject to greater variation in actual farm irrigation than in field plot experiments heretofore reported.

TABLE 3.—FARM CONSUMPTIVE USE ( $U_f$ ) AS MEASURED ON FIELD PLOTS IN THE SNAKE RIVER VALLEY, IDAHO, BY LEWIS.

Crop.	$U_f$ on plots of high production.	$U_f$ on plots of average production.
Wheat.....	1.78	1.18
Oats.....	1.84	1.45

Alfalfa.....	2.89	2.55
Mean, if crops are given equal weights.....	1.75	1.53

Investigations of the net duty of water in Sevier Valley, Utah, by Israelsen and Winsor (9) during the 7-year period, 1914 to 1920, gives some information concerning farm consumptive use. In these experiments, the quantities of water found necessary to deliver to the farm for sugar-beets, potatoes, and alfalfa, excluding farm run-off,  $R_f$ , were 2.5, 2.0, and 2.8 acre-ft. per acre, respectively. The crop-season rainfall was 0.3 ft., and assuming a draft on the soil moisture of 0.3 ft., the farm consumptive use,  $U_f$ , is as follows: Sugar-beets, 3.1; potatoes, 2.6; and alfalfa, 3.4 acre-ft. per acre. Further reference is made to these quantities in connection with a report for  $U_o$  for the Sevier Valley.

TABLE 4.—FARM CONSUMPTIVE USE AS DETERMINED BY HEMPHILL IN CACHE LA POUDE VALLEY, COLORADO.

Crops.	Maximum yield, in tons, or bushels per acre.	Farm consumptive use for maximum yield per acre.	Average yield, in tons, or bushels per acre.	Farm consumptive use for average yield per acre.
Sugar-beets.....	15.1	3.6	12.6	3.0

Oats.....	80.0	3.6	48.1	1.4

## PROJECT CONSUMPTIVE USE

It is important to remember that farm and project consumptive use in general are likely to be, respectively, equal to or greater than the consumptive use, and also that during the early years of irrigation the difference between these quantities is likely to be greater than after many years of farming under the canal. The following are examples of some approximations of project consumptive use.

*Steward's Idaho Work.*—In the Boise Valley, Idaho, in connection with drainage operations, Steward (20) found project consumptive use on the Pioneer District Drainage area (approximately 13 500 acres) by subtracting the drainage run-off from the sum of the rainfall plus the irrigation water applied, a difference of 2.13 acre-ft. in 1916 and 2.18 acre-ft. in 1917. On the Twin Falls South Side Project, in 1915, Sloan (20) found, by working on a 12 000-acre tract, a project consumptive use of 2.95 acre-ft.

Steward and Paul (21) made a careful study of sources and disposition of water on the Nampa Meridian Drainage Districts in 1917. These investigators found on the Mason and Indian Creek tracts, having an area of approximately 50 000 acres, a transpiration plus evaporation of 1.9 ft. from April to October, inclusive. The factors of supply,  $H_p$ , of Equation (5) were as follows: (a) The inflow consisted largely of irrigation water and was 4.16 acre-ft. per acre; (b) the draft on soil moisture was neglected, probably without greatly influencing the results; (c) the absorption from the ground-water was not estimated; and (d) the crop-season rainfall was 0.36 ft. The factors in project run-off of Equation (5) were measured as follows: (a) Run-off was measured at all drainage outlets, and amounted to 2.02 acre-ft. per acre; (b) the deep-soil percolation losses were measured by making direct observations on water-table fluctuations and amounted to 0.60 acre-ft. per acre; and (c) the deep-soil percolation losses which re-appeared at the boundaries of the project, were measured as waters commingled with those in Factor (a). Applying Equation (5), the approximate project consumptive use,  $U_p = (4.16 + 0.36) - (2.02 + 0.60) = 1.90$ . A complete report of the work of Steward and Paul is beyond the scope of this report.

*Crandall's Snake River Valley Work.*—Crandall (1) measured consumptive use in the Lower Snake River Valley. He considered an irrigated area of nearly 90 000 acres in 1917 and of more than 100 000 acres in 1918. Using three different methods, he obtained close agreement. These methods were:

- 1.—Measurement of percolation losses from the irrigated land by finding the annual increase in discharge of springs below the tract.
- 2.—By making soil moisture determinations before and after irrigations.
- 3.—By computations from water-requirement studies under somewhat similar climatic and soil conditions.

A brief review of each method and of the results obtained are given as follows.

#### 1.—Crandall's Measurement of Percolation Losses

The normal annual discharge of the springs as determined by measurements for a period of 5 years prior to irrigation was 3 885 sec.-ft. By allow-

ing a 2-month lag period—the time required for the seepage losses to appear in the springs—Crandall found the increases in the spring discharges from all irrigation sources and from deep percolation from farms, and knowing the total deliveries to irrigators, he determined the consumptive use as shown further in Table 5.

Crandall believes that delay in water deliveries until the middle of May in 1917, due to maintenance work, is the cause of the smaller consumptive use during the first year of the measurements.

## 2.—Crandall's Soil Moisture Measurements

By taking samples of soil before and after irrigation, Crandall found that the moisture content of the forage-crop soils increased from 10 to 20% of the dry weight of the soil and that the moisture content of the grain-crop soils increased from 8 to 20%—each to a depth of 4 ft. The water-free soil weighed 80 lb. per cu. ft.; hence, the upper 4 ft. of the forage-crop soils absorbed 0.5 ft. per irrigation, or 2.5 ft. for the five irrigations; the same depth of the grain-crop soils absorbed 1.8 ft. from three irrigations, or 0.6 ft. in each irrigation. About 54% of the project was in forage crops and 45% in grain crops; hence, the consumption of irrigation water on this basis was 2.2 ft., and adding the crop-season rainfall, 0.15 ft., and the draft on soil moisture, about 0.25 ft., the consumptive use becomes 2.6 acre-ft. per acre.

TABLE 5.—PROJECT CONSUMPTIVE USE AS DETERMINED BY CRANDALL ON THE TWIN FALLS NORTH SIDE PROJECT, SNAKE RIVER VALLEY, IDAHO.

	From June, 1917, to May, 1918, included, in acre-feet.	From June, 1918, to May, 1919, included, in acre-feet.
Increase in springs discharge from all irrigation sources.....	816 800	878 900
Losses from canal system by seepage plus spring water contributions from other irrigation projects.....	612 627	650 439
Contributions to spring discharge by seepage from irrigated lands.....	204 173	228 461
Deliveries to irrigators less run-off or recovered wastes.....	389 909	434 838
Irrigation water consumed; Total on the project.....	185 736	256 377
by the crops..... } Acre-feet per acre.....	2.1	2.5
Rainfall during crop season, April to September, inclusive....	0.15	0.15
Draft on moisture in soil.....	0.25	0.25
Project consumptive use, $U_p$ .....	2.5	2.9

## 3.—Crandall's Computations on Basis of Water-Requirement Studies

At the beginning of this Committee's consideration of experimental observations, the difficulties and common sources of error in the use of water requirement studies from pot or tank experiments as a basis for consumptive use determinations over large areas were briefly enumerated. That determinations of the consumptive use on this basis could be considered only as approximations was also asserted. Despite these facts, it is interesting to note the agreement obtained by Crandall using this method with the two methods just presented. The analysis made by him is quoted herewith from his report:

"Detailed experiments have been made by Widtsoe at Logan, Utah, under climatic and irrigation conditions similar to those existing on the North Side tract, to determine the amount of water required to produce a pound of dried crop. The amount of water so required varies with the different factors including kind of crops, degree of fertility, amount of water applied, amount of soil moisture at beginning of season, etc. Detailed results are published in *Bulletin 285* of the U. S. Department of Agriculture and *Bulletin 116* of the Utah Experiment Station. For the conditions existing on the North Side Tract during 1917, these experiments indicate that approximately 1 300 lb. of water would be required to produce a pound of dried crop. This includes the transpiration requirements of the plants and evaporation losses from the fields. The average yield of the hay and pasture crops during 1917 was 4½ tons per acre. As the hay when cured in the stack contains about 15% moisture, this is equivalent to about 7 600 lb. of dry matter per acre for the hay and pasture crops. The average yield of wheat was determined as approximately 25 bushels per acre and the straw as 1½ times the weight of the grain making a total production of 3 800 lb. of crop per acre for wheat. As the wheat and straw contain about 10% moisture, this is equivalent to 3 400 lb. of dry matter per acre, which is taken as the average yield for crops aside from hay and pasture. The low average grain yields were due to the large acreage on which grain was planted late in the spring as a nurse crop for alfalfa.

"The average yield over the entire tract for all crops was then approximately 5 600 lb. of dry matter per acre. At an average water cost of 1 300 lb. of water per pound of dry matter this would require for its production 2.65 acre-ft. of water per acre. This quantity includes the water withdrawn from the moisture stored in the soil and precipitation during the growing season."

The water requirement, 2.65 acre-ft. per acre, is equivalent to the consumptive use as herein defined. It must be noted, however, that percentages of moisture in the hay and in the grain are estimates only, that the probable error in measuring the crop yields is unknown, that the percentage of wheat and straw likewise is estimated, and that in the light of these conditions the close agreement of the determinations of the consumptive use by the several methods should not be considered as conclusive evidence of the dependability of the method.

#### VALLEY CONSUMPTIVE USE

In the early years of irrigation of any valley, the valley consumptive use is relatively large because the deep percolation losses,  $D_v$ , go to moisten dry soil to great depths and build up the water-table, and are, therefore, temporarily non-recoverable. Moreover, the non-cropped area is relatively large during the early years of irrigation, and losses therefrom are larger than in later years.

*Sevier Valley, Utah.*—The Sevier Valley, in Utah, is typical of the older irrigated valleys in which deep percolation losses have become very small, since nearly all these losses shortly reach the high water-table which slopes toward the stream channels (or is quickly built up and thus made to slope toward the channels) so that there are very small, if any, non-recoverable losses from percolation. Likewise, the non-cropped area is small, and hence its losses are practically negligible. In this valley it is very probable that the consumptive use is almost equal to valley consumptive use; hence, from Equation (7),  $U = H_v - R_v$ . The inflow to, and the outflow from, the Sevier Valley for the 7-year period, 1914 to 1920, has been measured by the Utah State Engineer's Office

and reported by Ullrich (22). The average annual inflow of the river at Sevier, including the inflow of tributaries from Sevier to Gunnison, for this 7-year period was 295 000 acre-ft., and the average outflow was 211 000 acre-ft., thus leaving 85 000 acre-ft. which was applied to 65 000 acres giving a consumptive use of 1.3 ft. The crop-year rainfall is approximately 0.3 ft. As the mean annual rainfall is only 0.7 ft., the draft by the crops on moisture stored in the soil from winter rains and from ground-water is probably not to exceed 0.3 ft., the quantity previously assumed in connection with the net-duty work. On this basis, therefore, the consumptive use,  $U$ , for the Sevier Valley, as herein defined, is 1.9 ft. This value of the consumptive use is much less than farm consumptive use as determined by the Utah Experiment Station for standard crops on a typical soil.

If one-half the irrigated lands of the valley were in alfalfa and one-fourth in sugar-beets and potatoes, respectively, then farm consumptive use, according to the values presented heretofore, would be 3.0 acre-ft. per acre. For crops thus distributed and for yields equal to those of the experimental farm it would mean either that farm percolation  $D_f = 1.1$  acre-ft. per acre, since  $U_f = U + D_f$  (provided no water entered the valley through underground sources that could not be measured), or that 71 500 acre-ft. percolated into the valley if  $D_f = 0$ . In all probability the truth lies somewhere between these two extremes, meaning that some unmeasured water entered the valley and that some water was lost by deep-percolation from the experimental plots, the sum of the two for the entire valley being approximately 71 500 acre-ft., provided the experimental farm yields were not much greater than those of the valley as a whole.

*Cache la Poudre Valley, Colorado.*—The Cache la Poudre Valley, in Northern Colorado, is one of the foremost irrigated valleys of that State. Irrigation practice there is diversified, well-balanced as to crop rotation, and economic as to use of water. The need for water has raised water values and forced economy of use in irrigation. A 2-year investigation of irrigation in that area furnishes some valuable information on consumptive use. According to Hemphill the average consumptive use of river water, during the 2-year period of 1916-17, was 1.25 acre-ft. per acre over an area of 220 000 acres net. Adding 0.92 acre-ft. crop-season rainfall which is 80% of the 1.14 acre-ft. mean annual rainfall, gives a valley consumptive use of about 2.17 acre-ft. per acre. Data are not available concerning draft on soil moisture.

*Truckee River, Nevada.*—In connection with duty-of-water studies on the Truckee River, in Nevada, Harding (3) estimated the valley consumptive use by subtracting the valley outflow at Vista from the inflow at the California-Nevada line. He made estimates also based on direct measurement of drains and found fair agreement for seasonal consumptive use between the two methods. In making monthly comparisons by the two methods the results are less consistent. The gross area of cropped land considered was 27 000 acres, approximately three-fourths of which is cultivated land and the remainder largely wild hay land. The cultivated land produced mostly alfalfa,

but also some native grass on land that might have been used for other crops. Based on these studies, Harding concludes that the valley consumptive use during the six months of April to September, inclusive, for 1900 to 1918, including the 0.19 ft. rainfall, is 3 ft., but excluding the draft on soil moisture, if any. The local practice of applying water at frequent intervals in small quantities is considered in part responsible for this high consumptive use. Moreover, the meadow areas are irrigated almost continuously. The irrigation season is about 165 days. A high precision is not claimed for the results, as evidenced in the following comments by Harding:

"The records are not as complete as would be desired, and the resulting consumptive use is higher than would be expected. The area is typical of two cuttings of alfalfa with either a light third cutting or good fall pasture valley such as occur in the Mountain States."

*Columbia River Tributaries.*—Parker (14) estimated the average valley consumptive use, exclusive of rainfall, on 12 tributaries of the Columbia River for the "climatic years" 1909-10, 1910-11, and 1911-12. The estimated irrigated acreages during each of the three years were 99 000, 103 000, and 108 000, respectively. It is noteworthy that the magnitudes of consumptive use obtained, namely, 2.9, 2.7, and 2.8, respectively, agree closely, despite significant differences in the run-off.

#### METHODS OF ESTIMATING VALLEY CONSUMPTIVE USE

*Hedke's Method.*—It is desirable to estimate the consumptive use of water in irrigation, in different valleys, in advance of complete agricultural development. Recognizing the importance and complexity of the consumptive use problem, Charles R. Hedke, M. Am. Soc. C. E., (7) has investigated the relation of consumptive use of water to the quantity of heat available to the crop during the growing season, and has found substantially that under favorable agricultural conditions the use of water is directly proportional to the use of heat available. The relative approach of the actual agricultural practice to the best practice is designated by Hedke as the "Standard of Agriculture". The application of the direct relation between water consumption and available heat, proposed by Hedke, to a valley in which the agricultural practices are of a high standard, necessitates the following assumptions:

- 1.—That the heat consumed by a particular crop, during any day or other time period, is determined by the amount of heat available to the crop above the germinating or minimum growing temperature.
- 2.—That under favorable agricultural practices, each crop consumes water in direct relation to the heat available as defined.
- 3.—That the soils considered are abundantly supplied with moisture and plant-food so that the yield of a crop will be limited only by the amount of heat available.
- 4.—That the influence of variations in wind velocity, relative humidity, and vapor pressure on consumptive use of water are relatively small as compared to the influence of available heat.

Under these assumptions, Equation (1a) may be written,  $U = f(Q_h)$ , or simply  $U = K Q_h$ , which is the basic relation assumed by Hedke.

To determine  $Q_h$ , Hedke subtracts the minimum growing temperature of each crop from the mean temperature of each month, or fraction thereof, within the growing season. The result thus obtained, multiplied by the number of days in the month, represents the available heat units in day-degrees for a particular crop during the month considered. The sum of the heat units available to each crop for each month gives the available heat units for the crop-year. Hedke found in the Cache la Poudre Valley of Colorado in 1916 that heat was available to alfalfa during the eight months of March to October, whereas, to potatoes it was available only from May to September, inclusive. To find the total heat units available on a project, the heat units available to each of the crops are multiplied by the proportion of the project lands in the respective crops, and the sum of the products thus obtained gives the available heat units for the project.

Hedke has applied his proposed principle to several typical valleys and has obtained some gratifying results. The result of his work in the Cache la Poudre Valley and its application to the San Luis Valley, in Colorado, and the Rio Grande Valley, in New Mexico, suggests that  $Q_h$  is a predominating factor in fixing the magnitude of the consumptive use.

Hedke defines consumptive use as the "total amount of water transpired incidental to farming an area"; thus the inclusion of the water evaporated from the crop-producing land is implied, but not specifically stated. He states further that the consumptive use "is here covered by the net depletion from the stream plus one-half the total yearly rainfall". However, his applications do not show that "net depletion" includes the crop-year draft on soil moisture plus the water derived from the ground-water, both of which should be considered as indicated in this Committee's enumeration of the elements of supply, as used in Equation (7).

Based on Hemphill's measurements of valley consumptive use for the Cache la Poudre Valley, and using the equation,  $U_v = K Q_h$ , Hedke has found that  $K = 0.000423$ , approximately. Having the magnitude of  $K$ , Hedke considers it possible to determine the valley consumptive use for the highest "standard of agriculture" in any valley in which dependable crop distribution and temperature records are available. His analysis of crops and temperatures in the Middle Rio Grande Valley shows a normal available heat,  $Q_h$ , of 6200 day-degrees, and applying the value of  $K$ , finds,  $U_v = 0.000423 \times 6200 = 2.6$  acre-ft. Considering the Rio Grande Project, he finds that  $Q_h = 6800$ , and, hence,  $U_v = 0.000423 \times 6800 = 2.9$  acre-ft. By deducting the "effective precipitation" from each of these values, he arrives at an estimate of the net depletion in the stream system. The application of these estimates without modification is of necessity based on an actual or an assumed high "standard of agriculture" in the Rio Grande Valley and on the Rio Grande Project similar to that of the Cache la Poudre Valley of Colorado.

In this connection it is essential to remember that Hedke urges the importance of making careful observations concerning the relative agricultural practices in different valleys for which information is available, concerning

the total available heat termed by him the "thermal location", and that the magnitude of  $U_v$ , as computed from a known constant and the available heat, be reduced in proportion to the lack of attainment of the highest possible standard of agriculture. The dependability of such reduction in the computed valley consumptive use obviously rests on the experience and judgment of the engineer. The method proposed by Hedke, therefore, seems to give the greatest promise in those valleys where a high standard of agriculture has been attained, thus eliminating the necessity of applying the so-called "personal equation of judgment and experience". Obviously, the method may likewise be applied to the newer irrigated valleys under an assumed ultimate distribution of crops and high agricultural standard for the purpose of estimating the consumptive use of water which will occur after the agricultural development of the valley concerned has been completed.

*Harding's Method.*—Harding has studied project and valley consumptive use on extensive areas in the San Joaquin Valley, California (4, 5). A complete report of his California investigations is beyond the scope of this report, which is restricted to a brief statement of the extent of the work, a description of his methods, and a summary of his observations.

The Kings River area included about 700 000 acres of irrigated land and the Kaweah area, 184 000 acres. Harding measured the factors of water supply and run-off of Equation (5), as follows:

- (a) The channel inflow is based on records of current-meter rating stations.
- (b) The crop seasonal draft on soil moisture was not measured; in effect, however, it was reduced to a minimum by so modifying other factors as to provide an equivalent elevation of water-table.
- (c) The necessity of computing the quantity of water absorbed from the ground-water was eliminated by the same method as the moisture content in Factor (b).
- (d) The crop-seasonal rainfall on the projects investigated is negligible.
- (e) There were no appreciable surface run-off losses.
- (f) The need for measurements of deep percolation losses was eliminated by determining graphically the quantity of canal water needed to maintain the water-table at a constant normal elevation (see Fig. 1).

A similar statement applies to Harding's method of determining  $H_v$  and  $R_v$  in Equation (7).

*Harding's Method as Applied to the Kings River Area.*—The conditions in some of the areas served by the Kings River (4) are such as to furnish a basis on which the consumptive use may be estimated. These conditions are most favorable in the Fresno, Consolidated, and Alta Irrigation Districts. For these districts adequate records of ground-water fluctuation were available for 1922 to 1925, which include one year of more than normal run-off, one year of about 80%, one of about 70%, and one of about 25% run-off. The relative diversions vary even more widely than the run-off due to the later priorities of rights of the Consolidated and Alta Districts. Adequate

diversion records are also available for the districts as a whole and for their main laterals.

In connection with the engineering studies made by the State Engineer's Office of the Kings River Water Conservation District, Harding made a detailed analysis of the ground-water records.

The rainfall at Fresno averages 0.81 ft. annually, and occurs mainly in the winter months. Diversions for irrigation extend from February to October, varying with the available water supply, the period of diversion being longer in the Fresno District due to its earlier priority of right.

The method of analysis consisted in determining the seasonal ground-water fluctuation and comparing it with the acre-feet of water conveyed into the area, per acre of cropped land. In all these areas there is extensive pumping for irrigation. Some land was supplied with water entirely by pumping from local ground-water; other land was furnished canal water when available and pumped water during the remainder of the season. The gross area of farms served was used in estimating consumptive use. As the projects are highly developed, the net area cropped is nearly as large as the gross areas herein used.

The year was divided into two periods, namely, March 1 to November 30 and December 1 to February 28, because an examination of the ground-water fluctuations in the winter indicated no influence from the delivery of water during the preceding irrigation season. The winter fluctuations vary largely with the winter precipitation, but this is probably an indirect relationship, since with larger rainfall there is less irrigation pumping, and there is also some local tributary run-off.

The canal deliveries necessary to maintain the ground-water were taken as the quantities necessary to cause a rise or fall from March 1 to November 30 equal to the fall or rise that would occur from December 1 to February 28 in a year of normal rainfall. The quantities of water delivered to each tract each year, together with the accompanying water-table fluctuations, were plotted as illustrated in Fig. 1, which typifies Harding's method of analyzing consumptive use data. This diagram gives the results obtained, respectively, on the entire area under the Fresno Irrigation District, the Consolidated Irrigation District, and the Alta Irrigation District.

The summarized results of canal deliveries and ground-water fluctuations for these three areas for 1922 to 1925 are given in Table 6. The resulting estimated requirements for diversion into each area to supply the consumptive use and maintain the ground-water are also given in Table 6. These estimates were arrived at by plotting the ground-water fluctuation against the deliveries, as shown in Fig. 1, and selecting the intersections of the line drawn through the resulting points with the axis of zero change in level of ground-water, as representing the deliveries that would be required to supply the consumptive use and maintain the ground-water for the periods, March 1 to December 1. The estimated total annual requirements were based on allowing for the ground-water fluctuations from December 1 to March 1 in years of normal rainfall as previously explained.

The indicated consumptive use as obtained from Fig. 1 and Table 6, is based on the surface diversions into the areas. It does not include any unmeasurable ground-water movement into or out of the area. Ground-water inflow is considered to be relatively small as the areas above these districts are unirrigated and the adjacent Kings River channel shows a gain rather than a loss under normal conditions of supply. Ground-water outflow may occur, although its extent is considered to be relatively small in proportion to the consumptive use so indicated by other records.

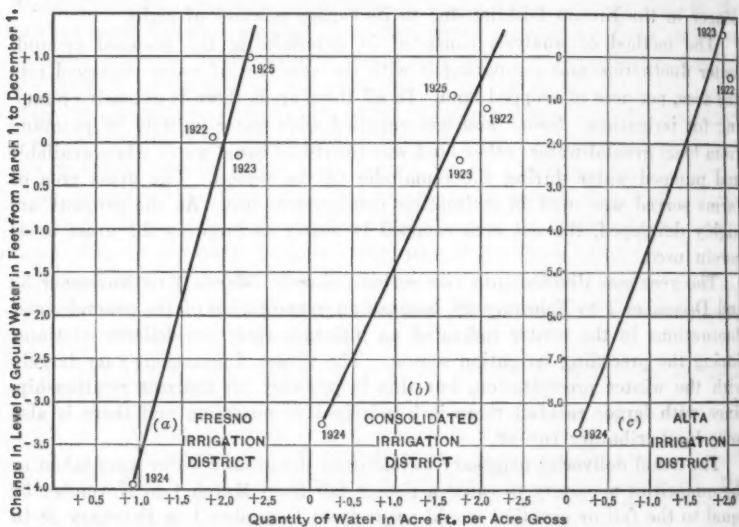

FIG. 1.—RELATION OF VOLUME OF WATER DIVERTED IN AREA TO CHANGE IN LEVEL OF GROUND-WATER.

In 1922 and 1923, in some parts of each of these three districts the ground-water was within 6 ft. or less of the ground surface. In some areas it rose within less than 4 ft. of the surface. The estimated delivery requirement to maintain the crops and ground-water includes evaporation from the soils in such areas, as well as plant transpiration. The consumptive use indicated may be affected by these conditions. The numerical results presented are considered as illustrating the method used rather than as a final determination of the quantity of the consumptive use of these areas. A final determination will require additional length of record under present ground-water conditions.

In addition to the areas of the district as a whole, the areas served by several of the main laterals were similarly studied. Such areas had varying conditions as to the type of crop grown and ground-water elevations. From these results the following conclusions were drawn by Harding:

"Records to date from different areas indicate, as tentative conclusions, that in areas of trees and vines having limited ground-water outflow, the crop

needs for moisture will be supplied by an average annual delivery into the area of about  $1\frac{1}{2}$  acre-ft. of water per acre of crop. For forage crops an average delivery of 2 to  $2\frac{1}{2}$  acre-ft. of water per acre of crop may be required. For other crop conditions other amounts of supply are found necessary. Where ground-water outflow occurs or where the ground-water is close to the ground surface, larger amounts are required to supply the crops and maintain the ground-water."

TABLE 6.—DIVERSION OF WATER AND GROUND-WATER FLUCTUATIONS IN FRESNO, CONSOLIDATED, AND ALTA IRRIGATION DISTRICTS FROM MARCH 1 TO DECEMBER 1, WITH FLUCTUATIONS FROM DECEMBER 1 TO MARCH 1 IN YEARS OF NORMAL RAINFALL.

\*Covers only portion of the district served by the Fresno Canal; gross area, 169 000 acres.

**Kaweah River Area.**—Some data indicating valley consumptive use are given by Harding (5) for the Kaweah River area during 1920 and 1921, the records indicating a valley consumptive use,  $U_v$ , of about 2.2 acre-ft. per acre. The crops consisted of approximately 34% orchard and vines, 29% alfalfa, 28% corn and grain, and 9% miscellaneous. There were some areas of high ground-water, but these were relatively small in extent. The climatic conditions were typical of those of the main San Joaquin Valley areas. The ground-water is dependent on the Kaweah River and the diversions therefrom. Available data indicate that the ground-water basin is closed. About 183 500 acres were cropped in a gross area of 365 000 acres.

*Meeker's Valley Consumptive Use Studies in Colorado.*—Meeker has conducted investigations concerning consumptive use in several typical valleys in Colorado and has also assembled and compiled data for other valleys. His analyses were made with the viewpoint of determining the net depletion of river water by irrigated lands either naturally or artificially drained. Wasteful evaporation from seeped areas, therefore, was excluded as a form of consumption. Re-use of seepage or return waters and water recovered by drainage systems within an area were automatically included and served to decrease the burden on the original river flow. Large irrigated areas were used and records of stream flow were considered of from 5 to 10 years to eliminate minor irregularities of climatic and variations in crops in irrigated lands.

The crop-year draft on soil moisture and the water drawn from ground-water sources, being, respectively, Factors (b) and (d) of  $H_v$  in Equation (7), were not evaluated in Meeker's studies. The values of the valley consumptive use reported herewith, therefore, may be slightly smaller than the actual magnitudes of consumptive use in the respective valleys. Unpublished records supplied the Committee by Meeker contain interesting data concerning gross and net duty of water in 18 river systems, and on 9 of these consumptive-use data are available. The observations on these 9 systems are reported in Table 7.

It will be noted in Column (9) of Table 7 that the consumptive use, defined as diminution in stream flow, varied from 0.9 acre-ft. per acre per year in the Little Laramie River Basin to 1.3 acre-ft. per acre per year in the Sevier River Basin and on the Boise Project. Column (9a) which has been added to Table 7 by the Committee, gives the valley consumptive use as here defined, with the exception noted that there are no measurements of draft on soil moisture or ground-water. Assuming the seasonal draft on soil moisture and ground-water to be 0.3 acre-ft. per acre, as was assumed for the Sevier River Basin, then valley consumptive use varies from 1.5 to 2.2 acre-ft. per acre for the river basins reported in Table 7.

Investigations of the return flow on the Cache la Poudre and South Platte River by Meeker (13) and on the Lower South Platte by Parshall (15) give further evidence concerning consumptive use. In a résumé of factors affecting return flow, Meeker places the consumptive use (not including crop-season rainfall or draft on soil moisture) at 1.25 ft. and reports that from 35 to 65% of waters diverted for irrigation appear as return flow in the Colorado streams mentioned.

Meeker's conclusion, based on rather extensive investigations, is as follows:

"The conclusion from these studies and from comparisons with the natural return flow from large older irrigated areas is that the amount of water actually consumed by crops is relatively small compared with the amount diverted, and further that with efficient drainage on an irrigated project, the actual plant consumption has decidedly low limits regardless of the water applied."

#### DISCUSSION

It has been pointed out that many independent factors influence the valley consumptive use. However, there is urgent need for arriving at some relatively simple method of estimating its magnitude. Therefore, in order further

to study the merits of Hedke's proposal, the determinations of valley consumptive use made by Crandall, Harding, and Meeker are assembled in Table 8. Each river system is designated by a number given in Column (1). The minimum growing temperatures given in Column (5) were selected on the basis of the minimum growing temperatures for the predominating crops in the respective areas. Column (6) contains the names of the U. S. Weather Bureau stations from which temperature records were taken as the basis for computing the available heat as given in Column (8).

The data presented in Columns (7) and (8) are plotted in Fig. 2, which suggests a straight line relation between  $U_v$  and  $Q_h$ . The slope of the line in Fig. 2, or the magnitude of  $K$  in the equation,  $U_v = KQ_h$ , is 0.00039, which is about 8% less than the magnitude of  $K$  as determined from Hedke's analysis of Cache la Poudre experiments. This is considered a close agreement, particularly when it is recognized that the minimum growing temperatures of so many crops under such varied conditions can only be approximated. The Snake River results seem to be the most erratic. It is hoped that this report will elicit additional data on valley consumptive use, particularly from areas of high mean annual temperatures, so that the straight line relation indicated by Fig. 2 may be affirmed or modified.

### SUMMARY AND CONCLUSION

1.—The term, "consumptive use of water", has been given an important place in engineering literature.

2.—Definitions of consumptive use are proposed in this report both in its basic sense and with respect to the area concerned, whether a farm, a project, or a valley.

3.—Some of the common difficulties in measuring consumptive use are enumerated.

4.—That measurement of project and valley consumptive use under some physical conditions is impractical is indicated.

5.—Investigations concerning consumptive use, as made in California, Colorado, Idaho, Nevada, Nebraska, Oregon, and Utah, and in Alberta, Canada, are briefly reviewed.

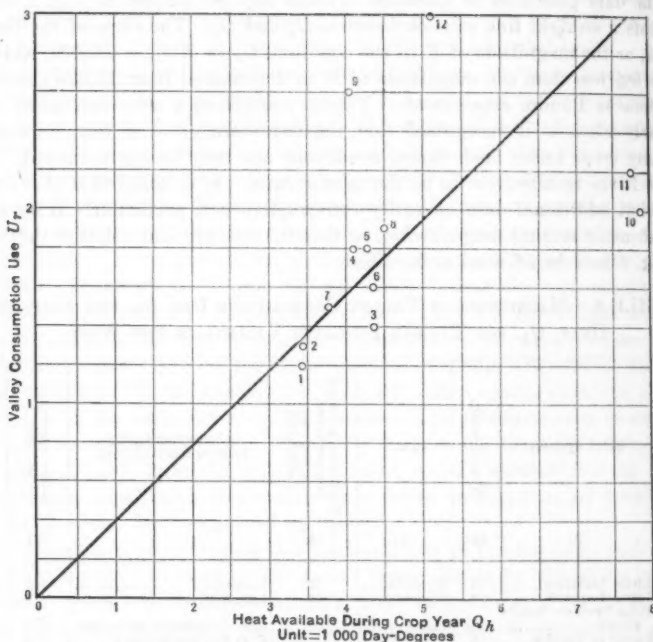

FIG. 2.—VALLEY CONSUMPTIVE USE OF WATER ON TYPICAL PROJECT AS RELATED TO AVAILABLE HEAT.

6.—The engineering reports and publications reviewed contain information which is considered valuable as a guide to approximations of consumptive use. If the factors affecting the consumptive use do not vary greatly, and particularly if the crop yield is approximately the same throughout a valley as on experimental plots within the valley, then the valley consumptive use must be either equal to or greater than the net consumptive use. It, therefore, seems reasonable to believe that quantities of valley consumptive use,  $U_v$ , which are less than the net consumptive use,  $U$ , if obtained by careful measurements, indicate that the soil conditions and crop yields for the valley are too low, and that, if the average yields for the valley are increased to those secured on experimental plots, the valley consumptive use will also be increased.

## DISCUSSION

HAROLD CONKLING,\* M. A. M. Soc. C. E. (by letter).—This report on the consumptive use of water in irrigation will be welcomed by the great body of engineers in Western States who are engaged in the problem of water supply for irrigation and domestic use. About 1918 the writer was engaged in a series of studies undertaken by the U. S. Reclamation Bureau for a comprehensive and complete development of some of the major stream systems of the West. The Rio Grande, North Platte, Humboldt, and Colorado Rivers were the principal streams studied.

It was soon apparent that as far as the water supply was concerned, the first effort must be to determine the consumptive use for different areas. The quantity that it was necessary to divert was a detail for any particular project which governed the size of the works, but was not usually a factor in determining the possibilities of a stream system, since consumptive use is not greatly influenced ordinarily by the volume diverted. It also seemed probable that more water is consumed per acre in the warmer climates than in the cooler and some of the streams studied, notably the Rio Grande and the Colorado, furnish water for lands in climates ranging from the high cold valleys of Colorado to the sub-tropical heat at the Mexican border.

A thorough search for data on consumptive use was made because, before the investigations could proceed intelligently, this basic matter of water supply had to be settled. Very few determinations of consumptive use had been made at that time; some of those used by the writer are included in its report, modified by later information. It was believed at the time that those determinations, which were made by measuring the total quantity of water reaching a considerable tract of irrigated land and the total quantity leaving the tract, were the most reliable as they gave directly the average result of all the multitudinous factors that may affect the consumptive use on any individual acre. Accordingly, an investigation of all the Reclamation Bureau projects was made to find such areas as were favorable to determination in this way, but such tracts were very scarce.

Since 1923 the writer has had charge of an investigation of the water supply in San Gabriel Basin of Southern California. The term, San Gabriel Basin, applies to the entire San Gabriel stream system. The streams of this system, like most of those in Southern California, flow across detrital filled valleys of unknown depth, and these valleys form huge reservoirs from which the water supplies of the region are drawn. Without these reservoirs the life of the region as it is to-day would be impossible because long series of dry years are characteristic of the climate. A determination of the consumptive use in the upper of the two detrital filled valleys across which the San Gabriel flows was made by balancing inflow against outflow. In that region—because of the large quantity of water pumped from the underground reservoir—change in underground storage is a much larger and more important item than in the usual determination of this nature in the inter-mountain country. Any attempt to convert the measured change in elevation of water-

---

\* Chf., Div. of Water Rights, State Dept. of Public Works, Sacramento, Calif.

plane into acre-feet of storage may result in serious error. In this investigation a determination of voids in various classes of materials encountered by the well driller was made and then from well-logs the percentage of voids at each well was calculated. With many well-logs to use, a map showing lines of equal voids was made. When there was superimposed on this map the data showing lines of equal annual change of ground-water level, a calculation of the acre-feet change could be made. Even with this elaborate study, chance for large error exists and unless the water-plane has moved in both directions there is no check to determine such error. In this case the average water-plane fell two years, remained stationary one year, and rose one year. The final results were such that the determination of acre-feet put into or withdrawn from underground storage each year is believed to be reasonably accurate.

Another factor which affects the apparent consumptive use in any one year is the large difference in rainfall. This affects it in two ways. If the rainfall is deficient the growth of vegetation on unirrigated land is less than normal and, consequently, the actual consumptive use is less. Furthermore, it is probable that, in such a year, more water is released to the water-plane from that part of the vertical section of the valley fill above the water-plane and below the root zone than reaches it from deep percolation of rainfall. Hence, there is a depletion in this area which cannot show in the hydraulic equation and the apparent consumptive use is less than the actual. This possibly is a considerable item as the ground surface over a large part of San Gabriel Valley is 200 ft. or more from the water-plane. It is believed, however, that after two years of nearly the same precipitation, conditions will have reached an approximate state of equilibrium. In Table 9 are shown data as to inflow and outflow for four years (1923-27), the first two of which were very dry and the second two slightly wetter than normal. It is believed therefore that the second and fourth year average should give results that eliminate, to a large extent, the uncertainties noted in the foregoing. By a coincidence the average for four years is about the same as for the two years in question.

One other unknown quantity enters into the determination. The underflow out of the valley is uncertain. The approximate cross-section of the pervious area of the valley outlet is known and the approximate underflow is computed from this knowledge. While the variation from the figure used may be large, it does not seriously vitiate the figure for total consumption. The hydraulic equation is arranged in Table 9 to show the different items entering into it. The resulting "apparent consumptive use" is found by subtracting the total output from the total supply to the valley floor.

It will be noted (Table 9) that the apparent consumption is 191 000 acre-ft. This is believed to be close to the actual consumption, but for various reasons is probably a little larger than the actual (value assumed for underflow treated as definitely known). This supplied the water consumption of 129 600 acres of valley land, of which 81 700 acres are using water (irrigation or domestic), 33 200 acres are irrigable, and 14 700 acres are non-irrigable (country roads

and washes). In addition, water is pumped to 3 240 acres of hillside land. Crops are produced as follows: 30 334 acres of citrus trees; 19 758 acres of deciduous trees, mostly English walnuts; 8 831 acres of truck gardens; 2 960 acres of alfalfa; and, 23 111 acres of urban area. Adding the land irrigated on the hillsides to that irrigated in the valley gives 84 940 acres irrigated or using domestic water.

\* The annual rainfall in the valley averages 19.56 in., of which 78% falls in the four months from December to March, inclusive.

If the 191 000 acre-ft. consumed is divided by the gross area, the consumptive use is 1.44 acre-ft. per acre. Does this value compare with that given in Column (9a) of Table 7 of the report? Nothing is said there as to whether the irrigated areas given in Table 7 are net or gross, but from the writer's knowledge of these various tracts he is inclined to believe that the acreage given is the gross and that the net irrigated is from 75 to 85% of the gross.

To obtain consumptive use in San Gabriel Valley on a comparable acreage basis, it is necessary to estimate what the increased consumption will be when the entire irrigable land is placed under cultivation. The fallow land consumes only rainfall, while the irrigated land consumes both rain and irrigation water. To determine this increased consumption it is necessary to find the differences in the ability of native and cultivated crops to capture rainfall. These differences are more profound than is generally supposed, and work is in progress (1928), which tends to show that in the areas of heavier precipitation the difference in total water consumed by native vegetation and by cultivated crops is not great, except in the case of alfalfa and the area of this crop in the valley is negligible. In the absence of final determination on this point it is here assumed (for the purpose of finding a figure approximately comparable to that used in the report) that the consumption on irrigated areas is 1.9 ft. in depth and that on fallow irrigable land is 0.8 ft. in depth, so that when the valley is entirely irrigated the total consumption will be 36 000 acre-ft. greater than at present, making 227 000 acre-ft. in all.

It is believed that this figure, divided by the gross valley area plus the land irrigated on the hillside will give a value comparable, so far as percentage of area irrigated is concerned, with those used in the report. When this is done it results in a consumption of 1.7 acre-ft. per acre.

While this value is believed to be comparable on the basis of acreage, it may not be comparable in other ways. It is a measure of the total water consumed, whether from irrigation or rainfall, during the entire year, whereas that given in the report is for consumption from rainfall and irrigation during the crop-year. However, if the rainfall had not occurred in San Gabriel Valley, it is believed from other data that consumption of irrigation water (if irrigation had continued through the twelve months) would not have been greatly different from 1.7 acre-ft. per acre. In explanation, it should be stated that the growing season extends throughout the entire year and that cessation of irrigation occurs only because of the winter rains.

Referring to Fig. 2, wherein "heat units" are compared to "valley consumption", it is found that this value for San Gabriel Valley would plot a little lower than that for the Kings River and the Kaweah River areas on approximately the same location as to "heat units". Examination of the data from which this graph was plotted shows a substantial disagreement between values from the Truckee and Snake River areas and those for similar climates, such as the Boise, Cache la Poudre, Sevier, and South Platte Valleys. The reason for the excess consumption in the Truckee Valley may rest in the combination of the peculiar underground conditions and the excessive applications, but this does not apply to the Snake River area. An examination of

the indirect methods used in securing the data for this area shows that many errors could occur.

The Committee raises the question as to whether a curve of heat units against consumptive use is justified. It may be that it is, if it is restricted to showing the relation between the consumptive use of areas growing essentially the same crops. The crops of the inter-mountain country are mainly alfalfa, grain, and roots, and are essentially the same from north to south, but nothing quite comparable is found in California except in the extreme northern part or in the small areas east of the Sierras. In most places the irrigated crops are different and contain a larger proportion of trees. Then, too, humidity is less in the inter-mountain country than it is west of the Sierras. It would seem improbable that a comparison of consumptive use based on heat units is logical between such divergent types of crops. If the Kings and Kaweah values (see Fig. 2) are neglected and only the values from the inter-mountain region considered, the curve becomes almost vertical. If the Snake River and Truckee values are given little weight—the first because of possible inaccuracies and the second because of unique conditions—there is little basis for a curve. If one is drawn it could as well be in a much different direction than the one which appears as Fig. 2.

The addition of the San Gabriel Valley to the group, its rather close check with the other California areas, and the fair consistency in the type of crops grown in these areas, suggest that while heat units may be a determinant in increasing the consumptive use, the higher type of crop grown in the hotter regions where land values are high requires less water. Therefore, if marketing conditions are such as to justify the higher type of crop, and high land value, a curve of "consumptive use-heat relation" will not be of value when applied to all the different conditions encompassed in the data published by the Committee.

CHARLES H. LEE,\* M. AM. SOC. C. E. (by letter).—The subject of this report is an increasingly important one in all regions where agriculture depends on irrigation. It not only enters into questions of the management and economics of irrigation projects, but also water supply problems, both surface and underground. It has become a very important factor in the settling of controversies on great stream systems where the public welfare of valleys, States, and even nations is involved. Not only is correct knowledge of the absolute loss in irrigation of interest to several branches of the Engineering Profession, but also to public officials, legislators, and the public. Therefore, the Committee in selecting the subject of this report has struck upon a very live topic, as well as one which embodies the essence of its work.

The term, "consumptive use of water," although not strictly involving a correct use of the word, "consumptive", has been more or less accepted by those interested in the subject. Like "duty of water" and many other technical terms it may be considered a distinctive identification mark which common usage has sanctioned and the profession has accepted.

The proposed definition of "consumptive use" the writer believes is sufficiently comprehensive, with the possible exception that it does not recognize

\* Cons. Hydr. Engr., San Francisco, Calif.

either double cropping or intercropping. Both are practiced in California, particularly in Southern California and the Imperial Valley, and the annual consumptive loss per acre is materially increased thereby, especially in the case of double cropping. In order to recognize the practice in the definition, the words, "or crops", might be added after the word, "crop".

The mathematical form for analysis of consumptive use data is somewhat confusing at first reading, but its use is probably justified from the standpoint of completeness and simplicity. The writer has followed this method satisfactorily for many years in working out individual cases, both for determination of consumptive use and for equating ground-water absorption and discharge for valleys of the closed-basin type.

*Net Consumptive Use.*—The practicability of determining working values for net consumptive use,  $U$ , by means of tanks or potometers, is dependent on reproduction of natural conditions. The water supply is under control and is supplied more regularly and uniformly than is possible in practice and in more exact synchronism with plant requirements. This probably tends to increase rather than decrease evaporation and plant transpiration. Also, there is more complete exposure of the plant to light and wind, and there may be the absence of the vapor blanket present under field conditions. The tank in relation to the field is in fact the counterpart of the small land evaporating pan as compared with the lake or reservoir. The work of Sleight, at Denver, Colo.,\* and of the writer in Owens Valley, California,† has shown conclusively that the evaporation from a small land pan considerably exceeds that from a lake or reservoir. Similarly, it is to be expected that the transpiration from a crop growing in a small tank not surrounded by growing vegetation of a similar character will exceed that from a cropped field. The conditions surrounding tank experiments should be ascertained before placing dependence on the results.

The method by field plot measurements on the other hand, while it has many advantages over the use of tanks, has the disadvantage that draft on the ground-water and deep percolation loss are both unmeasurable. In the effort to avoid the former, experimenters have endeavored to select sites having great depth to ground-water, while in the case of the latter, small and frequent irrigations have been given in the hope that deep percolation loss would be reduced to zero. In each determination of  $U$  presented by the Committee there is more or less uncertainty whether or not deep percolation occurred and whether its value is really so small as to be negligible. Without more convincing proof, it is open to doubt whether in all cases deep percolation can be considered as negligible even with a deep water-table.

*Farm Consumptive Use.*—The conditions under which farm consumptive use ( $U_f$ ) occurs, differs but little from that of net consumptive use from field plots. The elements of difference are principally with respect to the application of water in accordance with actual farm practice rather than under experimental control, and frequently a shallower depth to the water-table. As is to be expected, the measured values of  $U_f$  are generally greater than

\* "Evaporation from the Surface of Water and River Bed Materials," *Journal of Agricultural Review*, Vol. X (1917), pp. 229-230.

† *Transactions, Am. Soc. C. E.*, Vol. LXXVIII (1915), pp. 176-181.

those for  $U$  determined at field plots. This is due to the inclusion of deep percolation in the former.

Table 10 assembles all comparable values presented in the Committee's report, those of Lewis in Snake River Valley being omitted because of lack of data regarding soil moisture and crop season rainfall. A striking feature is the wide variation in apparent values of  $U$  and  $U_p$ . This is probably due both to errors of measurement and to difference in crop-growing conditions. Table 10 serves to emphasize the conclusion of Kisselbach that "there is no such thing as a definite water requirement which is constant for any kind of crop", and points clearly to the fact that the acceptance and use of  $U$  and  $U_p$  data on any basis other than as an aid to judgment are not justified.

§ Crop season rainfall, 0.92 ft.; draft on soil moisture, 0.30 ft.

¶ Crop season rainfall, 0.30 ft.; draft on soil moisture, 0.30 ft.

The unusually large values for  $U_p$  found by Hemphill in Cache la Poudre Valley, where the crop season rainfall was 0.92 ft., or more than twice that in any other location, raise a question as to the propriety of adding the full depth of the observed rainfall. The writer's own observations and a study of the observations of others lead to the conclusion that most or all of the summer precipitation in valley parts of semi-arid and arid regions is lost, either through surface run-off or immediate evaporation from foliage and the soil; and that very little percolates to a depth sufficient to make it available to any but the most shallow rooted crops. In view of this condition the addition of the total rainfall for the crop season does not carry out the purpose of the Committee, which was to arrive at basic values capable of use in any locality. It is believed that this item needs experimental study and that, pending the availability of further data, consumptive use values which include total rainfall should be used with caution. This suggestion obviously applies to consumptive use in all its phases—basic, farm, project, and valley.

*Project and Valley Consumptive Use.*—The determinations of "project use" ( $U_p$ ) and "valley consumptive use" ( $U_v$ ), as defined by the Committee, are far from simple problems. Unlike  $U_f$ , in which the ultimate disposition of  $D_f$  is immaterial, in the case of  $U_p$  and  $U_v$  it is necessary to trace  $D_p$  and  $D_v$  at least to the extent of ascertaining the quantity returning to stream channels and the evaporation and transpiration loss from non-cropped land. Both  $U_p$  and  $U_v$  should be less than  $U_f$ , since a portion of  $D_f$  is accounted for where larger areas are considered. In the case of the project the unaccounted portion is that continuing as percolating water beyond the project boundary to appear later in a surface stream or pass into the atmosphere from an area of shallow ground-water. For valley consumptive use the unaccounted portion, if any, passes from the valley as sub-surface flow. If there is no sub-surface flow, as in the case of a closed geologic basin,  $U_v$  should be equal to  $U$ . The complications surrounding the determination of the values of  $U_p$  and  $U_v$  arise, first, from the inability to see the geologic formations beneath the surface of the ground; second, from the hidden course and slow movement of deep percolating water from irrigated land; and, third, from the mingling of such water with percolating water from other sources. An analysis of the Committee's report shows that the proposed method of determining  $U_p$  and  $U_v$ -values is still in a formative state and that the complications which are encountered in practical application are being dealt with either at arm's length or not at all.

The earlier investigators attacked the problem in its simplest form and attained roughly approximate results. Later investigators, recognizing the omissions and assumptions, have introduced refinements. The Committee's report is the latest step in this process and represents a notable advance. It is to be recognized, however, that practically all investigators have thus far approached the subject from the viewpoint of irrigated agriculture. From this background, the basic units of time and area have been the crop year and the cropped area. These units are essentially artificial and until natural units are adopted the concepts must continue to be in terms of special cases.

The next step forward is the adoption of the climatic year, instead of the crop year; and the topographic or geologic unit of area, instead of the project or project group area. The following examples will serve to illustrate the advantages of these units. In most localities where irrigation is practiced the crop year covers six to eight months, or from one-half to two-thirds of the full year. Due to the slow movement of ground-water there is a considerable lag between the diversion of water from a stream and its return as seepage or spring flow. Water which passes beyond the plant roots joins the general ground-water body below (thereby raising the water-table), and remains in sub-surface storage until the water-table returns to its initial level. The lag period may vary from a few weeks to five or six months, depending on the character of the subsoil, the relative elevation of irrigated land and adjacent drainage channels, and the distance of the irrigated land from drainage channels flowing direct to the main stream. Observations which do not extend over the lag period fail to indicate the amount of delayed return reaching the outlet stream or evaporated from moist non-cropped soil during

the non-irrigation period, and hence give consumptive use values which are too great. The writer's observations indicate that in certain cases the degree of error from this source may be very large and that it is seldom negligible.

Another illustration in which the scope of the Committee's analysis might be broadened is with respect to area. Consideration of inflow and outflow has been limited to the cropped area and the immediately adjacent land from which evaporation or transpiration from natural vegetation occurs. The attempt has been made to list the *H* and *R*-factors with respect to a single project area or group of project areas within a valley. This procedure has given rise to difficulties of measurement. For instance, it is impossible in practice to measure the sub-surface flow into the crop area. This is recognized by the Committee in commenting on the many valleys of the Southwest where inflowing ground-water is important. The statement is made that, in such instances, it is "impractical to obtain dependable measurements of project or valley water supply."

Although not mentioned, the same difficulty exists with respect to sub-surface flow from the cropped area. Some of this may appear as seepage or spring flow and be measured as outflow, but, on the other hand, there may be loss by evaporation from shallow water-table outside the project area, or sub-surface outlets other than the adjacent stream. There may also be storage accumulation as represented by rise of the water-table in non-cropped areas outside the project. By approaching the problem from the aspect of a topographic or geologic unit, however, these difficulties largely disappear.

The illustrations are sufficient to indicate the errors into which the investigator may fall if the methods outlined by the Committee are his only guide. It is not the writer's purpose to outline a method to replace that of the Committee, for the latter is well adapted for use in many cases, but rather to suggest a broader foundation for analyzing the individual problem more comprehensively and if necessary to modify the Committee's method to fit the case.

Since about 1910 there has been a notable accumulation of knowledge in the field of ground-water hydrology. The existence has been shown of many natural ground-water reservoirs occupying geologic basins more or less co-extensive with topographic valleys.\* The source, movement, and ultimate disposition of the ground-water in these basins have been traced and methods have been developed for quantitative measurement of inflow and outflow.† These methods have now become sufficiently standardized for practical use in determining the dependable yield from ground-water sources.

In 1926 the City of Los Angeles, Calif., completed a program of ground-water development in the Independence Region of Owens Valley the extent of which was originally planned from the results of a quantitative ground-water study made under the direction of the writer from 1908 to 1911. The development work, consisting of wells and pumping plants, cost approximately \$250 000 and yields an auxiliary supply to the Los Angeles Aqueduct System of more than 100 sec-ft. The same investigational methods have also been

\* "Occurrence of Ground-Water in the United States," by O. E. Meinzer, *Water Supply Paper 489*, U. S. Geological Survey, pp. 291-303, 1923.

† "Water Resources of Part of Owens Valley, California," by Charles H. Lee, *Water Supply Paper 294*, U. S. Geological Survey, 1912.

applied to the solution of other problems. It is the writer's conviction that the methods of ground-water hydrology used in making quantitative determination of ground-water supply have direct application to the problems of project and valley consumptive use. They will serve to point out unsuspected items in the inflow-outflow equation, to evaluate unknown factors, and to make possible a solution in valleys with inflowing ground-water which is claimed to be impractical by the Committee.\*

In adapting the methods of ground-water hydrology to the measurement of consumptive use, the first step is a geological survey to determine the character and extent of the impervious bed-rock basin, the limits of the hydrologic water-shed, the character and distribution of the porous alluvial fill, and the probability of sub-surface inflow or outflow. A more or less complete water-table map with typical fluctuation graphs covering the annual cycle should also be available, and a general knowledge of local precipitation, run-off, stream channels, irrigated land, seeped or swamp land, springs, etc. With such information it should be possible to list all ground-water sources and outlets and to ascertain whether there are any negligible or compensating items so that the problem can be reduced to its simplest terms.

Three general types of valleys are met in consumptive-use determinations:

1.—There are those without underlying alluvial fill in which the bed-rock formation is covered with a thin veneer of decomposed rock and soil in place. This type seldom occurs in practice. If the bed-rock is non-porous rock, such as granite, the valley can be treated under one of the other two classifications. For a porous, fissured, or cavernous bed-rock, the measurement of consumptive use may be impracticable.

2.—There are valleys of the "open-basin" type in which the underlying bed-rock basin is filled with porous alluvial material having one or more areas of direct contact with outside porous formations which may extend even beyond the topographic drainage area. This type also includes valleys where the bed-rock is leaky, due to the occurrence of porous or soluble bed-rock, such as open sandstones, limestones, etc.

3.—There are valleys of the "closed-basin" type, in which the porous alluvial fill has no connection with outside formations, being completely enclosed by non-porous bed-rock bottom and sides continuous with the surrounding hills or mountains.

*Proposed Method of Determining  $U_v$ .*—To illustrate the application of the proposed method of determining valley consumptive use, the various quantities will be defined and equations formulated. The period of time for which equations are set up is the climatic year and may be October 1 to September 30, November 1 to October 31, or January 1 to December 31, depending on local precipitation and run-off conditions.

The area, in the case of a closed geologic basin, is the superficial area of the porous alluvial fill, usually extending to the margin of the valley at the base of the surrounding hills or mountains. For an open geologic basin, the porous material of which extends beyond the margin of the topographic val-

\* "Quantitative Methods of Estimating Ground-Water Supplies," by O. E. Meinzer, Bulletin, Geological Soc. Survey, 1912.

ley, the limits of the area may be chosen with respect to practicability of measuring or estimating the sub-surface inflow and outflow, although they should be restricted as much as possible.

The list of quantities has been designated by symbols which correspond wherever possible to those used by the Committee, as follows:

For annual inflow:

$I_v$  = measurable surface stream flow, in acre-feet per cropped acre, entering the valley at the margin, including both main and lateral streams.

$F_v$  = measurable or estimated sub-surface flow, in acre-feet per cropped acre, entering the valley at the margin.

$P_v$  = the portion of direct precipitation falling upon the surface of the porous valley fill, which is not immediately evaporated and contributes to direct surface run-off, soil moisture, or ground-water, expressed in acre-feet per cropped acre.

For annual outflow:

$R_v$  = measurable surface stream flow, in acre-feet per cropped acre, at valley outlet.

$D_v$  = measurable or estimated sub-surface flow, in acre-feet per cropped acre, escaping from the valley, usually at the lower margin, although possible at other points.

$U_v$  = evaporation and transpiration from cropped valley land, in acre-feet per cropped acre.

$E_v$  = evaporation and transpiration loss from non-cropped valley land and natural vegetation, in acre-feet per cropped acre.

For annual sub-surface storage:

$G_v$  = addition to or withdrawal from valley ground-water storage, in acre-feet per cropped acre.

$S_v$  = addition to or withdrawal from valley soil water, in acre-feet per cropped acre.

The relation upon which equations are based is the annual equality for any valley of inflow and outflow with appropriate correction for sub-surface storage in the porous valley fill.

Expressing this equation by symbols:

$$I_v + F_v + P_v = R_v + D_v + U_v + E_v (G_v + S_v)$$

Solving for  $U_v$ , there results the general equation:

$$U_v = I_v + F_v + P_v - R_v - D_v - E_v (G_v + S_v)$$

For valleys of the closed-basin type, this reduces to the form:

$$U_v = I_v + P_v - R_v - E_v (G_v + S_v)$$

In arid regions where direct precipitation does not contribute appreciably to surface run-off, ground-water, or soil moisture, the equation reduces still further to the form:

$$U_v = (I_v - R_v - E_v) G_v$$

If the area of cropped land is of minor importance and it is desired to determine losses from natural vegetation, the last equation may take the form:

$$E_v = I_v - R_v - U_v G_v$$

To evaluate  $E_p$  in terms of acre-feet per acre of natural vegetation and seeped land, it should be multiplied by the ratio of the area of cropped land to that of natural vegetation.

The  $I_p$  and  $R_p$ -quantities are capable of measurement by ordinary stream-flow methods. The  $F_p$  and  $D_p$ -quantities are difficult and expensive to measure, but as they are ordinarily small in amount, they can often be estimated from data available from geological and water-table surveys. For closed basins they are zero.

The value of  $P_p$  although difficult to determine in semi-arid and humid regions is capable of measurement. Direct addition to run-off from precipitation on the valley floor can be determined from continuously recording water-level gauges on streams. Immediate addition to ground-water can similarly be determined from shallow well records and porosity data. Soil moisture additions are easily determined by ordinary soil moisture tests made before and after storms. The extent to which it is advisable to go in making detailed observations to determine the distribution of direct precipitation upon the valley floor is a question to be answered in each individual case.

The value of  $E_p$  is usually quite small relative to  $U_p$  and can be determined with sufficient accuracy from a knowledge of the area of moist land and natural vegetation, from local water evaporation, and from the results of observations in other localities.\*

For determination of ground-water storage quantities,  $G_p$  and  $S_p$ , the standard methods can be used. Ground-water storage can be determined either from water-table fluctuations, as measured in shallow wells and test holes and porosity data, or by indirect methods, such as those used by Harding and referred to in the Committee's report. It may also be eliminated from consideration where observations of other quantities covering several years are available and ground-water conditions as modified by irrigation have become stabilized. The variation in soil moisture from year to year is in most cases so small that it is negligible, and  $S_p$  may be eliminated altogether.

Many special cases are encountered in practice, which permit of modifications of the general equation, in addition to the simplifications stated. Harding, in his San Joaquin Valley work, follows essentially the method outlined by the writer; he adopts an interesting modification with respect to the ground-water storage correction. In his work in San Luis Rey and in other valleys in San Diego County, California, the writer used still other modifications, as suggested by the local synchronism in the periods of run-off and ground-water fluctuation.† Every locality and valley has its special conditions and in almost every case study will disclose important simplification in the application for the general formula.

*Committee's Discussion and Conclusion.*—The proposal to study consumptive use in conjunction with heat available during the crop year is logical. Temperature is by far the most important factor governing evaporation, the direct straight-line relation between the two having been clearly shown by

\* *Transactions, Am. Soc. C. E.*, Vol. 90 (June, 1927), pp. 334-338.

† "Geology and Ground-Water of the Western Part of San Diego County, California," by A. J. Ellis and Charles H. Lee, 1919, pp. 142-155.

Sleight\* and other investigators. Transpiration being a special form of evaporation is controlled largely by temperature as is also the plant life process of which transpiration is a phase. The straight-line relation between valley consumptive use and heat available during the crop year, which is indicated by Fig. 2, is therefore a reasonable assumption. It should be pointed out, however (in view of the present uncertainties regarding consumptive use values as determined without the aid of a standard method by various investigators, as well as the limited range of available heat values to draw from), that at present neither the straight-line relation nor the equation of any line can be considered as established. The first requisite is dependable data; the second, sufficient data.

The writer's experience leads him to modify the Committee's Conclusion 4 "that measurement of project and valley consumptive use under some physical conditions is impractical", to read, "that measurement of project and valley consumptive use is possible under most physical conditions met in practice." Under the method proposed by the writer, the determination of valley consumptive use in the only case specifically excluded by the Committee as impractical, is made entirely feasible.

The last conclusion (6) of the Committee would appear to be correct provided the data are accurate. The writer, however, does not believe that the data now available are sufficiently dependable to permit conclusions of such far-reaching importance to be drawn.

*Results of Measurements in Owens Valley, California.*—The Owens Valley, California, is a desert valley typical of the Great Basin. It lies at the eastern base of the Sierra Nevada Mountains with an elevation of about 4 000 ft. The run-off from melting snows on these mountains has provided water for the irrigation of approximately 50 000 acres of land in the valley as well as the major part of the supply of the City of Los Angeles. This valley, because of its physical and meteorological conditions and the wealth of hydraulic data available, offers opportunities for determining values of  $U_v$  and  $E_v$ . The writer has had intimate familiarity with it since about 1905 and presents the following from personal knowledge.

The valley is a closed geological basin from which the only natural escape for water in appreciable quantities is by evaporation and transpiration. Precipitation on the valley floor varies from 3 to 5 in. annually, most of which occurs during the winter months. The average annual depth of evaporation from a free water surface is 67 in. Many lateral streams fed by snows falling upon the eastern slope of the High Sierra enter the valley along its western border. Such waters as are not locally consumed in irrigation find their way into the Owens River which flows down the trough of the valley and finally empties into Owens Lake. The latter is without surface or sub-surface outlet and is a great evaporating pan from which all residual waters of the valley are dissipated into the atmosphere. Its fluctuations are an accurate index of meteorological and cultural changes in the valley above.

\* "Evaporation from the Surfaces of Water and River Bed Materials," *Journal of Agricultural Research*, Vol. X, 1917, pp. 229-230.

Owens Valley is divided into three nearly equal parts by two ranges of granite hills lying across the axis of the valley and extending from the Sierra Nevada Mountains almost to the Inyo Range on the east. These ranges are known as the Poverty Hills and the Alabama Hills. The upper part of the valley thus subdivided has been termed the Bishop-Big Pine Region, the middle part, the Independence Region, and the lowest subdivision, the Owens Lake Region. The alluvial fill of the valley in the narrow necks opposite the east ends of these ranges of hills is composed of fine material consisting of fine sand, silt, and clay. The hydraulic grade of the main valley is so flat that subsurface flow from one region to another is negligible. Each of these smaller valleys, therefore, constitutes a geologically closed basin from which the only escape for water is the surface flow of Owens River, or by evaporation.

When white men first settled in the valley, the higher lands were dry and sandy, supporting a sparse growth of desert shrubs. Stream borders and the broad bottoms of the Owens River supported meadow grass and willows. Green meadows also occurred along the valley borders in the vicinity of springs. Depressions in the valley floor supported coarse grasses, and occasional moist alkali areas occurred where little vegetation grew. Irrigation commenced in the early Sixties and by 1875 the available supply from the lateral streams was being led out in small ditches on to the adjacent lands for the raising of grain and general field crops. In the late Seventies the construction of large ditches to divert the waters of Owens River was commenced. The irrigated area was rapidly extended, alfalfa being introduced in the Eighties. By 1905, the available flow had been completely diverted and since then no further important extensions have occurred.

The effect of irrigation has been to raise the water-table in the vicinity of irrigated land and to greatly extend the meadow-grass and alkali areas of the main valley floor. The area of Owens Lake, on the other hand, has decreased and its level has been permanently lowered. As an incident to the latter, the Owens River has cut back on a new grade, developing a new channel in the river bottom, varying in depth from 20 ft. near the margin of the lake to zero at a point northeast of Bishop, approximately 70 miles up stream. The new conditions brought about by irrigation, including the water-table and return water, had stabilized by 1905. The condition thus described existed prior to the diversion of water from Owens River through the Los Angeles Aqueduct, which commenced in 1913. The latter did not become important in its effect on Owens Lake until 1918.

*U and  $E_v$  in the Independence Region.\**—The Independence Region, during the period of intensive water supply study from 1908 to 1913 prior to the completion of the Los Angeles Aqueduct, had a total area (from which soil evaporation and transpiration occurred) of 37 950 acres. This acreage was made up of 3 010 acres of irrigated land planted to alfalfa and general crops, and 34 940 acres of natural meadow, salt-grass, and moist alkali land. The irrigated area consisted of ten or more detached groups of ranches on as many small streams, making it impracticable to determine a value for  $U_v$ . The conditions were ideal, however, for determining  $E_v$ , a quantity which is usually indeterminate.

\* Transactions, Am. Soc. C. E., Vol. LXXVIII (1915), p. 148.

The water-table beneath most of the irrigated land was too far below the surface to furnish an appreciable supply to crops, and the Owens River did not receive measurable sub-surface accretions. The water absorbed by the porous alluvial fill found its escape by evaporation and transpiration from meadow, salt-grass, and alkali land moistened by capillary water drawn up from the water-table. There was also escape in the form of spring flow reaching the main drainage channel of Owens River. The average annual percolation into the porous material of the valley which reached the water-table, as determined by the writer from observations made during a three-year period, was as follows:

Source.	Acre-Feet.
Direct precipitation on mountain slopes between canyons...	19 700
Direct precipitation on outwash slopes.....	9 780
Seepage loss from lateral streams.....	57 100
Return from irrigation.....	13 000
Absorption from flood water.....	6 500
<hr/>	
Total .....	106 080
Deduct spring discharge.....	22 400
<hr/>	
Net consumed by meadow, grass, and moist soil.....	83 680

$$E_e = \frac{83\,680 \text{ acre-ft.}}{34\,940 \text{ acres}} = 2.40 \text{ ft.}$$

A check determination based on a detailed survey of depth to water-table and two years of tank observations of evaporation and transpiration from typical sods with differing depth to the water-table, resulted as shown in Table 11.

TABLE 11.

Depth to water-table, in feet.	Area, in acres.	Average depth to ground-water, in feet.	TRANSPIRATION-EVAPORATION.	
			Feet.	Acre-feet.
3	7 610	2.5	3.48	26 400
3 to 4	11 300	3.5	2.80	31 600
4 to 8	16 030	5.5	1.33	21 100
<hr/>		<hr/>		<hr/>
Total.....	34 940	....	2.26	79 100

It is believed that the second value of 2.26 ft. for  $E_e$  is closer to the truth than the first, as the detailed observational control was more complete. In the first set-up the only item based on systematic and detailed observation was seepage loss from lateral streams constituting 54% of the total. The other items were in part based on estimates. All items involved in the second set-up were the result of observation. Unusual precautions were taken to have natural conditions for the tank experiments.

*U for Alfalfa in Independence Region.*—Observations were also made near Independence, on August 9, 1910, to determine transpiration losses from

alfalfa in a typical field stand. The method was that used by certain European investigators—determining the rate of loss of water from freshly cut plants, on the assumption that this would approximately represent the rate of loss immediately prior to cutting. Four samples were cut from measured areas at different times during the day. These were weighed at short intervals until no further appreciable loss occurred. Visible wilting did not occur during the first 15 min. after cutting, and this period was used in making calculations. The results were reduced to a 24-hour average, using a factor based on standard transpiration experiments. The local growing season extends from April 15 to September 30, and the production of dry hay amounted to about 5 tons per acre with three crops. The samples used for observation were almost ready for the second cutting. Assuming that the average transpiring surface during the entire growing season was 50% of that on the day of the experiment, the total loss for the season would have amounted to 935 lb. of water per lb. of dry hay, or 3.4 ft. in depth. The total depth of water applied in irrigation on this field during the crop season was 16 ft.

This value for  $U$  is consistent with the quantity of water available and the results of tank experiments elsewhere. The method, however, involves unnatural conditions. The samples were dried at the margin of the field out of the main vapor blanket, and the ends of the stems were cut, thus interrupting the life processes of the plant. It is not believed that the results by this method are any more dependable than those obtained by the use of standard tanks.

$U_v$  and  $U_p$  in the Bishop-Big Pine Region.—The moist area of the Bishop-Big Pine region, although including considerable meadow and salt-grass, is primarily irrigated land, and the physical conditions are favorable for determining values for  $U_v$ . The region as here considered extends from Pleasant Valley on the north to the Poverty Hills on the south, including both sides of the valley. Stream measurements are sufficiently complete for the six years, 1918 to 1923, to determine total inflow from various streams at the margin of the valley as well as outflow in Owens River at Charlie's Butte. Acreage data were also quite complete. The water-table was shallow and  $D_v$  negligible. The soils vary from those of a coarse sandy granitic character to black loam. Water was taken from Owens River by means of thirteen ditches, the annual net head-gate diversion varying in depth from 9 to 4 ft. on the land, depending on the position of the ditch on the stream and the available supply. The average annual duty for the larger ditches with earlier rights exceeded 6 ft. The length of the irrigation season averaged 213 days, from March 15 to October 15. The land was irrigated from the Owens River, as follows:

Crop.	Acres.
Alfalfa .....	8 174
Orchard .....	850
Annual crops .....	4 684
Pasture (not cultivated).....	20 809
Total .....	34 517

Approximately, 6 340 acres had a supplemental supply from Bishop and Big Pine Creeks, and, in addition, 10 427 acres, mostly in alfalfa and general crops, were irrigated entirely from creek ditches.

The total area of irrigated land, moist soil, and water surface during the period, 1918 to 1923, based on surveys by the City of Los Angeles and the U. S. Reclamation Service is:

Land Under Canals and Ditches:

Irrigated (cultivated and pasture).....	42 984 acres
Corrals, roads, etc.....	1 590 "
Tule and willows.....	1 960 "
Water surface (canals).....	450 "
Salt-grass and rabbit-bush.....	5 405 "

Total .....	52 389 acres
-------------	--------------

Land Not Under Canals:

Meadow and salt-grass.....	2 465 acres
Water surface (river, creeks, and lakes) .....	930 "

Total .....	3 395 acres
-------------	-------------

Grand total .....	55 784 acres
-------------------	--------------

The daily inflow into the valley from Owens River and Bishop-Big Pine and Baker Creeks, and several large springs, is summarized in Table 12, together with the outflow at Charlie's Butte. The inflow figures also include estimates for Horton, Birch No. 1, McGee, Tinemaha, and Birch No. 2 Creeks, aggregating 10% of the total inflow. The period of observation, although including several dry years, was characterized by wasteful use, and it is believed that the results for net loss are representative of average conditions for this valley. The period of observation preceded any appreciable withdrawal of land from irrigation by the City of Los Angeles.

The total evaporation and transpiration loss of 168 600 acre-ft. (Table 12), if spread over an area of 55 784 acres, indicates a value for  $U_v$  of 3.0 acre-ft. per acre.

In explanation of the apparently large value of  $U_v$ , the following classification of moist lands in the Bishop-Big Pine Region, made by the U. S. Reclamation Service in 1920, is illuminating:

Seepage water on surface.....	5 450 acres
Water, 0 to 2 ft. below surface .....	24 480 "
Water, 2 to 4 ft. " " .....	11 250 "
Water, 4 to 6 ft. " " .....	13 720 "

Total .....	54 900 acres
-------------	--------------

This statement shows an unusually large percentage of badly seeped land from which a high rate of evaporation and transpiration loss occurs. Much of

this seeped land is classed in the area already noted as "irrigated pasture". The effect on  $U_v$  of the wasteful methods of irrigation and the paralleling of earthen ditch systems at successive levels, one above the other, is apparent. The value tends to confirm the results obtained by Harding in Reno Valley where methods of irrigation and meteorological conditions are similar. In both cases,  $U_v$  could be reduced materially by the reconstruction of the ditch systems and improved methods of irrigation.

TABLE 12.—INFLOW AND OUTFLOW FOR BISHOP-BIG PINE REGION OF OWENS VALLEY, IN ACRE-FEET.

Year.	Total inflow.	Outflow.	Difference.
1915.....	400 200	260 800	139 400
1916.....	353 500	197 600	157 900
1920.....	348 400	170 600	177 800
1921.....	345 300	166 900	178 400
1922.....	481 900	294 200	187 700
1923.....	341 500	171 100	170 400
Average.....	.....	.....	168 600

The change in area and specific gravity of Owens Lake between 1878 and 1909, during which period the thirteen ditches diverting water from Owens River were built and put into operation, affords a method for determining the value of  $U_p$  for the area in the Bishop-Big Pine Region covered by these ditches. The shrinkage of the lake surface and increase in specific gravity of the water with the corresponding reduction of evaporation, should represent the combined loss from the newly irrigated land. An element which might materially modify the result, however, is the extent to which the channeling of Owens River on the new grade established by the lower lake level has reduced the evapo-transpiration from the river bottoms. Prior to irrigation in the valley the Owens River spread out more or less over its bottoms in high water for a width of  $\frac{1}{4}$  to  $\frac{1}{2}$  mile, and at all times had a shallow, meandering and frequently subdivided channel. The bottoms were thickly overgrown with willows and grass from which large losses occurred. This condition was greatly changed for a distance of more than 70 miles by the cutting of the new channel. The water level in the river and the adjacent water-table are both lower than formerly, and flooding occurs only in very wet years. Also, the river channel is narrower and more concentrated. This results in great decrease in the amount of vegetation and change in its character, with reduction of losses. The degree to which these changed conditions confuse the results for irrigation is not known, but the data will be presented for what they are worth, since the method is unique and may be applicable in other localities.

The changes which took place at Owens Lake have been carefully determined by the writer and are as shown in Table 13.

The lake being without outlet, is highly mineralized, and its specific gravity has exceeded that of sea water even at the highest historic lake level. A long

record of lake levels is available, together with accurate area and capacity curves of the lake basin, a "specific gravity-lake level" curve and a "specific gravity-evaporation" curve.\*

TABLE 13.—CAPACITY CHANGES IN OWENS LAKE.

Period.	Stabilized lake level, in feet.	Area of lake surface, in acres.	Specific gravity of lake water.	Annual depth of evaporation, in inches.	Total evaporation, in acre-feet.
1872-78.....	3 597	71 142	1.04	64.6	384 000
1909-15.....	3 576.5	61 600	1.093	61.1	318 500
Difference....	20.5	9 542	.....	....	70 500

The value of 70 500 acre-ft. for the reduction in annual evaporation from Owens Lake between 1878 and 1909 the writer regards as reasonably accurate. If all the reduction was occasioned by the increased area of irrigated and seeped land, the value of  $U_p$  for the net area irrigated from river ditches of approximately 34 517 acres, is 2.00 ft. As this value is considerably less than  $U_p$  as determined previously, it is possible that the shrinkage in flooded river bottom-lands along 70 miles of river channel, due to channel cutting, should also be taken into account in order to get the true value of  $U_p$ . The detailed conditions along the river as they existed prior to 1878 are so difficult to determine, however, that it is doubtful whether it will ever be possible to get an accurate value for the correction.

*Results of Measurements in San Luis Rey Valley.*—The San Luis Rey Valley is a coastal valley on the Southern California coast about 50 miles north of San Diego. It extends from the seashore into the mountainous interior for a distance of more than 20 miles, varying in width between steeply sloping hills from 300 ft. to nearly 2 miles. The grade of the valley floor averages 20 ft. per mile, being least near the coast. The run-off from precipitation, mostly in the form of winter rainfall on a drainage area of 565 sq. miles, discharges into the valley from various tributaries and flows thence to the Pacific Ocean. The flow of the San Luis Rey River is confined to storm periods during the winter months, except at the head of the valley where there is a small living stream.

The bed-rock formations underlying and surrounding the valley are relatively impervious and no leakage into them occurs from the porous alluvial fill immediately underlying the valley floor. The fill of the main valley has a superficial area of 7 646 acres and its maximum depth varies from 100 to 200 ft., thinning out to zero at the margins of the valley. The material is largely water-bearing sand with gravel at lower levels. The water-table stands near the surface, the depth varying at different points from zero to 10 or 12 ft. The average annual fluctuation of the water-table is 3 ft., the source of supply being percolation from the flow of San Luis Rey River and direct-rainfall. The escape is by evaporation from moist sand and soil, and by transpiration

\* *Transactions, Am. Soc. C. E.*, Vol. 90 (June, 1927), p. 333.

from meadow and salt-grass and from willow, alder, cottonwood, and sycamore trees. Underflow, as measured, was found to be so slow that sub-surface escape to the ocean is negligible. The total area from which evaporation and transpiration take place is 6 640 acres.

The annual precipitation on the valley floor varies from 10 in. at the coast to 12 to 16 in. at the head of the valley above Pala. Most of this falls during the winter months. The annual depth of evaporation from large bodies of water varies from 58 in. near the coast to 66 in. farther inland.

The writer made an intensive study of the underground water supply of the San Luis Rey Valley during the years, 1913 to 1916, and from these data it is possible to determine  $E_v$  for the valley. During the period of observation the area of cultivated crops did not exceed 4% of the total evapo-transpiration area, so that separate classification for irrigated land is unnecessary.

TABLE 14.

\* Based on total acreage of natural vegetation plus very small cropped acreage.

† Based on total cropped acreage plus irrigated pasture, seeped land, and water surface.

‡ Based on total cropped acreage plus irrigated pasture. No correction for reduced river-bottom area.

There being no leakage and negligible underflow to the ocean, the valley may be considered a closed basin. The annual fluctuation of the water-table is within definite limits and storage fluctuation due to wet and dry years is small. With these conditions,  $E_v$  may be considered as equal to the average annual volume of water reaching the water-table by percolation from run-off and direct precipitation. Without going into details which are fully set forth elsewhere,\* it was found that the average annual recharge based on three years' records, was 14 450 acre-ft. This recharge, spread over 6 640 acres of moist land, gives a value of  $E_v$  of 2.19 ft. A check determination made independently and based on a detailed classification of moist areas and the application of the principles controlling soil evaporation and transpiration, as developed in the Owens Valley work and elsewhere, but using local rates for water evaporation, indicated an annual loss of 13 980 acre-ft., or a value for  $E_v$  of 2.10 ft.

Table 14 summarizes the values for  $U$ ,  $U_p$ ,  $U_v$ , and  $E_v$ , as found for the Owens and San Luis Rey Valleys.

\* Water Supply Paper 446, U. S. Geological Survey, pp. 149-153 (1919).

M. R. LEWIS,\* M. Am. Soc. C. E. (by letter).—The consumptive use of water is a very definite element of great importance in irrigation, which has long been recognized in regions such as Southern California, where all the available water has been pumped from the pervious fill of closed valleys. More recently its importance has been recognized in studies of the water supply available for whole valleys rather than for individual projects.

The very great increase now taking place (1929) in pumping from wells for drainage and to supply supplementary water is certain to make the determination of consumptive use of vital importance in many areas. Heretofore, the water supply for an irrigation project has generally been based on the quantity of water required to be delivered to the farmers' head-gates plus transmission losses. If, in the course of time, return flow to the stream by natural seepage or by gravity drains has warranted, and if lower lands were available, the irrigated area has been extended. In places where pumps are used for drainage the water becomes available for use on the lands which are being drained or on other lands at approximately the same elevation. In every such case the question arises as to whether there is an excess of either land or water. Old data on the duty of water do not apply. For these reasons, the report of the Committee is especially opportune.

The writer wishes to suggest a few additions to and modifications of the detailed statements of the report.

The terms,  $D_f$ ,  $D_p$ , and  $D_v$ , all include seepage losses from ditches and canals in the respective areas. A specific statement to this effect would have added to the clarity of the report.

If in determining  $H_p$  any negative value of  $(c)$ , the depletion of groundwater, is considered, it should not also be considered in the determination of  $R_p$  in  $(b)$ , such deep-soil percolation losses as contribute directly to a measurable rise in the height of the water-table.

The writer believes that it would be better to define  $U_p$  as being equal to  $\frac{W_p}{A_p}$  and  $V_p$  as equal to  $\frac{W_v}{A_v}$ . Then, Equations (4) and (6) become,

$$U_p = \frac{A_{cp}}{A_p} U + D_p + E_p \dots \dots \dots (8)$$

and,

$$U_v = \frac{A_{cv}}{A_v} U + D_v + E_v \dots \dots \dots (9)$$

in which,  $A_{cp}$  and  $A_{cv}$  are the cropped areas in the project and valley, respectively;  $A_p$  and  $A_v$  are the total areas in the project and valley, respectively; and  $W_p$  and  $W_v$  are the volumes of water, in acre-feet, consumed in the project and valley, respectively.

If these equations are used, the error in defining the word "consumptive", as discussed in the report, would not occur and Equations (5) and (7) would be numerically correct.

\* Irrig. and Drainage Specialist, Oregon State Coll., and Div. of Agri. Eng., U. S. Dept. of Agriculture, Corvallis, Ore.

The writer is glad to see so many different studies of consumptive use brought together in a single report. The conditions leading to inaccuracy inherent in plot determinations of evapo-transpiration are realized. It is believed, however, that the difficulty of preventing or even of recognizing deep percolation losses in plot experiments is so great that it overshadows the errors in large-scale pot experiments on the one side and in valley consumptive-use studies on the other.

Paper No. 1761

### INTERSTATE WATER MATTERS

#### PROGRESS REPORT OF THE COMMITTEE OF THE IRRIGATION DIVISION\*

WITH DISCUSSION BY MESSRS. R. I. MEEKER AND M. C. HINDERLIDER

The Chairman of the Committee on Interstate Water Matters submits the following progress report.

At the Summer Meeting of the Society in Seattle, Wash., in 1926, a resolution concerning interstate agreements or compacts, was adopted by this Committee, but was presented to the Division too late to be acted upon at that time. This resolution, as amended and adopted by the Division at the Denver meeting, in July, 1927, is as follows:

"Whereas, experience has plainly demonstrated that the problem of interstate river controversies, if left to chance solution, leads to costly and protracted litigation involving tremendous economic loss to all concerned; and,

"Whereas, efforts to adjust interstate river problems by means of treaties or compacts between the States and the United States Government directly interested promises a more direct and practicable solution of the problems involved;

"Now, Therefore, Be It Resolved that the Irrigation Division of the American Society of Civil Engineers definitely recommends that the proper State agencies at the earliest possible date take the initiative in starting and completing such negotiations as will bring about the solution of interstate water difficulties, through treaty or compact, on such broad lines as are best fitted to the individual streams in which such rights may be in controversy."

The tremendous commercial development of this nation within recent years, has forced the Federal Government to take active measures looking to the

\* This report has been compiled from two reports published in March, 1928, and March, 1930, *Proceedings*, respectively.

The membership of the Committee of the Irrigation Division on Interstate Water Matters is as follows: M. C. Hinderlider, *Chairman*, George M. Bacon, Frank C. Emerson, A. L. Fellows, C. E. Grunsky, C. S. Heidel, R. I. Meeker, and J. C. Stevens.

improvement of its rivers, harbors, and inland waterways, and the development of some of its great water power possibilities.

Likewise, the pressing demands of irrigation, flood control, power development, and of stream pollution in some of the more thickly populated sections of the East where interstate streams are involved, have accentuated the need for interstate understandings, and have accelerated attempts to solve such problems through interstate compacts or agreements. Such attempts to date have resulted in the ratification of several such compacts and the initiation of studies on many streams interstate in character.

Prior to systematic or efficient development of these great potentialities, it is first needful to ascertain definitely the relative interests of the States affected, and of the Federal Government, in such waters, in order that the reasonable and equitable use of these great resources may be properly conserved for the generations that will live in these various States in the years to come.

Questions of right and necessity arising out of the uses of these natural resources are varied, and, in many instances, most complicated and difficult of adjustment. Controversies respecting international rivers are settled either by treaty or by war. Interstate controversies must be settled by interstate compacts or agreements, or by decree of the United States Supreme Court.

With regard to the sovereign rights of this Nation to withhold from another nation, any of the benefits arising out of the use or enjoyment of the waters of an international stream, the Attorney General of the United States held in substance that the recognition of such a requirement is entirely inconsistent with the sovereignty of the United States over its natural domain; that the United States has a perfect right to divert all the waters of an international stream at any point above an international boundary, irrespective of the effect of such diversion upon the flow of the river in the lower nation, or along that part of its course which may form the boundary between the two nations.

Since the several States of the Union are sovereign in all respects except in so far as they have surrendered or delegated to the Federal Government certain sovereign prerogatives, it might appear that the aforementioned rights of the Federal Government to withhold uses of the water in an international stream, applied with equal force as between the several States; but such is not the case.

With regard to interstate streams, the Supreme Court has heretofore laid down certain general principles applicable to certain conditions, but such decisions fall far short of completely pointing the way in the settlement of all problems interstate in character.

One of the fundamental principles laid down by the Supreme Court is that all States stand on the same level. No State can impose its own legislation on one of the others, and is bound to yield its own views to none.

In one important interstate case the Supreme Court held that "the one cardinal rule underlying the relations of the States to each other is that of equality of right", and in this particular case held that there must be an equitable apportionment of the benefits arising out of the use of an interstate stream.

Upon first consideration it may appear that a settlement of these interstate matters may be determined more expeditiously and effectively by Court procedure than through treaty or compact between the States interested.

This Committee and the Irrigation Division have, through the adoption of the aforementioned resolution, given their approval to the Compact Method as the more desirable means for settling such matters. On the other hand, experience indicates that it would be more difficult to change or modify provisions embodied in interstate compacts, once they have been agreed to, than if the adjustments were the result of a Court decree subject to modification from time to time by the Court having jurisdiction.

While, as stated, it is believed that a compact or treaty is the more logical method for settling questions arising between States, it should be obvious that in such procedure it is essential to approach such questions with ample caution, and that compacts should be signed or ratified only after the most mature deliberation has been exercised in a consideration of the ultimate effect which the same may have upon the future welfare of the peoples, since, when once ratified, such compacts may be practically irrevocable.

The Chairman of the Committee believes that one of the greatest benefits resulting from the application of the compact or treaty method for the settlement of interstate problems, is a desired recognition by the Federal authorities of the principle of State autonomy as opposed to Federal bureaucratic usurpation and control of State resources, a question of growing importance to the Eastern States and one of long standing in the Western States.

The conference on the Colorado River, held in Denver in October, 1927, by the seven interested States, seeking a common basis on which the waters of this stream and the benefits to be derived through the use of the same, may be equitably apportioned, definitely brought to the forefront the paramount question of State *vs.* Federal ownership and control of the natural resources of the West.

While a determination of the relative rights of these States to the use of the water of this great river system is of vital importance, probably it is of less importance to the Western States than the age-old principle of State sovereignty and the inherent rights of these States to control the natural resources therein.

As evidence of the importance of this question, is the so-called Pittman resolution adopted by the Denver Conference of the Governors and Interstate River Commissioners of the Colorado River Basin States, at Denver, in October, 1927, which, on account of the importance, is herein quoted in full:

*"Whereas, it is the settled law of this country that the ownership of and dominion and sovereignty over lands covered by navigable waters within the limits of the several States of the Union belong to the respective States within which they are found, with the consequent right to use or dispose of any portion thereof, when that can be done without substantial impairment of the interests of the public in the waters, and subject always to the paramount right of Congress to control their navigation so far as may be necessary for the regulation of commerce with foreign nations and among the States, and whereas:*

"It is the settled law of this country that subject to the settlement of controversies between them by interstate compact, or decision of the Supreme Court of the United States and subject always to the paramount right of Congress to control the navigation of navigable streams so far as may be necessary for the regulation of commerce with foreign nations and among the States, the exclusive sovereignty over all of the waters within the limits of the several States belongs to the respective States within which they are found, and the sovereignty over waters constituting the boundary between two States is equal in each of such respective States, and whereas:

"It is the sense of this Conference that the exercise by the United States Government of the delegated constitutional authority to control navigation for the regulation of interstate and foreign commerce does not confer upon such government the use of waters for any other purposes which are not plainly adapted to that end, and does not divest the States of their sovereignty over such waters for any other public purpose that will not interfere with navigation:

"Therefore, *Be It Resolved*, That it is the sense of this Conference of Governors and the duly authorized and appointed Commissioners of the States of Arizona, California, Colorado, New Mexico, Nevada, Utah, and Wyoming, constituting the Colorado River Basin States, assembled at Denver, Colorado, this 23rd day of September, 1927, that:

"The rights of the States under such settled law shall be maintained.

"The States have a legal right to demand and receive compensation for the use of their lands and waters except from the United States for the use of such lands and waters to regulate interstate and foreign commerce.

"The State or States upon whose land a dam and reservoir is built by the United States Government, or whose waters are used in connection with a dam built by the United States Government to generate hydro-electric energy, is entitled to the preferred right to acquire the hydro-electric energy so generated or to acquire the use of such dam and reservoir for the generation of hydro-electric energy, upon undertaking to pay to the United States Government the charges that may be made, for such hydro-electric energy or for the use of such dam and reservoir to amortize the government investment, together with interest thereon, or in lieu thereof agree upon any other method of compensation for the use of their waters.

"We, the undersigned Committee, to which has been referred the foregoing Resolution, as presented to the Conference on August 29, 1927, by Senator Key Pittman, having adopted certain amendments unanimously which are now incorporated therein, recommend that the Resolution set out above be adopted."

Since July, 1927, many important problems concerning interstate streams have arisen. Some of these problems have been settled by Court decision and others by compact, but the solution of the majority of them is still pending. Other important problems are in the offing. The West probably still occupies the center of the arena of interstate water matters, due to the magnitude of the current problems, but during the last two and one-half years several important interstate water controversies have arisen in the East.

Only a few interstate water controversies have been decided to date by the Supreme Court of the United States, the most important of which are: *Wyoming vs. Colorado*; *Kansas vs. Colorado*; and the controversy over diversions by the City of Chicago, Ill., of Lake Michigan water. The first two cases were between States in which the principle of appropriation was in effect. That principle was recognized by the Court, in the *Colorado-Wyoming Case*. The

last, the Chicago Diversion Case, was a controversy between riparian right States, and it was hoped by the States in which that principle applies, that the Court in its decision would establish a precedent by defining the relative rights of riparian owners along a stream system. Such was not the case, the Court basing its decision on the power of the National Government to regulate commerce between States, and more specifically on an act imposing upon the Secretary of War the obligation of removing obstructions to navigation. Two suits have been filed, *viz.*: New Jersey *vs.* New York and Connecticut *vs.* Massachusetts, in the Supreme Court of the United States, which should result in a decision establishing a precedent to be followed in riparian right States. The Special Master in the latter suit has given his opinion which if upheld by the Supreme Court will materially clarify the relative status of riparian right States. He said in effect that the principle of equality of right should be applied and that specific damage must be shown.

Several important international questions over waters are in progress of solution. These are discussed in more detail later.

There is a growing consciousness among the States that have interstate streams, or of which water is an important resource, that the question of Federal *vs.* State control of unnavigable unappropriated waters should be definitely determined.

It is probably true that the principle that States have full control of their waters so long as they are not navigable, is well established, due to the intricate systems of administration and rules of appropriation that States have built up to administer and distribute those waters; the repeated recognition of those systems by decisions of Federal Courts and Executive orders; and the implied recognition of the States' ownership of such resources by various acts of Congress. Yet there are still some attorneys who maintain that the Federal Government has control of interstate streams. The question should be settled. Much discussion has been had on the subject during the last two and one-half years.

The subject is considered of major importance by the Association of Western State Engineers. Since the creation of the Federal Power Commission, New York State has been fighting for the right to control her own water power resources and she has been in a large measure successful. Maine has done likewise, and not only controls her water power resources, but has a law which prohibits the export of power. The law to date has been effective. The States of the South are fighting to control their own water power resources as against Federal control. In a decision by the Supreme Court of the United States over a power case in Wisconsin, the Court pointed out the sovereignty of a State over navigable streams subject to the higher authority of the Federal Government. A certain power company in Wisconsin had failed to comply properly with a law passed in 1925 requiring all owners of power dams to acquire a permit from the State to continue operation, etc. The dam in question was built in 1878 and riparian ownership was claimed. The United States Supreme Court upheld the State law.

It is interesting to note that the Federal Power Commission in its annual report for 1928 advocated legislation in States providing for a joint commis-

sion to regulate the transmission of power between the States. If the power were sold direct to consumers the final jurisdiction was to rest with the States, but if the power from one State were sold to distributing companies in another State, the State decisions were to be subject to Federal Court review since such sales would come under the head of interstate commerce.

On the other hand the exigencies of some of the major problems before the country have led some leading engineers to believe that the Federal Government should have control of interstate waters. As an example of this, American Engineering Council's Committee to consider Mississippi Flood Control, composed of John R. Freeman, Past-President, Am. Soc. C. E., and Gardner S. Williams, Baxter L. Brown, and Arthur E. Morgan, Members, Am. Soc. C. E., at the meeting in January, 1928, made the following statement:

"It is the opinion of this Committee that the authority of the General Government to deal with such questions as are involved in the Mississippi River problem should no longer hang upon such slender threads as the general welfare clause or the regulation of commerce clause of the Constitution, but that the Constitution of these United States should be amended to confer upon the General Government the authority to control and administer the national waters and to assess damages and allocate benefits and costs in connection therewith.

"It is our further opinion that only by the procedure which such an amendment, followed by the passage of a Federal Water Control law, would make possible, can an equitable or justifiable distribution or allocation of the costs of river improvement and flood protection be assumed."

The same view was expressed by Mr. Morgan at the Assembly of American Engineering Council held in Washington, D. C., on January 14 and 15, 1929, and it is understood that steps are being taken, looking to the introduction of the necessary legislation to bring about the proposed amendment.

It is believed from discussion that has taken place in the West that such a procedure as that stated would not meet with favor among the Western States. The Western States prefer to settle their own differences as to interstate waters by compact, or even by Court action when necessary, rather than to submit the administration of those waters to the remote control of a Federal Bureau which would have no knowledge of the complex, intricate problems of a local nature involved in their administration.

It is believed further that the Western States are opposed to submitting control of the upper tributaries of the Mississippi which rise in those States to any Federal Commission—the Mississippi River Commission or otherwise. Such control is gradually being sought on the plea of the necessity of regulating the flow of those tributaries as a part of the Mississippi Flood control plan. The following statement by the Engineering Council Committee cited is worthy of note:

"Storage reservoirs on the remote head-waters of tributary streams have too limited an effect upon the floods of the Mississippi River to justify their inclusion in the flood protection program for that river."

This discussion is given to indicate the importance and complexity of the problem, and the desirability of full discussion by all interested parties to the end that a constructive program might be evolved for its solution. It is believed that now is an opportune time to bring the problem to the front. The National Executive is an engineer, and it is understood that he is in favor of as little Federal control of National resources as is possible. The Federal Land Commission appointed by him to consider the desirability of turning over to the States, the Government land within those States, and allied matters, should properly consider the all-important question of the control of interstate streams and unnavigable unappropriated waters.

The following gives a brief discussion of some of the most important interstate problems that were in evidence during 1928 and 1929.

Very truly yours,

M. C. HINDERLIDER, *Chairman,*  
Committee of the Irrigation Division  
on Interstate Water Matters.

#### ST. LAWRENCE RIVER

(Canada and United States)

Negotiations have been under way since 1921 between Canada and the United States in an endeavor to reach an understanding concerning the development of the St. Lawrence River as a waterway. In 1921, Messrs. Bowden and Wooten made a joint report to the International Joint Commission concerning the proposed development. In 1924, the United States Government appointed a National Committee called the St. Lawrence Commission of the United States, headed by President Hoover, then Secretary of Commerce. Canada appointed a National Advisory Committee to meet with the United States Committee. These two Committees met and appointed a board of engineers composed of members from the two countries to review the Bowden-Wooten report. The Engineering Board made its report in November, 1926.

The plan of development as finally recommended provides for the construction of a navigation channel 25 ft. deep in the 183-mile section of the river between Lake Ontario and Montreal, Que., Canada, together with nine locks, twenty-five miles of canal, an initial power development of 2 700 000 h.p., and an ultimate development of 5 000 000 h.p.

Some discussion was carried on between the two countries during 1927 and 1928. It is reported that the views of both countries are close together as regards the major features of the project. Canada desires a 27-ft. channel, credit for certain improvements completed on each side of Montreal, and for the Welland Canal, and does not want to develop power beyond her ability to absorb it, as she is opposed to the export of power. It is reported that the United States is of the opinion that Canada should receive credit for only those improvements which will be embodied in the final plan of development, and while the United States Government concedes that all the power devel-

oped in Canada and one-half of that developed on the border should go to Canada, yet it believes full development of the potential power possibilities should be made in one stage.

Difficulties arose in Canada over the question of ownership and control of the power that was to be developed by the St. Lawrence Project. The controversy was between the Dominion Government and the Provincial Governments of Ontario and Quebec. The question was referred to the Canadian Supreme Court, but the decision rendered by the Court appears not to have been conclusive. This condition has precluded the possibility of further negotiations between the two Governments pending some sort of agreement between the Dominion Government and the Provinces.

It is reported that Premier MacKenzie King announced in the early part of 1929 that at the close of the session of Parliament a conference would be called between representatives of the Dominion and the Provinces of Ontario and Quebec in an attempt to arrive at an agreement in order that negotiations might be resumed with the United States. It was further stated that no treaty would be finally negotiated until Parliament had ratified each clause.

The New York State Government has recommended the development of power on the St. Lawrence at State expense, the distribution to be made by private interests.

In the meantime Canada has granted the Beauharnois Light, Heat, and Power Company a permit to construct a power canal between Lakes St. Francis and St. Louis, on the St. Lawrence River, to divert 40 000 sec.-ft. for the development of an initial output of 500 000 h.p. The permit, however, provides that the canal shall be of sufficient size for navigation, and the whole development is made subject to subsequent additions to make it a part of the St. Lawrence Project should the treaty between the two countries be consummated. Work was commenced on this project in October, 1929.

### NIAGARA FALLS

(Canada and United States)

A Special International Niagara Board was created by Canada and the United States in 1925, to investigate the change which was being made in the course of the Niagara River, which it was reported threatened to ruin the beauty of Niagara Falls, and to formulate plans to correct this condition. The Board submitted its report on December 14, 1927, in which it recommended the construction of certain submerged weirs and the enlargement of certain channels to distribute the flow more uniformly over the Falls for the purpose of affecting the desired results and also of providing opportunity for increased diversions.

Following negotiations, a treaty was formulated and a protocol was signed on January 2, 1929, providing for the construction of the remedial works as recommended by the Special Board and for an additional diversion of 10 000 sec.-ft. of water on each side of the river between October 1 and March 31

of the following year, for a period of seven years. The treaty of January 11, 1909, provided for a diversion by New York State of 20 000 sec.-ft. and by Canada of 36 000 sec.-ft.

The ratification of the treaty by the Senate was opposed by the City of Chicago. It is reported that the municipal authorities of Chicago maintain that the treaty should not be ratified until the negotiations for the St. Lawrence Project and the Illinois Waterway are completed, and, further, that the remedial works would lower the lake levels, and the diversion of an additional 20 000 sec.-ft. would increase the flow from Lake Erie. This latter view is discounted by Army engineers.

What is said to be considered a victory by New York State in her fight to retain control of power development within the State, was the obtaining from the Niagara Falls Power Company (the beneficiary of the diversion of the additional 10 000 sec.-ft. at Niagara Falls) of an agreement to withdraw all objections to rentals now being paid the State for waters, and an agreement on the part of that Company to pay an equitable rental for the use of the additional diversion at Niagara Falls and to seek from the State a license for the use of that water. It is stated that New York considers this a complete recognition of the rights and sovereignty of the State to license power companies and to demand a rental charge for all water now being used and to be used under the treaty.

#### DELAWARE RIVER

(State of New Jersey *vs.* State of New York and City of New York, Commonwealth of Pennsylvania, Intervenor)

The State of New Jersey has filed suit in the Supreme Court of the United States against the State of New York, to enjoin New York City from making certain diversions from the headwaters of the Delaware River which she has planned for augmenting her water supply. The State of Pennsylvania has filed a motion with the Court to present an intervening petition, and has filed a petition for leave to intervene. The first hearing was set for January 6, 1930.

The plan of development as proposed by New York, provides for a supply of 600 000 000 gal. daily from the flood waters of five tributaries of the Delaware River, and 100 000 000 gal. daily from Rondout Creek, a tributary of the Hudson. This plan provides for the construction of five reservoirs and the necessary aqueducts and appurtenances to bring the water to New York City. The plan also provides for releasing certain quantities of water, when necessary, to maintain a certain specified minimum rate of flow, as was provided for in the last proposed compact. The contemplated development is wholly within the State of New York about 30 miles from the main stream, and affects 600 sq. miles of the total of 2 389 sq. miles of drainage area of the Delaware River in New York. It is maintained by New York that flood waters only are to be stored, and that due to releases from New York reservoirs the low flows will be greater after the development than at present.

The State of New Jersey maintains that it has a right to the undiminished flow of the river, and it is reported that it further alleges that New York State is contemplating the development of power with some of the water diverted.

This controversy is one of several years standing, and it was anticipated that settlement would be made by compact. A compact was negotiated in 1925, was signed by the Commissioners appointed by the three States, and was ratified by the State Legislature of New York, but failed of ratification in New Jersey and Pennsylvania. Another compact was formulated in 1927. It was signed by the representatives of the three States, but again failed to be ratified in Pennsylvania and New Jersey although it was ratified by the New York State Legislature.

The City of Trenton, N. J., was one of the principal objectors to the compact in New Jersey.

After failure to consummate a compact, New York City retained Attorneys Hughes and Davis to give their opinion as to the right of New York to make the proposed diversion. Both attorneys held in effect that if the facts were as they were purported to be, the Supreme Court would probably allow the diversion and provide for the payment of damages, if any, to lower interests; whereupon New York decided to proceed with the development, which action precipitated the suit.

It is believed the following portion of Mr. Hughes' opinion is of particular interest in the light of growing importance over the country regarding Federal vs. State control of unappropriated non-navigable waters. Mr. Hughes says:

"Whether Congress has power to provide the diversion of navigable waters from one water-shed to another is a question which may be regarded as not yet finally determined' if 'Congress has this power it would be exercised only in interest of interstate commerce, that is, navigation.' Similarly the Secretary of War could not act except to protect navigation. Therefore unless the proposed diversion would injuriously affect navigation, 'the United States will not be entitled to complain.'"

The taking of testimony started on April 21, 1930, at Trenton by Charles N. Burch, Special Master.

The outcome of the suit should be of great importance to riparian right States. Many future water supply developments in the East must be along lines similar to those proposed by New York, that is, involving riparian rights in two or more States.

#### CONNECTICUT RIVER

(State of Connecticut *vs.* Commonwealth of Massachusetts and Boston Metropolitan Water District)

The State of Connecticut filed a suit in the Supreme Court to restrain the City of Boston, Mass., from diverting water from the Swift and Ware Rivers, tributaries of the Connecticut River. Charles W. Bunn was appointed on December 2, 1929, by the Supreme Court as Special Master to take testimony.

In May, 1930, Mr. Bunn in his report upheld the right of the City of Boston to construct the proposed project and held that the damage that will result to navigation, to agriculture, and to the sanitary condition of the Connecticut River by the project will be inconsequential. He recommended the payment of a certain sum for damages that will result to a certain proposed water project if and when the project is constructed.

Mr. Bunn's report is noteworthy in that he held against the principle as set forth by Connecticut that any invasion of the rights or privileges of a State calls for an injunction regardless of damage. Although both States have adopted the doctrine of riparian rights, Mr. Bunn held that the principle of equality of right should be applied and that specific damage must be shown to justify an injunction.

#### LAKE MICHIGAN

(Pollution of Chicago Water Supply. Chicago and Indiana Towns on South Side of Lake)

Negotiations are under way between the City of Chicago and certain Indiana towns on the south side of Lake Michigan to provide for the elimination of the pollution of the Chicago water supply by phenol wastes from coke-oven plants in the Indiana towns. The pollution occurs when unusually strong winds blow from the south carrying the phenol across the lake in the vicinity of the intakes of Chicago's water supply system.

As an example of the amount of the pollution, it is reported that during the occurrence of strong winds in the latter part of 1927, it required 13.6 lb. of chlorine per 1 000 000 gal. for purification purposes while the normal quantity of chlorine necessary is 2 lb. per 1 000 000 gal. The excessive quantities of chlorine and phenol cause the water to have a bad taste.

It is reported that plans are already under way or completed for the elimination of the phenol nuisance in the Calumet and Michigan City Districts.

#### CHICAGO DIVERSION FROM LAKE MICHIGAN

The United States Supreme Court by a decision rendered on January 14, 1929, ended a 20-year controversy between the City of Chicago and all the Lake States, except Illinois and Indiana, regarding certain diversions that the city has been making from Lake Michigan for sewage dilution and other purposes. The controversy finally involved thirteen States, practically all the Mississippi River States supporting Chicago on the plea that the diversions aided navigation along the Mississippi. The Supreme Court held in its decision that the diversion as made by Chicago was illegal; that no diversion was legal except in the interest of navigation; that the increase in diversion made by Chicago from 4 167 sec.-ft. to 8 500 sec.-ft. defied the authority of the National Government resting in the Secretary of War; and that Chicago must proceed with dispatch to remedy the condition. Provision was made for further hearings to determine the minimum quantity of water necessary to be diverted in the interests of navigation, and to determine the length of time that should be allowed the City of Chicago to reduce the diversions to that point.

Hearings to determine these questions were held before the Hon. Charles E. Hughes, Master, during 1929. Mr. Hughes submitted his report to the Supreme Court on December 17, 1929, in which he specified a certain program of construction of sewage treatment works that Chicago should follow to enable the diversion from the lake to be reduced from its present amount of 8 500 sec.-ft.

to a permanent amount of 1 500 sec-ft., on December 31, 1938. Mr. Hughes also recommended that Chicago should be required to install control works to prevent the reversal of flow through the Chicago River during storms; the plans for the control works to be approved by the Chief of Engineers of the War Department; and those works to be completed within two years after receiving the authorization of the War Department.

On April 14, 1930, the Supreme Court approved substantially the report of Mr. Hughes.

The plaintiffs in the case alleged that the diversion of water as made by Chicago from Lake Michigan interfered with navigation on the Great Lakes by lowering the surface of the lakes by as much as 6 in.

The carrying out of the provisions of the decision of the Supreme Court will necessitate, probably, the greatest expenditure of money ever made to conform to a Court decision regarding water matters. Chicago engineers estimate that the works necessary to carry out the Court order will cost \$176 000 000. However, the Court decision was not important from the standpoint of precedent. It did not determine relative rights of riparian owners which is an important question in the East. The decision was based upon an act passed by Congress in 1899, which gave to the Secretary of War and the Chief of Army Engineers authority to prevent obstruction to navigation. However, the decision did state that Congress "may not arbitrarily destroy or impair the rights of owners by legislative action which has no real or substantial relation to the control of navigation or appropriateness to that end."

#### RIO GRANDE, COLORADO, TIAJUANA

##### (United States and Republic of Mexico)

Probably the most important and involved question concerning international streams in the United States is that of allotment of waters of the Rio Grande (from Fort Quitman, Tex., to the Gulf of Mexico), Colorado, and Tiajuana Rivers, between the United States and Mexico.

A large body of land is irrigated in Texas along the Lower Rio Grande. Several millions of dollars are now being expended in the further development, and more development is contemplated. Most of the water originates in Mexico and comes to the Rio Grande through tributaries, the main ones of which are the San Juan and Salado. There are large areas of land in Mexico susceptible of irrigation from those streams. Development in Mexico is far behind that in the United States, but some development on a large scale has been started. The Don Martin Project being constructed by the Mexican Government will provide for the irrigation of about 165 000 acres of land from the Salado. A treaty is necessary to provide for a proper allocation of the water supply, or future Mexican uses might encroach upon present uses being made of the waters by American land owners.

On the Colorado River conditions are the reverse of those on the Rio Grande. The water supply originates in the United States, whereas there is a considerable acreage of land in Mexico being watered by the Colorado River which might be deprived of its water supply by future uses in the United States unless an allocation is made by treaty.

Tiajuana River meanders back and forth across the western end of the international boundary between the United States and Mexico. The City of San Diego, Calif., and water users in that vicinity need Tiajuana water; so do Mexican users. Due to the character of flow, storage is required. The Mexican Government is now building a reservoir for that purpose. An allocation of those waters should be made.

A commission was appointed by the United States, composed of Elwood Mead and Lansing H. Beach, Members, Am. Soc. C. E., and Mr. W. E. Anderson, to meet with a similar commission representing the Republic of Mexico, to discuss these matters and devise a basis for settlement. The Mexican Commission was appointed in 1927, while the American Commission had been in existence for some time.

The Joint Commission was very active in 1929, several meetings having been held. More are scheduled for 1930. No report has been made public as to progress, but it is hoped the basis for an early settlement has been reached.

For some time the Rio Grande between El Paso, Tex., and Fort Quitman has been under discussion by the International Boundary Commissions of the United States and Mexico. The questions involved are flood control and means to prevent channel changes which have caused some difficulty in determining ownership of certain tracts of land. Considerable time was spent by the two Commissions in making detailed investigations and apparently an early settlement is in view. The American International Boundary Commission made a report to the Secretary of State in June, 1929, on the engineering feasibility of a plan to solve the problems involved.

#### RIO GRANDE

(Colorado, New Mexico, and Texas)

A series of conferences were held between these States at Santa Fé, N. Mex., beginning in December, 1928, and ending in February, 1929, for the purpose of formulating a compact providing for the allocation of the waters of the Rio Grande. The conferences were presided over by Col. W. J. Donovan, representing the United States.

It developed during the negotiations that it would be impossible at that time to draft a compact which would make a definite allocation of water satisfactory to all the interested States, due principally to the fact that the ultimate water supply of the basin which was to be divided, was not known.

Of the water-shed of the Rio Grande in Colorado 2 900 sq. miles constitute a closed basin that is not tributary to the Rio Grande, but may be made so by the construction of an outlet drainage canal tapping the area. Such canal would materially augment the quantity of water contributed by Colorado to the Rio Grande.

A temporary compact was formulated and signed by the Interstate River Commissioners for the respective States, providing for a condition of *status quo* on the river for a period of five years, during which time concerted effort would be made by the three States to bring about the construction of the drainage canal from the closed basin in Colorado, together with the construc-

tion of a storage reservoir at the Colorado-New Mexico State line, all at Government expense. After the construction of these works, or at the expiration of five years, further negotiations are to be entered into for the consummation of a permanent compact.

The compact provides for the construction of these works by the Federal Government. The claim of the three States upon the Federal Government is predicated upon the fact that some years ago the United States Government entered into a treaty with the Republic of Mexico whereby there was ceded to Mexico in perpetuity 60 000 acre-ft. per annum from the waters of the Rio Grande. This treaty was not the result of any legal obligation upon the United States, but was in the interest of international comity. In an opinion rendered at the request of the Department of State, Attorney General Judson Harmon said in regard to the validity of Mexican claims:

"Whether the circumstances make it possible or proper to take any action from considerations of comity is a question which does not pertain to this department; but that the question should be decided as one of policy only, because the rules, principles, and precedents of international law impose no liability or obligation upon the United States."

The treaty specifically states that Mexican claims were not conceded and it stipulated that the settlement was not to be construed as a precedent.

The three States contend that the 60 000 acre-ft. which were ceded to Mexico were taken from the common water supply of the three States for the benefit of the whole Nation (to preserve international comity and peace) and, therefore, the cost of construction of the outlet drain and reservoir provided for in the compact, and which will result in returning to the States the equivalent of the water ceded to Mexico, is an obligation of the United States Government.

The compact as formulated was ratified by the Legislatures of the three States and by Congress. A bill has been introduced in Congress providing for the construction of the outlet drain as provided for in the compact.

#### COLORADO RIVER

(Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming)

*Progress of Negotiations Since July, 1927.*—In an effort to reach an agreement on the division of the waters of the Colorado River allotted to the Lower Basin States by the Santa Fé-Colorado River Compact of 1922, further conferences were held between representatives of Arizona, California, and Nevada during 1927, but to no avail, the major difficulty being a difference of opinion as to the proper allotment of water and of benefits derived from power that might be developed along the Colorado River.

The Swing-Johnson Bill, after many amendments and vicissitudes, passed the House of Representatives in June, 1928, and the Senate during the session of 1928-29. The bill as passed is termed the Boulder Canyon Project Act and among other things provides for the following:

- 1.—Construction of a dam at Boulder or Black Canyon of not less than 20 000 000 acre-ft. capacity to control floods, improve navigation, store water for use in the United States, and to generate power.

- 2.—An appropriation of \$165 000 000 to construct the project, of which \$25 000 000 was designated for flood control, the \$25 000 000 to be replaced out of 62½% of any revenue in excess of the amount necessary to repay the Government for the remainder of the cost.
- 3.—That contracts shall be made by the Secretary of the Interior for the sale of power, and water in sufficient amount to replace the Government investment in the dam and power plants in fifty years, before construction is started, the power to be sold at a price "justified by competitive conditions at distributing points or competitive centers."
- 4.—That 37½% of any moneys collected by the Secretary of the Interior above the amounts due the Government, shall go to Arizona and Nevada by virtue of their natural resources being taken for a public service.
- 5.—Allotment of 300 000 acre-ft. of water to Nevada and 2 800 000 acre-ft. to Arizona for exclusive beneficial and consumptive use in perpetuity. That Arizona may annually use one-half of the excess or surplus waters unapportioned by the Colorado River Compact and all the Gila River.
- 6.—That the Act would become effective when seven States ratified the Colorado River Compact, but, failing this, it would become effective by proclamation of the President six months after passage, if six States had ratified the Compact.
- 7.—All provisions of the Act and the future operation of the project were made subject to the Colorado River Compact.

The Act also provided that the All-American Canal may be constructed, the cost to be paid by the lands benefited.

The Act was approved December 21, 1929. Arizona did not ratify the Colorado River Compact, but Utah did so in March, 1929, which provided the necessary six States. In June, 1929, President Hoover declared the Act effective.

When notice was given that bids would be received for power, the applications were greatly in excess of the available power. After the Secretary of the Interior made his announcement of the tentative allocation of power and the price to be paid for it, some of the States, notably Arizona and Nevada, took exception to such allocation. Pending a further effort to reach an agreement between the Lower Basin States, the Secretary announced that no contracts for power or water would be let immediately, if Arizona, Nevada, and California would enter into further negotiations in an attempt to reach an agreement. Arizona had prepared a suit to be filed in the United States Supreme Court. The request of the Secretary was complied with, and Arizona refrained from filing her suit pending the outcome of conferences between the Lower States to start January 20, 1930.

The Lower States' Conference was held at Reno, Nev., but adjourned without an agreement having been reached. A controversy which arose at the conference between California interests over the proper division of the water allotted to California was later settled when it was agreed that Imperial Valley should receive 3 850 000 acre-ft., and the Metropolitan Water District, 550 000 acre-ft. of Class A water. From the unappropriated surplus the Metropolitan Water District is to receive an additional amount up to 550 000

acre-ft. Any surplus over 1 100 000 acre-ft. allotted to California should be given to the Imperial Valley.

The power contracts were signed April 26, 1930. The allotment of power was as follows: Primary power, Arizona, 18%; Nevada, 18%; Metropolitan Water District, 36%; Los Angeles, 13%; eleven municipalities in California, 6%; and the Southern California Edison Company and associated companies, 9 per cent. The Metropolitan Water District is to use all the secondary power it has need for, the remainder to be divided equally between Los Angeles and a group of four power companies. The specified present price for power at the switchboard to lessees is 1.63 mills per kw-hr. for primary power, and  $\frac{1}{4}$  mill for secondary power, and to allottees who are not lessees the price is 2 mills per kw-hr. for primary power and  $\frac{1}{10}$  mill for secondary power.

On June 24, 1930, an injunction suit was filed in the Supreme Court of the District of Columbia by Fred T. Colter as Trustee of the Arizona Highline Reclamation Association to restrain the Secretary of the Interior from taking any action under the contracts with the City of Los Angeles and the Metropolitan Water District.

An appropriation of \$10 660 000 has been made by Congress to start work on the project.

The Interstate Water Commissions of the Upper Basin States—Colorado, Wyoming, New Mexico, and Utah—held a preliminary conference in Denver, Colo., on December 5, 1929, for the allocation of the 7 500 000 acre-ft. of water set aside for the Upper Basin by the Colorado River Compact.

Due to the fact that some of the States did not have all their data prepared, the Conference adjourned to be reconvened at such time when all States were ready. From the preliminary discussion it is not anticipated that any great difficulty will be experienced in consummating a compact among these four Upper Basin States.

#### LARAMIE RIVER

##### (Colorado and Wyoming)

Discussions have taken place between the States of Colorado and Wyoming with respect to present uses of water in Colorado from the Laramie River, an interstate stream.

Some years ago as a result of a suit instituted by the State of Wyoming against the State of Colorado, the Supreme Court of the United States rendered a decision relative to the uses of the waters of this stream by the two States.

It appears from these negotiations that Colorado places a materially different interpretation on the decree of the Court than the State of Wyoming, which may require a construction of the decree by the Court to clarify the present situation.

#### LA PLATA RIVER

##### (Colorado and New Mexico)

In 1922, Colorado and New Mexico ratified a compact providing for the division of the waters of the La Plata River, a small interstate stream heading

in Southwestern Colorado and flowing into New Mexico. This compact is administered by the State Engineers of the States in question.

The provisions of the compact permit rotation of water between the two States during times of shortage. This practice resulted in a suit instituted by one of the water users in Colorado for the purpose of enjoining the water officials of Colorado from continuing such practice, which it is alleged results in injury to the plaintiff. This suit has been watched with interest since in reality it is a direct attack upon the validity of the compact which was the first one negotiated by Colorado with her sister States with respect to the use of waters of interstate streams. The District Judge before whom the case was tried recently entered a decree in favor of the State.

It should be borne in mind that the aforementioned suit is not of an interstate or international character, but at present is an internal affair.

#### NORTH PLATTE

(Colorado and Wyoming)

Negotiations have been carried on during the past two years between Colorado, Wyoming, and Nebraska with respect to the use of the waters of the North Platte River, which flows through the three States.

The Federal Government, through the Bureau of Reclamation, appears to be an interested party in this connection as a result of the construction of the Pathfinder Reservoir in Wyoming, and later of other reservoirs and canal systems in Eastern Wyoming and Western Nebraska. These Federal projects have an important bearing upon the equalization and administration of stream flow in Wyoming and Nebraska.

It is confidently anticipated that a successful termination of these negotiations will be had at a comparatively early date.

#### ARKANSAS RIVER

(Colorado and Kansas)

Litigation between the States of Colorado and Kansas over the waters of the Arkansas River has been practically continuous for the past twenty-eight years. In the noted suit brought by Kansas against Colorado in 1901 the United States Supreme Court decided that although certain irrigation interests in Western Kansas had been injured by diversions of water from the Arkansas River in Colorado, that such diversions in that State had not exceeded its equitable share of the waters of this interstate stream, dismissed the case without prejudice against Kansas to re-institute suit at a later date if continued diversions in her judgment justified such action. Kansas has not elected to do so to date.

Almost immediately after the settlement of that suit, certain ditches in Kansas instituted suits in the Federal Court for the District of Colorado against a large number of ditches and reservoirs in Colorado, seeking to restrain the latter from diverting water in Colorado to their alleged injury in Kansas. The first of these suits was settled out of Court, but a later suit was instituted in the same Court by one of the Kansas ditches not a party

to the former settlement. This condition resulted in Colorado in her sovereign capacity filing suit in 1929 against the State of Kansas for the purpose of requiring the latter State to enforce the provisions of the former Supreme Court decree and quiet further litigation by her agents. Testimony in this important case is now being taken before a Commissioner of the Supreme Court.

Negotiations between the Interstate River Commissioners of the two States for some years past looking to the formulation of an interstate compact with respect to the uses of the water of this river, have to date failed in their objective and, as a result of the present suit, have been entirely discontinued.

#### KOOTENAY RIVER

(Canada and Idaho)

Owners of reclaimed lands in Northern Idaho objected in the fall of 1929, to the proposed plan of the West Kootenay Power and Light Company of British Columbia, to construct a dam in Kootenay River at Granite, Idaho, on the plea that such a dam would cause the flooding of their lands. The development as proposed by the Power Company is for the purpose of providing additional power.

The International Joint Commission authorized the Company to make the necessary excavations for the dam, but stated that final decision would be withheld until data relative to possible damage were secured.

#### COLUMBIA RIVER

(Idaho, Montana, Oregon, and Washington)

In December, 1924, the Governor of the State of Washington, addressed a communication to the Governors of the States of Oregon, Montana, and Idaho urging the necessity of a compact for the allocation of the waters of the Columbia River and its tributaries, and the appointment of an allocation board to consider the matter. A similar request was addressed, at the same time, to the Secretaries of War and the Interior. As a result of these communications the Governors of the respective States and the Departmental Officials designated representatives to serve in such capacity. The more controversial issues on this stream appear to be between Washington, Idaho, and Montana in reference to storage of water in the upper two States of Idaho and Montana for use in the State of Washington. Immediate action was taken by these representatives looking to the formation of a compact between the interested States, which has been sanctioned by the Federal Government.

Conferences have been held for the purpose of considering an early draft of a proposed compact submitted by the representatives of the State of Washington and for studying the manifold phases of this problem. Due to the involved nature of the subject and the magnitude of the problem, no definite conclusions appear to have been reached at this time. Such studies have been very largely limited to Clark Fork, Pend' Oreille, and Spokane Rivers

and their tributaries, and to storage possibilities in Priest, Pend' Oreille, and Cœur d'Alene Lakes.

The State of Washington is interested primarily on account of the proposed Great Columbia Basin Irrigation Project in that State. Idaho and Montana are vitally interested in the preservation for future use of sufficient quantities of the waters which rise in those States to assure the legitimate development of their great natural potentialities.

Complicated problems involving power development, navigation, storage, private and corporate interests, etc., are involved. The Federal Government is also interested in any compact allocating the waters in the Columbia River, since certain reclamation projects may be involved, and since also the main river is international in character.

During 1925 and 1926 the State of Idaho made some study of the proposal offered by the State of Washington, but due to lack of definite information as to quantities of water required by the State of Washington and other related matters, the representative of the State of Idaho declined to enter into a compact at that time.

During 1925 and 1926 rather extensive investigations and studies were carried on by the State of Idaho under the direction of W. G. Swendson, Assoc. M. Am. Soc. C. E., former Commissioner of Reclamation of that State, the results of which are set forth in a comprehensive report.

The State of Washington has recently filed with Idaho and Montana a more definite plan of the proposed operations in that State as affecting the use of the waters of the tributaries of the Columbia River. The Committee appointed by the Allocation Board has held numerous conferences as a result of which a tentative draft of agreement on matters concerning Washington, Montana, and Idaho has been prepared.

The principal issue between Washington and Idaho appears to center about the use of Lakes Pend' Oreille and Cœur d'Alene for stream regulation. The owners of property rights about these lakes have raised serious objections against any regulation of the lakes which might be detrimental to their interests.

Similar negotiations in this connection are proceeding between the States of Washington and Montana, with the understanding that progress reports in this regard will be forthcoming at an early date.

#### SNAKE RIVER

(Idaho, Oregon, Washington, and Wyoming)

Congress has authorized the negotiations of a compact between the States of Idaho, Oregon, Washington, and Wyoming, for the allocation of the waters of the Snake River. It is understood that the initial steps in this matter were taken by Wyoming. From latest reports, negotiations in this regard are inactive, the other States concerned having taken no steps, pending further action by Wyoming.

It is understood that the Commissioner of Reclamation of the State of Idaho has requested an allocation of funds with which to take care of an

investigation on this stream. At present, the Federal Government is not involved in the proposed compact.

#### ST. MARY-MILK RIVER

(Montana, United States, and Canada)

It is understood that steps have been taken to re-open the St. Mary-Milk River case before the International Joint Commission on the ground that under the order of 1921 the United States received less than one-half the water of this stream in 1927, whereas it is contended that the treaty of 1909 should provide an equal division of the waters between Canada and the United States.

Records of stream flow are being obtained at a number of new gauging stations for the purpose of providing additional information essential to a proper consideration of this case.

#### CARSON-VIRGIN-OWYHEE RIVERS

(Nevada, Utah, Idaho, and California)

The State Engineer of Nevada reports that negotiations concerning the waters of these interstate streams may be initiated at a later date.

#### JAMES RIVER

(North Dakota and South Dakota)

The State of North Dakota is endeavoring to interest the State of South Dakota in an agreement looking to storage of the run-off from the James River in North Dakota for increasing the low-water flow on that stream.

North Dakota also desires to divert a portion of the flow of the Missouri River to the eastern part of that State, and improve conditions at Devils Lake and on the Cheyenne and James Rivers, for the purpose of supplementing the present run-off and providing domestic water supplies for the cities along these streams.

#### SOUTH PLATTE RIVER

(Colorado and Nebraska)

The compact was ratified and its administration by the State Engineers of the two States was initiated in the spring of 1926. The results to date are most satisfactory.

#### CANADIAN RIVER

(New Mexico, Oklahoma, and Texas)

On December 31, 1926, the Commissioners for the States of New Mexico, Texas, and Oklahoma, signed an agreement for the control of the Canadian River unit in the interstate control of the Arkansas River System.

This agreement provides for the control of the flood waters of the Canadian River and the apportionment of the use of such waters as well as the equitable apportionment of the cost of control according to benefits received by the

several States interested. Other features of the agreement establish the relative importance of the different beneficial uses of the water, promote interstate comity and friendly relations and mutual and common developments, remove causes of present and future controversies, and secure expeditious protection from said river and the expeditious agricultural and industrial developments of the Canadian River, the storage and use of its waters, and the protection of life and property from flood. It is anticipated that the State of Arkansas, also a party to these negotiations, will become one of the signatory States in this connection.

This agreement voices the hope that the States of Colorado, Kansas, Louisiana, and Mississippi may subscribe for the complete control of the entire Arkansas River System.

#### OHIO RIVER

(Illinois, Indiana, Kentucky, New York, Maryland, Ohio, Pennsylvania, Tennessee, and West Virginia)

One of the outstanding examples illustrating the effective application of the principle of interstate compacts is furnished by the agreement entered into between the States of Illinois, Indiana, Kentucky, New York, Maryland, Ohio, Pennsylvania, Tennessee, and West Virginia for the prevention of pollution of waters of the Ohio River and its tributaries through control of phenol wastes.

The pollution of the waters of the Monongahela, Beaver, and other tributaries of the Ohio River, had become so acute in the three States of Pennsylvania, Ohio, and West Virginia, that it appeared imperative to take some concerted action looking to a correction of the condition; and since the Ohio River is an interstate stream, corrective effort had to be applied along streams originating in different States, and, hence, stream pollution involves interstate negotiations.

The first step in this most important piece of interstate diplomacy was initiated by Surgeon-General Cummings, of the U. S. Public Health Service, in 1923, at the instigation of the Ohio State Health Department, by calling a conference in Washington, D. C., at which representatives of fifteen State Health Departments and the U. S. Bureau of Mines, U. S. Bureau of Standards, and the U. S. Public Health Service, were present. This was followed by a meeting of representatives of the manufacturers of by-products of coke, with the Ohio State Health Department, at which time an agreement was reached to keep the phenol wastes out of the streams of that State.

Early the following year (1924) the Health Departments of the States most interested met in Washington where an organization of the Health Departments of the States on the Ohio River water-shed was effected. In April, 1924, at a meeting in Pittsburgh, Pa., the State Health Departments most interested held a conference with representatives of all the by-product manufacturers from the several States, at which time joint similar policies for co-operating States to carry out, were adopted. In November, 1924, the Health Departments of Pennsylvania, Ohio, and West Virginia, through

their Health Commissioners, signed an agreement respecting the control of phenol waste disposal. The success of such an agreement has since led to the formation of plans by the nine States tributary to the Ohio River for the regulation of the pollution of other streams in this system.

The original group of three States has been enlarged to include the nine States mentioned, which have become signatories to this interstate compact known as The Interstate Stream Conservation Agreement. This agreement, affecting the health and lives of 15 000 000 people, is a monument marking the progress of constructive statesmanship, and as a result of such success, it is reported that the cry for "Federal control of stream pollution" is becoming less insistent. Dr. F. H. Frost, of the U. S. Public Health Service, is quoted as having stated that this concerted effort of the States co-operating with industry on a common policy, gives infinitely more promise of success than the enactment of Federal laws to regulate the pollution of interstate streams; and, hence, another menace to State autonomy has been eliminated.

## DISCUSSION

R. I. MEEKER,\* M. AM. Soc. C. E. (by letter).—This report is a valuable summary of the status of interstate water controversies confronting one-half the States of the Union, and of international river problems under consideration by the United States. A glance at the various headings is sufficient to show the importance, imminence, and widespread character of interstate river controversies, including those of power, pollution, drainage, flood control, and irrigation uses, with inter-water-shed diversions for municipal supplies, power, and sewage dilution. The problems involve navigation, power, irrigation, and flood control. The writer is in full accord with the prefatory statements of the report.

In the Arid West water has long been considered the critical resource, and the limit of future development is measured in terms of potential water supplies. Interstate rivers are a common resource, and State equities are subject to and limited by the needs and rights of the various interested States. A keen awakening is apparent in the natural units of river basins and among States as to the importance of defining future usable water supplies; hence, the competition and contests for water now under way to secure and define the rights in interstate rivers. Such action is logical. State titles to interstate rivers should be settled in advance of further utilization, in order that delays to development and financial losses may be avoided.

Almost without exception the Western States are spending considerable sums of State moneys to determine the facts as to their unused water supplies. This is especially true of Nebraska, Colorado, New Mexico, Utah, and California. California's marvelous growth is a direct result of utilization of its rivers for power and irrigation. While its rivers produce annually 75 000 000 acre-ft. of water, the water supplies of Southern California are meager and limited. Hence, the need for Colorado River water and the recent purchase by the City of Los Angeles of Mono Basin water which will be taken through an 11-mile tunnel to Owens Valley where diversion can be made by the present aqueduct. The Gila River in Arizona soon will be entirely consumed by irrigation and power uses. Its waters are involved in the Colorado River controversy. A water compact on the Gila between New Mexico and Arizona is inevitable, and is imminent. To-day, the Arkansas River is 85% consumed at the Colorado border. Since 1901 interstate titles to this river have been in dispute and are still unsettled between the States of Kansas and Colorado. Partition of its waters is correspondingly difficult at this late date because of attendant property values created by the use of its waters. The lesson to be learned is that interstate river titles should be settled while water utilization is in its infancy and before large property rights have been created by use of its waters. Conditions are then favorable to division by agreement without the interminable bickering and haggling always attendant upon ownership of water already put to beneficial use.

The South Platte River is 85% consumed by irrigation uses in Colorado. Fortunately, Nebraska's demands on this river are relatively small and per-

\* Cons. Engr., Denver, Colo.

mitted of an early interstate settlement by compact in 1923. Another example of an interstate river on which heavy development and consumption had taken place before settlement of interstate titles, is the Rio Grande above Fort Quitman, Texas. Large areas are irrigated in the States of Colorado, New Mexico, and Texas. The unused water discharging from the lower end of the El Paso Valley at Fort Quitman, is only 13% of the basin water supply originating above that point. Consumption above Fort Quitman is, therefore, 87% of the basin water supply of 2 260 000 acre-ft. In 1930, the three interested States of Colorado, New Mexico, and Texas perfected a preliminary interstate agreement concerning the waters of the Rio Grande, a difficult task when consideration is given to water claims, present and future, of citizens in three States, with water consumption practically 90% of the basin supply.

It should be obvious that interstate allocation, whether by Court procedure or compact, should be settled before development has crystallized too deeply and water consumption has advanced to the stages outlined on the Arkansas, South Platte, Gila, and Rio Grande.

The dominant principle underlying interstate river compacts has been the settlement of water titles in advance of large created property values; also the protection of future development in portions of river basins where economic conditions do not warrant utilization at the present time. Water appropriations with priorities invariably follow economic feasibility in the irrigated West. The doctrine of priority is limited to intrastate scope by interstate river compacts. State allocations provide both for present and future development. The virtue of the Colorado and Canadian River compacts is that water utilization and consequent consumption are still in their infancy in those river basins.

With reference to interstate river decisions, the case of *Missouri vs. Illinois* was omitted from the Committee report. This controversy was litigated in the Supreme Court of the United States. The primary matter in dispute was the pollution of the Mississippi River by sewage from the Chicago Drainage Canal. The gist of the decision was that insufficient injury was shown, and the case was dismissed.

Mention should also be made of *Nebraska vs. Colorado*, litigated in the U. S. District Court of Colorado and carried to the Supreme Court of the United States. This interstate dispute concerned the waters of the Republican River and their use through an interstate canal serving lands both in Colorado and Nebraska. The decision in substance held that Colorado water officials must permit waters to pass to the Pioneer Canal for the irrigation of lands in Nebraska, thus recognizing an interstate priority. The first suit was filed in 1914, reached the U. S. Supreme Court in 1917, and was affirmed in 1923.

The writer is especially interested in that phase of interstate rivers dealing with Federal and State titles. Having lived in the irrigated West for thirty years where the States own, control, and administer their rivers, the writer is unable to find himself in accord with the Eastern viewpoint, drafted by a committee of prominent engineers of Engineering Council, concerning Mississippi River flood control. This group proposes an amendment of the Constitution of the United States, whereby the Federal Government will be given

authority and control to administer the National waters. The States, and not the Nation, are superior regarding legislation concerning the use of public waters, except only in the matter of navigation, wherein the Nation controls. While it would undoubtedly be convenient to have complete Federal authority on some rivers, in order to effect flood control more readily, it is not necessary, and is viewed as a step in the wrong direction. Long-range control and administration of rivers by officials in Washington would not be countenanced by the Western States. The States have responsibilities and obligations that should be faced and met frankly and fairly at State expense without 100% recourse to the Federal coffers. Nearly every acceptance of Federal moneys results in a yielding of State autonomy. "Let Uncle Sam do it" is becoming a favorite pastime to the great injury of local government. At present, there is a decided tendency by various tributary areas in the Mississippi River Basin to seek Federal funds for purely local benefits under the guise of flood-control benefits to the Lower Mississippi Valley.

M. C. HINDERLIDER,\* M. Am. Soc. C. E. (by letter).—It was the hope of the writer as Chairman, and of the other members of the Committee, that its progress report on Interstate Water Matters would elicit more discussion. Since the viewpoint of the Committee in regard to interstate waters is the viewpoint of the Western Arid States where water is a principal asset and where the principle of appropriation, in general, is in effect, it was the desire of the Committee that in the discussion of the report the viewpoint of the Eastern States, where the riparian doctrine is applied to waters, would be expressed, particularly since several very important controversies over interstate waters are in the process of solution in that region.

It was also the hope of the Committee that there would be some discussion in regard to Federal *vs.* State Control of interstate waters, in which the viewpoint of those States where flood control is a major problem would be expressed.

The Committee is grateful to R. I. Meeker, M. Am. Soc. C. E., for his very excellent discussion of its report, and appreciates his calling attention to the omission from the report of two important interstate controversies that were settled in Federal Courts.

### DRAINAGE OF IRRIGATED LANDS

#### REPORT OF THE COMMITTEE OF THE IRRIGATION DIVISION\*

WITH DISCUSSION BY M. R. LEWIS, M. Am. Soc. C. E.

#### HISTORICAL OUTLINE

The necessity for providing drainage to remove water from irrigated lands seems anomalous. After paying the cost of supplying water to land, why should it be necessary to spend more money to take away a part of this water?

The earliest records of activities of the human race in irrigation show that the drainage problem has always been important and lack of drainage has been a factor in great historical events. The Valley of the Tigris and Euphrates Rivers in old Mesopotamia, to a large extent, has returned to the desert. At one time nearly 10 000 000 acres of land "in ancient Chaldea" were, to quote the late Sir William Willcocks, "as fertile as a garden." The greater part of this region now consists of alkali flats and saline areas, barren of all but meager feed for flocks and herds of wandering tribesmen. Lack of drainage no doubt played a large part in causing the people of this region to fall behind in the struggle for existence. Arabia and the Sahara Desert are dotted with the remains of abandoned irrigation works, saline lands, salt-marsh areas, and abandoned fields showing signs of former water-logging and accumulations of alkali. Egypt is now engaged in reclaiming from alkali areas which in the days of the Ptolemys were known as the most fertile along the Nile. The land of Goshen, to the east of Cairo, assigned the Children of Israel during their sojourn in Egypt, is now being brought back into cultivation after it had been abandoned to alkali for many generations. In India,

\* Published in March, 1928, *Proceedings*.

The membership of the Committee of the Irrigation Division on Drainage of Irrigated Lands is as follows: Thomas H. Means, *Chairman*, J. L. Burkholder, L. M. Holt, H. S. Kleinschmidt, and L. M. Lawson.

drainage problems for many years threatened to wreck the irrigation projects fostered by the British.

Even in America, historical facts point to the drainage problem as influencing the activities of early irrigators. The prehistoric irrigators in the Salt River Valley of Arizona must have been troubled with alkali, for along the ancient ditches alkali areas have been found in many places, indicating that drainage problems had an important part in the lives of these little known irrigators.

The first of the modern tribe to practice irrigation, the Mormons, found drainage an essential part of their irrigation works. They were many years in learning the remedy but, to-day, Utah has carried on more extensive drainage than any other State. The U. S. Reclamation Bureau has been beset with the necessity for continuously extending drainage works and adding new drainage to areas where none had been planned at the time the area was first watered.

The U. S. Department of Agriculture, a few years ago, estimated that approximately 20% of the area to which irrigation had been applied in the Western States had been damaged or rendered unfit to produce full crops from water-logging or accumulation of alkali. Other estimates place the damaged area as high as one-third the irrigated area.

The problem of drainage of irrigated lands, therefore, is one which has followed the history of irrigation and which now confronts all engineers interested in this branch of agricultural development. This Committee has endeavored to compile some of the most pertinent facts on the subject in order to place before the Society in concrete form much widely scattered information.

Much research is needed to render more certain the efforts to apply drainage. There are many individuals and organizations engaged in research. If this report encourages other research, it will greatly benefit the profession.

#### CAUSE OF NECESSITY FOR DRAINAGE

Drainage of irrigated lands differs from drainage of humid areas in this particular—under irrigation the control of the source of water is often possible, a condition seldom true under rainfall conditions.

Irrigation is the art of applying water for the growth of crops. If the quantity of water applied is greater than the quantity consumed, the excess must drain away or the land will be water-logged. It is seldom practicable to irrigate so carefully that exactly the quantity needed by the plant and consumed in plant growth is applied to the land. It is not always desirable to add the exact quantity consumed because flushing by excess of water seems essential to health in some plants just as in the case of human beings. Drainage problems arise, therefore, even in the most economically irrigated areas.

Aside from the advisability of removal of plant waste by application of water, it is almost impossible, if maximum crops are grown, to add just the right quantity so that there will be no excess or waste. The variation in soils as to water-holding capacity, the difference in use by crops, and the daily changes in the climatic factors, which influence evaporation and plant tran-

spiration, are all so variable that it is not practical to maintain in the soil the exact quantity of water which may be needed for crop requirements and for the incidental removal of wastes. An excess of water is usually applied—this must be removed by drainage. For the purpose of showing the variability of these factors, the following discussion will be of interest. Canal seepage is the second large factor of the drainage problem and will be discussed subsequently.

#### WATER-HOLDING CAPACITY OF THE SOIL

The water-holding capacity of the soil must be considered in many drainage problems. One of the most fertile sources of ground-water is that which results from the application of more than the soil will retain. Retentivity of soil for moisture depends on the following:

- (a) Texture—size of soil grains.
- (b) Structure—whether puddled or granular.
- (c) Presence of organic matter, alkali, lime, gypsum or other materials in either the soil or the water.
- (d) Colloidal matter in the soil.
- (e) Presence of natural drainage channels or porous material within the soil.
- (f) Temperature of soil and water.

More specific information about these properties is given later. The results of laboratory investigations on the moisture relations of soils must be used with caution, because no method has been devised of reproducing field conditions in a laboratory sample. In consequence, the results of much laboratory research, while important in consideration of fundamental problems, must be liberally interpreted to fit field conditions.

(a).—*Texture*.—Many schemes have been devised of classification of soils by size of particles. That of the Bureau of Soils, U. S. Department of Agriculture, is in most common use in the United States. In this classification the size of soil grains and the relative proportions of each govern the type into which the soil is placed.

Table 1 gives important classes of soils and the mechanical analyses of each.

Other things being equal, the finer the soil grains the greater the water-holding capacity. The relation between texture and water-holding capacity is, however, seldom simple, for other factors enter into the problem to a very large extent.

(b).—*Structure*.—The structure of the soil is of great importance in determining either its permeability or its water-holding capacity. Structure defines the arrangement of the soil grains. A soil may have its grains separate—may be puddled as commonly expressed—or may have its particles assembled in granules or aggregates, each of which has somewhat the action of a larger particle. In soils containing fine material, particularly clay, the structure is highly important, as is shown by the difference of the water-transmitting powers of a puddled clay and a friable clay.

Structure, to a great extent, is influenced and controlled by the presence of organic matter, soluble salts in either salt or water, colloidal material, and

the previous handling of the soil. There is no definite rule which can be followed in the estimation of these factors; experience alone must guide the investigator. As stated in another place, determination of the water-holding capacity and the permeability of soil in the field is the only certain method of arriving at dependable results.

TABLE 1.—MECHANICAL COMPOSITION OF VARIOUS SOIL CLASSES.\*  
(U. S. Bureau of Soils' Classification.)

Classification of soils.	Fine gravel, 2-1 mm.	Coarse sand, 1-0.5 mm.	Medium sand, 0.5-0.25 mm.	Fine sand, 0.25-0.10 mm.	Very fine sand, 0.10-0.05 mm.	Silt, 0.05-0.005 mm.	Clay, less than 0.005 mm.

\* From U. S. Department of Agriculture, Bureau of Soils, *Bulletin* 78, p. 12, 1911.

(c).—*Organic Matter, Lime, Gypsum, and Alkali.*—These constituents greatly affect the water-holding capacity. The first three usually increase the water-holding capacity and at the same time increase the permeability. Alkali usually puddles the soil and renders it difficult to leach. The amount of these salts greatly affects results. For example, small amounts of one salt will increase the water-holding capacity and greater amounts of the same salt will decrease it.

(d).—*Colloidal Material.*—Recent research in soil science has impressed upon investigators the importance of colloidal material, not only as influencing the water-holding capacity, but as affecting plant food retention and all activities of the soil and its relation to microscopic organisms and to plant life.

A high percentage of colloidal material has the effect of rendering a soil troublesome when leaching is conducted. The colloidal material absorbs saline material, releases it slowly under leaching, thereby causing a dispersion of the finest grains. The soil then becomes impervious, bakes hard upon drying, and is refractory to agricultural operations.

(e).—*Drainage Channels Within Soil.*—Larger openings than the interstices between the soil grains are found in nearly all soils. This is the reason why laboratory studies of movement of soil moisture are difficult to apply to field conditions. Insect burrows, root cavities, cracks, and other larger interstices are found in both soil and subsoil and to great depth. The larger part of the movement of water—downward usually—follows such openings. Capillary movements in the finer cavities and the soil interstices act in all directions. The larger openings, however, have little effect on capillary movements, but control drainage to a great extent.

(f).--*Temperature*.—This affects both capillary activities and movements by gravity. In the one case the difference in surface tension of the liquid is affected; in the other, variation in viscosity of the liquid is the measure of the effect.

Crandall\* has shown a general relation between temperature and reservoir and canal seepage, which compares well with viscosity changes due to temperatures (Table 2).

TABLE 2.—EFFECT OF TEMPERATURE ON SURFACE TENSION AND VISCOSITY OF WATER.

Temperature, in degrees centigrade.	Surface tension, in dynes per centimeter.	Coefficient of viscosity.
0	75.6	1.7991
10	74.3	1.3077
20	73.8	1.0050
30	71.4	0.8007
40	70.0	0.6560
50	68.6	0.5194

The water-holding capacity of a soil under field conditions results from a combination of all these factors. Field conditions cannot be duplicated accurately in the laboratory, consequently it has been found necessary to make determinations of moisture in the field to ascertain the quantity of water which will be absorbed and held. This can be done best by making moisture determinations of the soil before and after irrigation.

#### EXCESSIVE APPLICATION OF WATER AS CAUSE OF NECESSITY FOR DRAINAGE

Deep percolation from irrigated fields is often a large contribution to ground-water and, therefore, an important source of water to be removed by drainage. This statement is contrary to the opinion of some engineers and many water users, but where detailed study has been made of the subject, it has been found usually that the farmer often contributes through excess application more water than results from canal seepage or any other source. Many factors affect the situation and no such general rule can be applied to all cases without consideration of the local conditions.

The conditions which make for rapid movement of the water in soils also produce small capacity and cause large percolation losses from both canals and irrigated fields. Coarse sand soil or pervious subsoil are potent causes of large movements of water to underground strata. Long lands or checks over which water is spread, and the use of small heads of water in irrigating large checks, both result in deep percolation. Probably the most important cause of all is the habit of farmers to irrigate heavily in order to store up water in the soil on the theory that the number of irrigations can be decreased or that water can be stored in the soil to meet expected deficiency in late summer.

On average soils regularly irrigated, the application of 1 in. of water to each foot of depth to which the soil is to be moistened will fill the soil

\* *Engineering News-Record*, February 13, 1919.

interstices with as much water as can be absorbed by the soil and retained against the pull of gravity. Thus, 6 in. of water will irrigate the land to a depth of 6 ft. Many soils require less; in sandy lands half this quantity is all that is necessary. When the soil is very dry, more than 1 in. is required, for example, the first irrigation of annual crops. When the soil already contains moisture, as it does where perennial crops are grown, the amount of moisture present prior to irrigation should be considered in determining the quantity necessary for each irrigation.

The use of much larger quantities than those indicated is the rule in many irrigated areas. Testimony given by farmers in a recent irrigation water suit indicated the average use of 12 in. or more in depth per irrigation in soil which would hold that quantity. Rules for the distribution of water in some irrigation districts permit the use of 9 to 12 in. for each irrigation on soils which should be thoroughly irrigated with one-half to one-third that quantity of water.

If scientific preparation of the land and the application of the quantity of water which is absorbed without waste could be insisted upon, much of the necessity for drainage could be avoided. This condition is seldom practicable; drainage, therefore, becomes a necessary part of most irrigation projects.

TABLE 3.—MOISTURE RELATIONS OF IRRIGATED SOILS.

\* The wilting point is the percentage of moisture at which crop plants commence to wilt and below which moisture should not be allowed to fall.

† This is the percentage at which irrigation is ordinarily given. It is considerably above the wilting point, particularly in the soils of medium texture. Soils, with reasonable care, may be allowed to approach nearer to the wilting point in dryness than is shown in Table 3.

‡ Maximum field capacity represents the percentage of moisture which a long column (5 ft. or more) of the soil will retain a few days (generally 3 days) after it has been irrigated. It is the practical maximum water-holding capacity of the soil.

§ This is the weight per cubic foot of dry soil. This weight varies considerably.

|| Columns (5) and (6) give the calculated depth of water required to raise the moisture percentage as shown,

$$\frac{\text{weight per cubic foot} \times \text{percentage increase in moisture} \times 12}{62.5}$$

To illustrate the moisture-holding capacity of various types of soils, Table 3 shows the average percentage of moisture at the wilting point, the point where irrigation water is ordinarily applied, and the maximum field capacity of the soil. These figures are given for purposes of illustration only

and should not be taken as exact for any particular locality or group of soils, because the weight of soil per cubic foot varies and small changes in amounts of organic matter, alkali, or colloidal material, may produce wide variations from these averages. In any region where such problems are studied, determinations of the moisture relations of the soils should be made, in order to furnish the basis for more accurate estimate of the water-holding capacity of the lands being irrigated.

The irrigation of soil to a depth of 5 ft. is all that is ordinarily required. The deep percolation which, to some extent at least, cannot be prevented, will moisten the soil to a greater depth. Crop roots in irrigated areas seldom penetrate, to any extent, beyond 6 ft. The zone of most important root growth is from 2 to 5 ft. If enough moisture is applied to moisten the 5 ft., with a reasonable allowance for deep percolation, the irrigator can be assured that the full root zone will be irrigated.

A compilation giving acre-inches required to irrigate soil to a depth of 5 ft., with 25% for waste and deep percolation, is shown in Table 4.

TABLE 4.

Soil type.	Inches required to moisten 5 ft. of soil without waste.	Inches required to moisten 5 ft. of soil, with allowance of 25% for waste.
Sand.....	2.90	3.62
Sandy loam.....	3.65	4.56
Fine sandy loam.....	5.20	6.50
Loam.....	5.90	7.38
Silt loam.....	5.70	7.13
Light clay loam.....	5.50	6.88
Clay loam.....	5.00	6.25
Heavy clay loam.....	4.50	5.63
Clay.....	3.95	4.94

If the figures given in Table 4 are compared with the quantities of water per irrigation in any irrigation area, it will be seen that in few of them is the quantity of water used per irrigation as small as is shown in the column in which an allowance of 25% is made for waste. The excess water goes to ground-water and causes it to rise.

#### CANAL SEEPAGE AS CONTRIBUTING TO DRAINAGE PROBLEM

Seepage from canals contributes directly to the drainage problem. In some cases it may be the most important source of rising ground-water. In all drainage investigations, seepage from canals has some bearing on the problem and should be investigated as an element in the drainage study.

Canal seepage or percolation may be expressed in several ways; ordinarily, it is given as a percentage of the water carried. For purposes of comparison of canals and materials composing canal beds and banks, it should be expressed in depth per unit of bed area, that is, percolation per day in cubic feet per square foot of wetted area.

Canal losses consist of both seepage and evaporation. The latter is usually neglected because it amounts to less than the error in measuring the total

losses. As an example, take the case of a 1 000-sec-ft. canal with 100 ft. of water surface, where the total losses amount to 1% of the flow. This equals 20 acre-ft. per day. The water surface covers 12 acres. The total losses are 1.67 acre-ft. per acre of water area per day. Evaporation seldom exceeds  $\frac{1}{2}$  in., or 0.04 ft., in depth per day, or 2.4% of the total losses. Since this is less than the probable error in measurement of water, it is ordinarily neglected.

No exact relation between character of bed material and rate of percolation can be given. Generally, it may be said that coarse material has a high rate of percolation and fine material a low rate. A clay with joints and cracks well developed may have a high rate and, again, a gravel with the interstices well filled with fine sand may be very tight. Measurements alone can establish the facts. As examples of losses in canal systems and of losses in various materials, Tables 5 and 6 are quoted.

TABLE 5.—SEEPAGE LOSSES.\*

\* Reclamation Record, April, 1921, p. 181, Table 1.

Frequently, water-logging is caused by excessive seepage from certain parts of canals. Where a detailed study is made of canal losses, such sections of high percolation may be located. The lining of a few selected localities may greatly decrease the seepage menace. Effective removal of excessive water has resulted from lining or puddling of short sections of leaky canals.

#### MOVEMENT OF GROUND-WATER

Once in the subsoil, the ground-water originating in canal percolation as the result of excessive application by water users flows under the force of gravity down the slopes of the underground strata. Such movements are uncertain as only very meager information as to the character, extent, or

direction of the underground strata can ever be obtained. Inability to obtain such information makes the prediction of the rate or direction of movement of ground-water uncertain, and, for that reason, it is essential in irrigated areas to collect information with great regularity, from which these movements of ground-water can be deduced.

For the purpose of determining the movements of ground-water, observations on water levels are of great assistance. These records should be kept, if possible, from the time water is first turned into the irrigation canals. Since water may collect and move at different levels, flowing along impervious materials, the observations should include both shallow and deep wells. When equilibrium has been established, or where it has been demonstrated that there is free movement between deep and shallow strata, surface wells alone will be all that is required.

In many irrigated areas, records have been kept on water levels over long periods of time. In the Salt River Valley of Arizona these records cover a period of more than 10 years. In the Modesto and Turlock Districts, wells approximately at every section have been read at intervals over a period of 13 years. These wells are located so as to be as free as possible from local influences of ditches or pumping plants and give, by comparison with other years, a close approximation of the fluctuations of the water surface.

\* *Reclamation Record*, April, 1921, p. 182, Table 2.

In the Merced Irrigation District, both deep and shallow wells are observed. The shallow wells are located at frequent but irregular intervals throughout

the district. Some of these wells are used to determine the general ground-water conditions, and they are established as far as possible from local influences, such as canals, drainage wells, or other sources of fluctuating ground-water. Other wells are located and read to collect information on local conditions, such as water levels around drainage wells or in localities threatened with high ground-water. These data are promptly plotted and made available for use. Engineers in operation work, land owners, realtors, bank appraisers, and others use such records a great deal.

#### EFFECTS OF LACK OF DRAINAGE ON IRRIGATED LANDS

The effects of lack of drainage on irrigated lands are shown in several ways. In part, the effects are only temporary, but in some respects they are more or less permanent.

1.—*Water-Logging*.—This is usually the first noticeable effect. This term is one in common use among irrigators and means an excess of water, over that essential to plant growth, for a sufficient length of time that the normal functions of roots are affected. Most agricultural plants require both air and water around the roots. When water is present in such quantities that circulation is retarded and air is not present, the roots cannot function normally.

The effects of water-logging are to retard root growth and to check plant development. This effect may be important, even though the plant continues to live and have a healthy appearance. Partial water-logging is manifested by reduction in yield and may not be apparent to the eye. The relations between water applied and plant yield have been determined in many places. Typical of these are the results of five years' (1910-14) irrigation of alfalfa at the Davis Farm by the University of California. The results appear in Table 7. It is apparent that beyond 30 in. of water, there is no practical good accomplished. Applications in excess of 48 in. cause lower yield.

48	9.43
60	9.19

2.—*Rise of Alkali*.—In the sense used by irrigators "alkali" means water-soluble salts. Any water-soluble material falls in this classification. While the number of water-soluble salts found in soils is large, practically only a few are of sufficient prominence to have any effect. Investigations have shown that in some localities small quantities of rare salts have highly destructive effects, as, for example, borax or barium salts. The broad classification into "black alkali" and "white alkali" has long been accepted and is

yet commonly used, although it is now known that this general classification may not always be applied.

Black alkali includes salts alkaline in the chemical sense. Sodium carbonate and sodium hydrate are the important salts. Such salts have, through their caustic nature, the power to dissolve organic matter, the resultant solution when concentrated appearing black, thus accounting for the popular name.

The so-called black alkali salts are white when pure and many times in desert soils the color is no indication of the kind of alkali present. The corrosive action of the soil on vegetable matter renders such salts very toxic, and amounts as low as 0.10% will usually prevent plant growth, while one-half or one-fourth this quantity may render agriculture unprofitable through the effect on the permeability of the soil. The alkaline nature re-acts on the mineral grains, dissolving silica and puddling the soil grains.

Such soils bake hard when dry and pass water slowly. Leaching does not remove the salt promptly. The gelatinous surface of the soil grains caused by the corrosive action on the silicates and quartz grains retains the soluble material almost indefinitely. Minute quantities of the salt cause the soil to be dispersed and makes leaching difficult. Chemical neutralization of the salt alone seems to correct the unfavorable soil characteristics. Gypsum (calcium sulfate) and sulfur have been found to change the black to white alkali. The cost of these chemicals is so high that it is not practical to carry out reclamation of black alkali salts except when small amounts only are present. Leaching to remove all but a small quantity and chemical neutralization of this last trace seem to be the most practical methods of reclaiming such lands. The time required for such action is long and it can be accomplished only where drainage is easy, the water cheap, and gypsum available at a low price. In spite of many attempts there has been no practical reclamation of any extensive areas of black alkali land.

White alkali salts are principally chlorides and sulfates of sodium, potassium, and magnesium. They occur mixed in all proportions. They have comparatively little effect on the physical properties of the soil and may be leached out much more readily than is the case of black alkali salts. Such salts are less toxic to plants. The limit of tolerance varies with the plant, the kind of soil, and other factors, but ordinarily 0.005% of white alkali salts in the soil is the limit in land which can be farmed. One-half this amount frequently causes serious losses.

White alkali salts are not retained by the soil as persistently as black alkali. For this reason they may be washed out of land by flooding and leaching. Large areas of land have been washed free of salt and alkali and profitably farmed.

3.—*Changes in Physical Condition of the Soil.*—Changes in the physical condition of the soil due to lack of drainage are of great importance. Land becomes harsh, difficult to cultivate, cloddy, and generally refractory. These changes frequently are noticed before there is any large accumulation of alkali and they persist after the drainage has become established and the salts leached out.

The re-establishment of good tilth in drained soil is the most difficult part of the reclamation process. Lands have frequently been drained and the alkali removed by leaching, only to find that the soil was so refractory that crops could not be grown. A long period was then required to incorporate organic matter, and restore in the soil the quantities which cause the land to be mellow and cultivable. This process is slow, frequently requiring years, and knowledge of how best to restore good physical condition in the soil is limited. An opportunity for research into this question still awaits the Agricultural Department and Experiment Stations.

4.—*Losses in Plant Food.*—Excessive use of water results in the leaching out of plant food from the soils. Comparatively little is known as to the extent to which this goes on, but it is probably an important factor in the decreased yield in many irrigated areas.

#### PREVENTION OF THE NEED OF DRAINAGE

The drainage problem can be at least partly solved in many cases by the removal of the cause of excess water in the soil. Three methods have proven of benefit:

- 1.—Control of the farmer's use of water.
- 2.—Prevention of canal seepage.
- 3.—Pumping from irrigated areas.

These methods are discussed in more detail as follows.

1.—*Control of the Farmer's Use of Water.*—This is in effect an attempt to control the use of water so that there is added to the soil at any time only the quantity the soil can absorb and retain against the force of gravity. The period between irrigations then being under control, the deep percolation losses may be reduced to a minimum.

In application of this method, the first and most important matter is the determination of the water-holding capacity of the soil. The use of laboratory studies of soil types and the determinations of moisture equivalent and water-holding capacity by laboratory methods are some help in forming approximations, but actual field determination of water-holding capacity is a more dependable method. Laboratory studies of soils do not show accurately field conditions, because it is never possible to place laboratory soils in the same physical conditions as are found in the field.

With an accurate knowledge of the absorptive capacity of each type of soil, the attempt should be made to direct the preparation of the land in such width and length of runs that this quantity of water can be absorbed with the use of a head of water of practical size.

With lands prepared properly, the size of the head (or quantity of water used at one time) determined, and the period of application found by experiment, the question of the frequency of irrigation is then to be determined. This, of course, is dependent on the weather, the time of year the crop is growing on the land, and the amount of moisture remaining in the soil.

The practical application of this method of water control is thus seen to be a complicated matter, into which many factors enter. In addition to the

physical factors of soil, climate, and crop, the human factor of how to encourage the farmer to apply these principles enters seriously into the problem. Such things become a matter of education of the water user. The drainage engineer is concerned with the education of the water user in better practices in the method and rate of application, but practical difficulties are met in any attempt to enforce correct use of water.

Rules for the distribution of water are a help, but their enforcement is often difficult of accomplishment. Rules usually require the farmer to keep his ditches in condition to handle water and to have his land prepared so that the water can be economically handled. How seldom is the strict enforcement of such rules carried out? One of the most practical rules is that in use by many irrigation districts in which a time limit is placed on the use of water; as examples, the Modesto Irrigation District delivers a uniform head of 25 cu. ft. per sec. and limits the time of use to 40 min. per acre of land; the Turlock and other districts deliver 15 sec.-ft. and limit the time to 30 min. per acre. Of similar effect is another type of rule, which prohibits the use of more than a given quantity per acre in one irrigation. The Corcoran Irrigation District's rules prohibit the use of more than 6 in. in depth in any one irrigation.

Placing a penalty on excessive use by a high charge for water in excess of a minimum quantity has long been applied to restrict use. This method has been only partly successful, although it has been of some benefit. While it may not altogether prevent waste, it has the satisfying effect of placing at least some of the burden of the cost of drainage on the lavish user of water.

The control of the use of water so that there will be no waste is therefore, theoretically, a method of promise. Practically but little can be accomplished in a short time and the engineer is forced to attack the problem from the angle of removing the excess of water. Discouragement should not prevent the continued attempt to reduce the losses into deep soil by rational practices of irrigation. Continued effort has produced results and more will no doubt follow. More immediate results will follow other lines of attack.

Excessive care in the preparation of land and in the application of water costs money. The farmer frequently finds it cheaper to pay for drainage than to use care in the handling of the water. This is particularly true in irrigated districts, where the land is newly prepared. The first attempt to fit the land for the distribution of water does not always result in economic distribution. Sometimes the land settles and becomes irregular; at other times, lack of capital or inexperience are the causes of the trouble.

It becomes practically impossible in many such cases for the practicing engineer to enforce rules requiring the land to be well prepared, and, consequently, he is forced to get along the best way possible. The result is wasteful use of water and a drainage problem.

2.—*Prevention of Canal Seepage.*—Losses by seepage from canals account for from 25 to 50% of the water diverted from rivers. These losses can be almost entirely prevented by lining canals with impervious materials. The

cost of lining is high, and it becomes a problem in economics to determine whether some other method is less costly. For example, it has been estimated that the lining of all canals in the Salt River Valley of Arizona will cost \$8 700 000. To do this as a prevention of drainage would save the removal by drainage of 170 000 acre-ft. of water. The annual cost of interest, depreciation, and repairs, all taken at 8%, would be \$700 000. This same quantity of water could be pumped from a depth of 30 ft. at a cost of about \$1.50 per acre-ft., or a total of \$250 000.

Since the source of water causing the need of drainage originates only in part in seepage from ditches, the lining of canals will not altogether remove the necessity for drainage. Usually the lining is carried out in the sections of ditches where canal losses are heaviest.

The result is that only portions of canals are lined. In well-established districts which have been under operation for some years, it is the policy to provide a sum of money each year for continuation of ditch lining. Thus, in the Turlock Irrigation District, about \$50 000 is provided in each year's budget for new lining. In the Merced and South San Joaquin Irrigation Districts from 5 to 10 miles of canal are lined each year. Few irrigation projects can afford to provide all ditches with lining at the time of the construction of the system, particularly projects where interest must be paid on funds spent on construction work. The result is the budget method of providing annually a sum to be devoted to concrete lining.

Accurate records of losses from canals by seepage are seldom available. Since many drainage problems are a determination of the extent of canal seepage as a contributing cause to the necessity for drainage, it becomes necessary in every case to determine the relative extent of seepage from various materials in which canals are built.

The U. S. Reclamation Service published in 1921 the results of seepage measurements in many kinds of soils.\* The seepage varies greatly with local conditions. The presence of alkali in the soil, thickness of strata, and particularly the presence of sand, gravel, or other coarse-grained material, all greatly affect the result. Accurate results are obtainable only after careful measurements.

For purposes of rough estimation of canal losses, the figures in Table 3 may be used.

3.—*Pumping from Irrigated Areas.*—Pumping of ground-water from irrigated areas lowers the water level and produces the same effects as drainage by any other means. In many regions this drainage effect has been produced as a by-product of the effort to secure ground-water for irrigation. Notable examples of this are in the irrigated areas on the Kaweah and Kings Rivers in the San Joaquin Valley of California.

Thirty years ago in the San Joaquin Valley, large areas of land were out of cultivation or producing meager crops because of the rise of ground-water and alkali following irrigation. Some of the colonies near Fresno, originally considered as the most fertile in the neighborhood, were to a large extent abandoned because of rise of water from 60 ft. or more to a few feet below

\* Reclamation Record, April, 1921.

the surface. The situation was nearly as bad under some of the canals diverting water from the Kaweah. The University of California established an experiment farm on the Kaweah Delta, near Tulare, to study alkali. At this farm some of the classical experiments on alkali lands were conducted by Dr. Eugene Hilgard. Both the areas mentioned were watered by canals diverting from unregulated streams. Water was frequently deficient after the middle of summer.

TABLE 8.—APPROXIMATE LOSSES BY SEEPAGE CANALS IN VARIOUS MATERIALS.  
(In feet in depth per square foot wetted.)

Soil material.	Area per day.
Gravels and coarse sand.....	1.5 to 2.0, or more.
Sand soil.....	1.05 " 1.5
Sandy loam.....	1.00 " 1.25
Loams.....	0.60 " 1.00
Clay loams.....	0.40 " 0.60
Clays.....	0.25 " 0.40
Concrete lining.....	0.25, or less.

The practice prevailed of heavy irrigation in early summer in an attempt to store water in the soil for late summer use by crops. This resulted in high ground-water. The improvements in gasoline engines which made them effective for farm use, about 1900, encouraged pumping as a supplemental supply. Electric power on farms became available to many irrigators after about 1908. Pumping became general, both as supplementary to canal water and as the supply for many farms having no canal rights. Around Tulare nearly all the canal water is pumped. The result is that the ground-water plane has lowered, lands once menaced by high water have been relieved of that menace, and alkali areas have begun to improve. Drainage has thus been effected as an incident to recovering ground-water.

The fact that pumping as a source of part of the water supply will relieve the drainage menace has become recognized practice among some engineers. The Merced Irrigation District of California in its original plans provided for securing 80% of its supply from the river by direct diversion and storage and 20% from ground-water. Similar provision has been made by the Kern River Conservation District, the San Joaquin Water Storage Districts, and other proposed irrigation projects.

This theory has been put into practice by other operating concerns. In the Salt River Valley, of Arizona, pumps capable of delivering nearly 500 000 acre-ft. annually from ground-water have been installed. The Salt River Project now depends to a certain extent on ground-water to carry it through dry cycles. Here, water is drawn far below the depth required to effect drainage at certain periods. The result has been effective recovery of water-logged and alkali areas.

#### DRAINAGE INVESTIGATIONS

The investigation of drainage problems involves the collection and interpretation of data of several varieties. Like many other engineering investiga-

tions, records over a period of time are of importance. It is difficult to arrive at dependable conclusions with observations made over a short time.

The prediction of the necessity for drainage in any newly irrigated region is difficult, because a great deal depends on the irrigation practices of the water users, and the movements of ground-water are a matter of conjecture. With so many unknown factors, prediction of either amount of drainage or place where high ground-water will develop, is very uncertain. For this reason it is highly important that records be collected and preserved at all times of the height of ground-water beneath irrigated areas, of the quantities of water run through canals, and of the seepage losses from canals and laterals. It is further desirable to have collected facts on the rate and extent of the use of water by irrigators.

If such information is collected from the time water is first applied to the land, the history will be sufficiently complete for the drainage engineer to design a method of taking care of the excess water. Lacking such information, it is necessary to delay drainage relief until a full year's records are collected. With periodical analysis of such records, it is possible to predict with some degree of certainty the time when drainage relief must be applied.

It has now become established practice in many well-organized irrigation projects to collect with great regularity the depth to ground-water beneath irrigated areas and to watch carefully such movements as occur. By such means the ground-water level can be controlled and held at the most desirable level. As examples of such collection and use of ground-water records, the following may be mentioned as typical. In the Salt River Valley of Arizona, records of levels of water in wells are collected at regular intervals throughout the year. The wells observed are in part auger holes and in part domestic or other wells. These records are promptly posted on maps. Land owners, bank appraisers, real estate salesmen, and many others have frequent use for these records. The project officials watch changes in water level with great interest.

In some California irrigation districts, water levels are observed with regularity. In the Turlock District, about 190 wells are measured both summer and winter. These are nearly all auger holes located at section corners or close by in some place as free as possible from local influences. In the Modesto District, 75 section corner wells are observed monthly. In the Merced Irrigation District, one man is employed reading water levels in wells. This district is relatively new and a reservoir was placed in operation in 1926. Ground-water conditions have changed rapidly and prompt information as to changes in water levels was essential.

For observation of ground-water level and determination of rise and fall with respect to the land surface, it is not necessary to connect such wells with levels so that they may be plotted with reference to a common datum. Levels are advisable, however, for the determination of the ground-water slope, both in direction and degree of slope, which are important when drainage is being studied. Maps showing depth of water below ground level and ground-water contours are both important.

## ALKALI AS ASSOCIATED WITH DRAINAGE

The term, "alkali", is generally used, in the irrigated regions, to mean any soluble mineral salts in soils. These salts result from the decomposition of rocks and minerals and remain in the soils because there is not sufficient water passing through the soil to leach them out, or they are absorbed by the surface of the soil grains. The salts present are largely chlorides, sulfates, carbonates, and bi-carbonates of sodium potassium, calcium, and magnesium. Occasionally, other salts appear; for example, nitrates are reported in some soil analyses.

Two reasons can be advanced to account for the presence of soluble salts in irrigated soils: First, the amount of rainfall is insufficient to leach out and wash away the soluble products of soil and rock decomposition; and, second, evaporation is great owing to the dry atmosphere, and where the ground-water is so close that capillary forces can draw the water to the surface, there is the constant tendency for an increase in soluble salts near the surface. Movement of salts by capillarity is more rapid than by water moving downward by gravity, because in gravity movement the larger pore spaces only are leached; the fine capillary spaces have little movement. In capillary movement, water moves through the finest spaces.

The drainage engineer is interested in alkali in several ways. The first and most important point is that where alkali is present it is necessary to keep ground-water levels so low that capillary forces cannot raise water to the surface. There, too, the movement of water must be downward, that is, the quantity of water used must be so great that there is drainage downward, otherwise soluble salts will increase near the soil surface.

Alkali salts, if present in considerable quantity, may have the effect of deflocculating the fine soil particles, causing the soil to be puddled. Leaching, when the soil is puddled, is slow and difficult. The difference in rapidity with which soils may be leached is very great. In some cases the leaching process proceeds rapidly; in others, it is so slow as to be impractical in operation. The reason for this difference is not known in all cases, but it may be generally observed that soils rich in lime and organic matter may be readily leached, whereas soils poor in these constituents are difficult to handle.

For practical purposes, alkali has long been classified into black alkali and white alkali.

Black alkali, carbonate of soda, has an alkaline reaction in the chemical sense and is corrosive of vegetable matter, and much more destructive than the white alkali salts. It further has a puddling effect on the soil, renders it difficult to leach, and causes it to bake and become refractory when irrigated. Black alkali cannot be easily leached from the soil. No practical method of draining and reclaiming such lands has been devised. Black alkali can be neutralized by chemicals, such as sulfur or gypsum (calcium sulfate), but these processes are so costly that they can be used only on small areas, where the value is high or where the quantity of salt to be neutralized is very small.

White alkali salts, in the classification of the textbooks, include the remaining soluble salts in the soil. These are neutral in the chemical sense. The

statement has long been accepted that the removal of white alkali salts by water and drainage is a simple matter and easy of accomplishment. Whether or not this will prove true depends on the composition of the soil.

Recent research has made great changes in the knowledge of alkali in soils and the old statements must be modified to some extent. Alkali can no longer be classified into black and white alkali, but many other factors should be taken into consideration.

The present conception of the alkali problem is that sodium salts are quite as injurious to the physical condition of the soil when they occur in high concentrations as sodium sulfate and sodium chloride, as when they occur as sodium carbonate. When the leaching of a soil containing sodium salts in excess is undertaken in the field, it is likely to be successful only when there is present a considerable amount of calcium and magnesium. These being absent, the soil becomes impermeable when moist and bakes hard when dry, producing the result formerly attributed to "black alkali".

The problem of alkali land reclamation, when this refractory condition is reached, becomes very difficult. There is, as far as is now known, no certain and practical method of restoring tilth to soil which shows the refractory state due to this alkaline reaction, except that of chemically changing the condition by the addition of gypsum or calcium sulfate. Whether or not this is practical, is a question of cost. Following the removal of the soluble material, the soil must be brought into such physical condition that it becomes acceptable to plant roots and workable by ordinary farm machinery.

The drainage engineer, therefore, is interested in the reclamation of alkali lands and the practical methods of bringing such lands into cultivation after the excess of water and alkali are removed.

#### USE OF SALINE WATERS IN IRRIGATION

Many Western waters carry appreciable amounts of soluble salts. As the quantity of water diverted for irrigation has increased and the percentage of return water has become higher, the quality of many sources of irrigation water has been changed greatly by the increase of soluble salts in the return and drainage water.

Drainage water, whether recovered by ditches or wells, is frequently saline and its use in irrigation is sometimes questionable. The release of drainage water at times serves to raise the salt content of streams below the drainage outlet. The rights of lower appropriators may thereby be affected by changing the quality of water in the stream.

The use of saline waters in irrigation is a subject beyond the scope of this report, for it is a matter of great complicity, involving the chemical and physical characteristics of the soil and the abundance and proportions of the salts present in the water. A great many facts as to the result of long, continued use of saline waters are unknown. There is here an interesting field for research. The drainage engineer cannot solve all the problems, but a general knowledge of the subject will assist in the consideration of questions which arise where alkali land or saline water are encountered.

In the most general terms, neutral waters (neither chemically alkaline nor acid) carrying more than 1 000 parts of solids per million should receive thorough examination before their use in irrigation is recommended. Below that amount there are records of long, continued use on a great variety of soils without serious damage to the soil, and there is little reason to anticipate trouble in any well-drained soil.

When the total salts exceed 1 000 parts per million, analyses are advisable to determine the proportion of soluble salts which do not crystallize on concentration and which may accumulate in the root zone. There are many cases on record where waters exceeding this limit of 1 000 parts have been used with no visible decrease in fertility of the soil, but there are also places where such waters have proved harmful.

As examples of use of water of high salinity, the following may be mentioned.

*Colorado River.*—The average of samples from each irrigation at the Experiment Farm of the U. S. Department of Agriculture at Bard, near Yuma, Ariz., shows the total solids in solution for the year's average to vary between 805 and 997 parts per million (October, 1922, to September, 1927). Weighted by flow—as would occur when a stream is completely reservoirized—the average yearly salinity will vary from 544 to 697 parts per million. For considerable periods, during low flow, the salinity has exceeded 1 000 parts, reaching in excess of 2 400 parts in October, 1924. Water of this average quality (except for slight changes due to alkali absorbed from the channel below Yuma) has been used in the Imperial Valley for 25 years without damage to well-drained land. Lands subject to seepage or high ground-water have been seriously damaged.

*Salt River Valley.*—The average salinity of the Salt River Project from Roosevelt Reservoir is high, chlorides predominating. The water from Salt River diverted at the joint head (in part, return seepage) averages 1 678 parts per million.

Several developments of ground-water in and adjoining the area irrigated from Salt River have produced water of salinity in excess of 1 000 parts per million. The Roosevelt Irrigation District Project, now under construction (1927), is designed to use drainage pump water from a part of the Salt River Project with an average salinity of 1 590 parts per million.

Waters of the quality described have been used in the Salt River Valley for more than twenty-five years.

*Pecos Valley, New Mexico and Texas.*—Waters of high salinity have been used for many years—occasionally exceeding 5 000 parts per million. Good drainage with excessive use has enabled good crops to be grown. The average salinity of three stations on the Pecos River, in New Mexico, is 2 350 parts per million. Lands using such water become badly alkaline where waterlogged. Drainage works have permitted lands to be reclaimed and farmed profitably.

Water supply resources have reached such a point that drainage water frequently has a value which offsets in part the cost of drainage. The quality

of the water, therefore, has to be considered by the drainage engineer. As a conspicuous example, the Salt River Project originally started construction of wells for drainage. The water is so valuable that to-day the well development exceeds that necessary for drainage, and in the effort to secure more irrigation water in dry seasons, water is now drawn down lower than needed to drain the land.

In many parts of the San Joaquin Valley, water can be obtained from wells, in areas needing drainage, cheaper than it can be stored in reservoirs in the mountains or secured from any other source. Drainage in such cases is a by-product of the effort to secure water.

In determining the value or suitability of water for irrigation purposes, chemical analyses should be made. In analyzing water it is important to determine the total solids in solution, the amount of lime, magnesium, and of each of the common acid radicals, chlorine, sulfates, bi-carbonates, and carbonates. Sodium and potassium should be determined in enough samples to estimate their approximate amount.

Lime and magnesium salts are of particular importance. Hard waters are desirable in agriculture; the lime in the water exchanges with sodium in the soil, the result improving the soil. As has been expressed, "hard waters make soft land." On the other hand, soft waters, particularly those alkaline in reaction (commonly called black alkali waters), may have the opposite reaction and in time change soft friable soil to hard land of refractory nature.

Neither of these changes takes place in the soil rapidly. Time—sometimes several years—is required before the full effect of the water is apparent. Much depends on the soil. Lime in abundance in the soil retards the effect of soft waters. A light soil easily permeated by water is not affected as is a heavy soil or one with a large amount of colloidal material.

The most important consideration in the use of saline waters is to have free and rapid drainage so that the land does not become water-logged. Care should then be taken that enough water be used to cause downward flushing into the drainage channels.

#### RECLAMATION OF LAND AFTER APPLICATION OF DRAINAGE

The most difficult part of many drainage projects in irrigated areas is the improvement or rehabilitation of the land, if such a word may be used, after drainage has removed the excess of water. This feature of the work is a part of the drainage engineer's activities, at least he should know enough about the matter to decide whether reclamation is possible or that there is a reasonable assurance of its success.

Land water-logged without accumulation of alkali is usually in physical condition for agriculture, as soon as the water is removed. Frequently the land is more fertile than before it was water-logged, because of the large amount of vegetable matter which remains in the earth from water-loving vegetation. Reclaimed swamps are usually of high fertility. Acid soil may be troublesome, but methods of neutralization of acid soil have been devised and, besides, many crops require acid soil for successful production. Acid soil is unusual in the arid regions, because of the abundance of lime.

Where alkali has accumulated, the improvement of the soil after drainage may be difficult. The clay in the soil may be dispersed, the soil rendered impervious, leaching difficult, and the land harsh with a tendency to bake and form clods. The organic matter may have been dissolved and washed away. In such cases, there is a tendency for the soil to become alkaline (in the chemical sense), or give those characteristics attributed to "black alkali". This condition may arise in the leaching of land which does not show black alkali characteristics at the time leaching commences—the alkalinity develops in the process of washing the soil.

The theories of agricultural chemists regarding alkali in soils have changed a great deal since 1917. Much important research is now going on in a number of States, in the U. S. Department of Agriculture, and in foreign countries. A drainage engineer will hardly find it possible to keep in touch with the latest information published by these research scientists. About the best he can do is to refer his alkali problems to some agricultural chemist familiar with most recent research.

The belief, prevalent among irrigation engineers for a long time, that "drainage solves the alkali problem", is no longer thought to be true in all cases. So many failures have been recorded that the question of alkali reclamation is still in the doubtful stage. It is believed that the time will come when alkali land will be reclaimed with assurance of success. At present, efforts can be best directed toward the prevention of the accumulation of alkali.

#### ENGINEERING STUDIES PRELIMINARY TO DRAINAGE

Ground-water follows the well-known and definite laws of hydraulics in moving down grade. The rate of movement is not so well understood, as the retarding influence of the material through which the water moves is not known, nor is the result of a number of factors, only a few of which can be evaluated. The variable nature of the strata also complicates the problem. The result is that there is a great deal of estimating in any effort to trace the direction, rate, or amount of underground flow.

It is possible, however, to remove much of the uncertainty if there is opportunity to make observations over an extended period of time. If this time includes the period in which the water is moving toward the place where drainage is needed, the solution of the problem can be made with a satisfactory degree of exactness. If no observations are made and water suddenly appears beneath and threatens the future of an area of land, it may be very difficult to determine the source of the water and the effort to remove it must to a certain extent be experimental.

Ground-water studies should be a part of the regular duties of the organization engaged in the operation and maintenance of irrigation works. These studies should be continued with regularity. It is important to know the depth to ground-water and the fluctuations through which the ground-water goes during the season. If, then, the rate of use of water is known and the canal losses are recorded, the drainage engineer will have data on which to base his studies.

## DRAINAGE CONSTRUCTION

Construction works to correct drainage problems may take several forms. The important ones are:

1.—*Removal of Water at the Source.*—This can be done by reducing canal losses or deep percolation losses from irrigation fields. Both these sources are important and frequently they can be reduced or controlled at less cost than by removing the water from the area affected.

2.—*Open Canals.*—Open drains to effect the reduction of water-plane level by excavating below that level are in common use in many irrigated areas. Cheap excavation by machinery has brought this method into popularity in recent years. The large area occupied by right of way and the annual cost of cleaning are the most important objections to open ditches.

3.—*Tile Drains.*—Tile drains are effective, but are used mostly in the details of farm drainage rather than in large works of great extent. Engineering methods of tiling are well developed. The first cost is the principal objection to tile. Concrete pipe, which now can be made in large sizes at costs less than clay pipe, has greatly extended the use of large tile drains. The effect of alkali salts on poorly made pipe has been troublesome in some regions.

4.—*Cut-Off Drains.*—Cut-off or intercepting drains, either open or tile, are often effective in collecting ground-water between source and place where it will cause damage. Where relatively water-tight strata cause the flow to follow overlying porous members within reach of drains, this method frequently proves effective.

5.—*Pressure Relief Drains.*—Where water is entrapped under relatively water-tight strata and is sub-irrigating under pressure, relief may be obtained by tapping this water by open wells or drains cutting below the confining material. Very simple works are sometimes very effective in improving large areas.

Conversely, to this method, there sometimes are encountered perched water planes which may be drained away by the penetration of the confining stratum by wells or open drains. Local basins or saucer-shaped areas of hardpan or rock in the subsoil, underlaid by porous materials not filled with ground-water, may be relieved by draining through wells.

6.—*Wells for Drainage.*—Pumping from wells is rapidly becoming recognized as an effective and, frequently, cheap method of removing excess of water. This is a vertical drain with the water removed by pumping. The development of deep-well turbine pumps in which a wide range of head below the pump is possible, has made this method of draining practical.

Where cheap power is available, this method should be considered. It has the advantage of collecting the water in such a way that it can be used for irrigation, the value of the water often paying a substantial part of the drainage cost.

This method apparently has a much wider application than was thought a few years ago. The vertical movement of water through strata seems easier to bring about than lateral movement. The reduction of pressure by pumping from beneath water-tight strata may expose a large area of the material to downward percolation and result in reduction of water levels to a surprising extent.

Drainage by wells has been used to a limited extent in many irrigated areas. It is used to almost the exclusion of other methods of drainage in the Salt River Valley of Arizona and in the South San Joaquin, Modesto and Turlock, and Merced Irrigation Districts in California. In these regions where electric power costs from  $\frac{1}{2}$  cent to  $1\frac{1}{4}$  cents per kw-hr., it has been found that drainage water can be removed by pumping from wells at less cost than by any other method.

THOMAS H. MEANS, *Chairman,*  
Committee of Irrigation Division on  
Drainage of Irrigated Lands.

## DISCUSSION

M. R. LEWIS,\* M. AM. SOC. C. E. (by letter).—This report is of great interest and, as a brief summary of the subject, is certainly of permanent value. It shows careful thought and a broad understanding of the problem. However, there are a few instances in which the writer believes it should be modified or elaborated.

In the section devoted to the "Cause of Necessity for Drainage", the influence of alkali is omitted. The almost universal presence of excessive quantities of soluble salts in irrigated areas necessitates much deeper drainage than is common in humid areas. Unless the water-table is lowered to such a depth that only negligible quantities of water will be brought to the surface and there evaporated, a concentration of alkali salts will occur. Where the drainage is shallow and, as a result, the water-table is only 2 to 4 ft. below the surface, the rise of alkali can be controlled only by complete flooding of the surface by irrigation water.

In most sections this water carries in solution comparatively large quantities of soluble salts. Frequently, the quantity of most of these salts exceeds that carried off by the harvested crops. As a result, in the absence of all downward percolation to the water-table, there will be a gradual concentration of alkali salts in the surface soil. Even where the water-table is at a satisfactory depth below the surface, this fact makes it essential that some water be allowed to percolate downward through the soil to the ground-water. This water also must be removed by under-drainage, either natural or artificial. For this reason, even if it were possible, it would not be advisable to irrigate with exactly the quantity of water which is used by crops.

In the discussion of the water-holding capacity of irrigated soils, two factors have become confused. Tables 3 and 4 purport to give the capacity of various types of soils to retain moisture. Actually, they give some combination of the capacity to retain moisture and the ability to absorb it under field conditions. The water-retaining power of soils is progressively greater as their texture becomes finer. (See Fig. 1.†)

There is considerable evidence that the moisture equivalent is a very fair measure of the field capacity of a soil, both relatively and absolutely. While it is difficult to demonstrate this fact in heavy clay soils on account of their impermeability, the conclusion seems reasonable that fair agreement will be found, at least in surface soils which are not under considerable pressure.

It is true that under field conditions it is difficult if not impossible to make the heavier clay soils absorb as much as they can retain. However, it is best to keep clearly in mind that this is a problem of application of water and not one of its retention. As given in the report, Table 4 would indicate almost as great danger of over-irrigation of clays as of sands. In fact, of course, there is no such danger.

\* Irrig. and Drainage Specialists, Oregon State Coll., and Div. of Agri. Eng., U. S. Dept. of Agriculture, Corvallis, Ore.

† Adapted from "Outline of Ground-Water Hydrology," by O. E. Meinzer, U. S. Geological Survey, *Water Supply Paper No. 494*.

In the reclamation of black alkali lands both the Oregon and the Idaho Agricultural Experiment Stations have secured promising results by planting sweet clover on the undisturbed surface of the ground and irrigating very frequently. As stated in the report, further studies of this problem are needed, and they are being made.

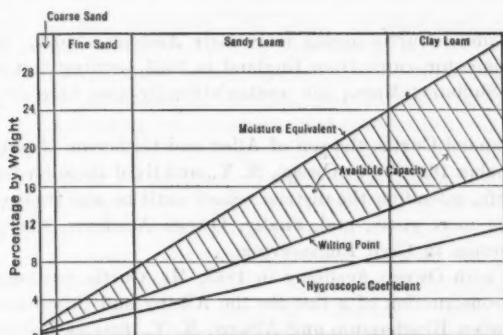

FIG. 1.—MOISTURE-HOLDING CAPACITY OF SOIL.

Control of the use of water by the farmer is a more complicated problem than is indicated in the report. Not only must the capacity of the soil to hold moisture be known, but also its ability to absorb that water. In tests on alkali lands the writer found that at the end of 1 hour the soil at one spot absorbed water at the rate of 0.16 ft. per hour, whereas at a point 75 ft. away, in the same border strip, the rate was 0.019 ft. per hour. Other tests on a supposedly uniform loess soil at Moscow, Idaho, showed a rate of infiltration three times as fast at one point as at another 5 ft. away. The problem of the rate of infiltration and application to the field of the facts discovered is a pressing one.

The use of pumping for drainage appeals to the writer as being the greatest single forward step made by irrigation engineers in many years. He expects to see its application very greatly extended, primarily because of the apparent ability to lower the water-table by this method to much greater depths than is feasible by either open or closed drains of the gravity type.

In this connection it may yet be found that "drainage solves the alkali problem" at least to a very great extent; but it must be real drainage, not just a feeble lowering of the water-table below the surface.

## MEMOIRS OF DECEASED MEMBERS

FAYETTE SAMUEL CURTIS, Past-President, Am. Soc. C. E.\*

DIED FEBRUARY 15, 1929.

Fayette Samuel Curtis sprang from early American stock. Henry Curtis, his paternal ancestor, came from England in 1635, settling first at Watertown and then at Sudbury, Mass.; his mother's family also were early settlers of that State.

Fayette Samuel Curtis, the son of Allen and Catherine (Steel) Curtis, was born on December 16, 1843, at Owego, N. Y., and lived there for the first twenty years of his life, attending the district school until he was twelve, then private school for two more years, and, finally, Owego Academy, where he received special instruction in Civil Engineering.

Finishing with Owego Academy in 1863, Mr. Curtis was employed on the location and construction of a line for the Albany and Susquehanna Railroad Company between Binghamton and Albany, N. Y., first as Rodman and, then, in 1864, as Transitman. Two years later, he went with the Southern Central Railroad Company on its line from Owego to Auburn, N. Y., serving as Levelman during the location, and then, with the commencement of construction, as Assistant to the Resident Engineer. On the completion of this work he accepted a position as Transitman with the Lake Ontario Shore Railroad Company on location between Oswego and Charlotte, in New York State.

In the spring of 1869, as Assistant to the late George S. Greene, Jr., M. Am. Soc. C. E., young Curtis was employed on surveys in the Towns of Morrisania, Tremont, and Fordham, now parts of Greater New York, which surveys have since served as the base of much of the later mapping in The Bronx. After two years of this work, in April, 1871, he returned to the railroads, as Assistant Engineer, under the late I. C. Buckhout, M. Am. Soc. C. E., on the New York and Harlem Railroad, and six months later, on October 1, he became Principal Assistant, first on the location of the tracks and yards at the old Grand Central Station, in New York, N. Y., and, later, on the plans and the construction of the Fourth Avenue Improvement between the Grand Central Station and the Harlem River.

On the retirement of Mr. Buckhout in 1874, Mr. Curtis became Chief Engineer of the Harlem Railroad Company and Superintending Engineer of the Fourth Avenue Improvement, continuing in the service of the former Company until the completion of its line. The Harlem Railroad, about this time, was leased to the New York Central and Hudson River Railroad Company, and while Mr. Curtis was still acting as Engineer for the Harlem Lines, the grain elevators, yards, docks, piers, sheds, and warehouses on the Hudson River, between Fifty-ninth and Seventy-second Streets, were designed and built for the New York Central under his direction.

\* Memoir prepared by Clarence Blakeslee, M. Am. Soc. C. E., assisted by E. J. Beugler, C. C. Elwell, Edward Gagel, H. C. Keith, H. L. Ripley, Henry B. Seaman, Paul Sterling, and E. W. Wiggin, Members, Am. Soc. C. E.

On December 1, 1882, Mr. Curtis was called to the New York, New Haven, and Hartford Railroad Company, as Chief Engineer, with headquarters first at New York, and later at New Haven, Conn. This position he held until May 1, 1900, when he became Fourth Vice-President in charge of "engineering and such other matters" as might be assigned to him by the President or the Board of Directors, his headquarters being at Boston, Mass.

As of June 1, 1903, his duties were more specifically set out as follows: "General supervision of the Engineering Department and construction, including the Electrical Department, except operation, also maintenance of way, and construction and maintenance of buildings and signals, except the operation of signals". This assignment remained unchanged when, on November 14, 1903, Mr. Curtis was made Second Vice-President, with headquarters at Boston, and also when, a year later, he was transferred to New Haven. As of October 1, 1905, however, he returned to Boston, to "represent the President with full authority in all matters requiring his attention", and remained in this position for two years. On April 1, 1907, he resigned the Vice-Presidency of the New York, New Haven, and Hartford Railroad Company to accept the Presidency of the Old Colony Railroad Company, which latter position, together with those of President of the Union Freight Railroad Company, of Boston, and Chairman of the Boston Terminal Company, he held at the time of his death.

Mr. Curtis came to the New York, New Haven, and Hartford Railroad Company very largely through the influence of Mr. Charles P. Clark, then Second Vice-President, who already had well in mind plans for a unified transportation system for Southern New England, and who correctly appraised the worth of Mr. Curtis as an assistant in the development. The latter had but just come to the property, however, when Mr. Clark accepted a position with the New England Railroad Company and the next four years in the engineering affairs of the New York, New Haven, and Hartford Railroad Company were marked merely by consistent rather than by extensive improvements.

In the spring of 1887, however, Mr. Clark returned to the New York, New Haven, and Hartford Railroad Company, as President, and immediately began to build up and to expand the property. In this work Mr. Curtis played a most important part as one of the group of trusted lieutenants who served not only in the fields specifically assigned to them, but as general advisers and assistants as well. How highly his judgment was esteemed is shown by an endorsement on a letter in the office files of the Company. President Clark had referred an inquiry to Mr. William E. Barnett, then Executive Secretary and Attorney, who returned it with the note: "I do not know; ask F. S.; he has second sight if any one has."

In December, 1882, when Mr. Curtis came to the New York, New Haven, and Hartford Railroad Company, the line had double track from New York to Springfield, Mass., approximately 123 miles, and single track elsewhere, the total single-track equivalent being but a little more than 400 miles. This was laid with 60-lb., or lighter, rail, most of the latter being iron. The great majority of its highway crossings were at grade, and in the year ending September 30, 1882, it had operated in round figures 185 000 000 passenger-miles and had moved 117 000 000 ton-miles of freight.

By 1907, the line from New York to New Haven had been completely four-tracked, as had that part of the Providence Division from Readville into Boston, so that at the close of 1907, when Mr. Curtis' assignment to Boston as "representative of the President, with full authority in all matters requiring his attention", made it desirable to relieve him of close control of engineering, there were being operated about 4 254 single-track equivalent miles with 89½ miles of line four-tracked and 651½ more, double-tracked, largely laid with 100-lb. rail on stone ballast. The section of this rail was designed by Mr. Curtis in 1893, its height of 6 in., with a 6-in. base, giving extra stiffness and stability. There was not a single grade crossing on the four-track sections, from New York to New Haven, and that in the vicinity of Boston, and a large number elsewhere on the System had been eliminated, notably in connection with very extensive improvements at Westerly and Providence, R. I.; Hartford, Conn.; and Attleboro, Brockton, Fall River, and Worcester, Mass.; while the traffic had so increased that in 1907 there were operated roundly, 1 256 000 000 passenger-miles, and 1 889 000 000 ton-miles of freight were moved.

This, however, is but the merest outline of the story of railway improvements for which Mr. Curtis largely was responsible. With much of the work in thickly settled communities, and all of it adjacent to, if not directly under, heavy traffic, engineering ability of the highest quality was demanded, both of the Chief and of his assistants. How well the test was met by Mr. Curtis' professional skill and the keen discernment with which he picked his lieutenants, is clearly shown in the fact that in the conduct of this great work not a single passenger was killed or seriously injured; and this record was practically duplicated as regarded the general public, except as to accidents resulting from the personal carelessness and disregard of barriers and warnings by the injured persons.

Nor is it without significance that, except as in some instances prospective increased loadings far above those for which they were designed have necessitated the replacement of some of the earlier structures, there have been neither failures nor indications of weakness in any of the structural work. This required that every contractor be held rigorously to his agreed performance, but it is quite characteristic of the fairness with which Mr. Curtis maintained his standards that in not a single instance was there an appeal to higher authority, either within the Company or without, relative to his decisions.

Carrying to an extreme his dislike for any publicity, there is on record very little regarding the engineering features of this work thus broadly outlined. To the engineer familiar with New England conditions, however, the bridges, particularly over the tidal estuaries and the larger rivers, the elevated work through Bridgeport, Conn., Attleboro, Brockton, and the approach to Boston, the "cuts" at Mount Vernon, N. Y., New Haven, and in Boston; the stations at Bridgeport, Hartford, and Providence, as well as many less important—all tell unmistakably of the hand of the master engineer.

Mr. Curtis also played an important part in the design of the South Station, Boston. He, with L. B. Bidwell, Chief Engineer of the New York and New England Lines, and Walter Shepard, Chief Engineer of the Boston

and Albany Railroad Company, representing the three roads for which the station was built, constituted the Consulting Engineering Board for that project. In 1895, Mr. Curtis accompanied President Clark and a party of officers of the New York, New Haven, and Hartford Railroad Company to the Fifth International Railway Congress in London, England. At the close of the Congress he, Mr. Bidwell, and Mr. Shepard, visited the more important railroad stations of England and the Continent, studying their operation, their advantages, and their shortcomings, later employing the knowledge thus secured to the great advantage of Boston.

"F. S." as he was very generally called, was a man of tremendous energy and splendid constitution. Up to less than a year before his death the average man of 65 would have found it very difficult to keep up with him. This was the more remarkable because he had never spared himself. His "day" ended when the work permitted, without reference to the time, and during the lifetime of Mr. Clark a long active day in the field or office frequently was followed by conference until early morning with his equally tireless President.

Possessed of a kindly disposition and a keen sense of humor, Mr. Curtis had the happy faculty of making and keeping friends. His consideration of, and advice to, the young engineers who came under his direction were such as to inspire them to high ideals of engineering accomplishment, and there are many one-time associates who owe their later successes to his early training. With all his duties and responsibilities he always found a minute in which to greet even casual acquaintances, and to exchange the latest stories, his hearty and contagious laugh telling his keen enjoyment of a good tale. He was very fond of horses, and was a regular patron of the old Morris Park Race Track, taking unusual pleasure in attending the races with a crowd of his particular cronies.

He was a member of the Connecticut Society of Civil Engineers, which he had joined on January, 9, 1900, and of which he was made an Honorary Member on February 19, 1924.

Socially, he was a member of the Beacon Society, the Boston Athletic Association, and the Engineers Club of New York; his membership in the Quinpiack Club of New Haven, which he had long held, he resigned about a year before his death.

Fraternally, Mr. Curtis was a prominent Mason, holding membership in Friendship Lodge, Harlem, in Jerusalem Chapter, of Tioga County, and in Constantine Commandery, Knights Templars, all in New York State.

On October 19, 1872, he was married to Mary J. Bishop, of New Haven, who survives him, as does a sister, Kate S. Curtis, of Owego, and a half-brother, Robert Curtis, of New York. Of his three children, Wallace, George Henry, and Mary J., only the latter, who is the wife of Capt. John D. Woodworth, Medical Corps, U. S. A., at Vancouver, Wash., is now living. There are, however, five grandchildren: John Fayette, son of Wallace; George Henry and Dorothy M., children of George; and Fayette Curtis and Mary Justin, children of Mrs. Woodworth. Mr. Curtis' death, after an illness of three months, occurred on February 15, 1929, at his home in Jamaica Plain, Boston.

An engineer and executive of outstanding knowledge and ability, an indefatigable worker, a staunch and loyal friend, and a gentleman, his death is a great loss to his friends, to his profession, and to all who had the privilege of being associated with him or knowing him.

Mr. Curtis was elected a Member of the American Society of Civil Engineers on April 3, 1889. He served as Director from 1895 to 1897, inclusive; as Vice-President in 1904 and 1905; and as President in 1919.

## CHARLES MACDONALD, Past-President, Am. Soc. C. E.\*

DIED JULY 8, 1928.

Charles Macdonald was born at Gananoque, Ont., Canada, on January 26, 1837. He was the son of W. Stone Macdonald and the grandson of Charles Macdonald, who married the daughter of Colonel Joe Stone, the founder of Gananoque. After attending the public schools of his native town, and, later, a preparatory school of what was then Queen's College, Kingston, Ont., he obtained a position on the surveys of the Grand Trunk Railway between Kingston and Brockville, Ont., on which he served during 1852 and 1853. In 1854, Mr. Macdonald entered Rensselaer Polytechnic Institute, at Troy, N. Y., which was then the only institution of its kind in the United States, and was graduated therefrom with the degree of Civil Engineer in 1857. At the time of his death he was a Trustee of the Institute and its oldest graduate. In later years, he also received the degree of Doctor of Laws from Queen's University, Kingston, Ont.

Following his graduation Mr. Macdonald was engaged on the construction of an extension of the Grand Trunk Railway from Huron, to Detroit, Mich. Little engineering work was done in Canada during the next few years, although Mr. Macdonald lived at Gananoque until 1863. In the early spring of that year he moved to the United States, taking a position in charge of the Engineer Corps of the Philadelphia and Reading Railroad Company, with headquarters at Pottstown, Pa. Shortly afterward, he joined the Pennsylvania Volunteers, advancing to the rank of Corporal. He was made a prisoner in the Battle of Gettysburg.

Following the close of the Civil War Mr. Macdonald devoted much time to the study of iron bridge construction which was then in its infancy. A pamphlet on this subject which he wrote, and which found favorable attention, caused him to be entrusted with the construction of the bridges in the extension of the Delaware, Lackawanna and Western Railroad, to Hoboken, N. J.

In 1869 he opened an office in New York, N. Y., devoting himself to the design and construction of iron bridges. Mr. Macdonald was also much interested in the development of swing bridges. In 1871-1872 he designed and built the Point Street Bridge† in Providence, R. I., which was in continuous service under constant traffic until it was replaced by a heavy, wide, modern structure during 1927. He was appointed by the City of New York as a Trustee of the East River Bridge, of which Colonel Washington A. Roebling was Chief Engineer, which was opened in 1883.

In 1884, Mr. Macdonald organized the Union Bridge Company (of which he later became President), with headquarters in New York and shops at Athens, Pa. Of his partners, George S. Field, M. Am. Soc. C. E., and the late Edmund Hayes, M. Am. Soc. C. E., had their offices in Buffalo, N. Y.; and the late Charles Kellogg and Charles S. Maurice, Members, Am. Soc. C. E., in

\* Memoir prepared by a Committee consisting of W. G. Triest, M. Am. Soc. C. E., Chairman, the late Clemens Herschel, Past-President and Hon. M., Am. Soc. C. E., and O. E. Hovey, M. Am. Soc. C. E.

† Description appears in *Engineering*, Vol. XV (1873), p. 202.

Athens; that of the late Thomas C. Clarke, M. Am. Soc. C. E., was in New York. The Union Bridge Company built many large bridges in the United States, including the Poughkeepsie Bridge, erected in 1887 and 1888. The Company also designed and built the Hawkesbury Bridge, in New South Wales, Australia, during 1886 and 1887. Both these structures had long spans and unusually deep foundations.

He was one of the earliest promoters of a suspension bridge over the Hudson River at 57th Street, New York. A large model of this bridge was on view in his office. He was active in the preliminary work and the organization of the American Bridge Company, to which he sold the Union Bridge Company in 1900; he served as one of the Vice-Presidents of the former company until the following year. He then retired from active business, but was occasionally engaged in consulting work, notably in 1910, as one of the Commissioners of the Quebec Bridge during its reconstruction.

Mr. Macdonald was very much interested in the growth and affairs of the Society, and contributed frequently to its *Transactions*.<sup>\*</sup> He also discussed many papers presented by others, particularly those relating to bridge construction and materials. He was an early advocate of the use of steel in place of wrought iron in bridges and during 1879 proposed the use of high carbon steel for eye-bars and suggested the practicability of making steel eye-bars having a yield point of 63 000 and an ultimate tensile strength of 106 000 lb. per sq. in., which has been accomplished during the past few years.

Socially, he was much interested in the Engineers' Club, of which he was made an Honorary Member, the Century, the Lawyers', the University, and Union Clubs, of New York, and the Engineers' Club, of Montreal, Que., Canada. Mr. Macdonald was accustomed to divide his summers between his home at Rumson, N. J., where he was one of the first summer residents, and his place "Blinkbonnie", at Gananoque, on the shores of the St. Lawrence River.

In 1861, he was married to Sarah Louise Willard, the daughter of Colonel Willard, of Troy, N. Y. There were three children—a son, William Stone Macdonald, and two daughters, Mrs. John Serson and Mrs. W. G. Triest. After his wife's death in 1912, Mr. Macdonald made his home with his children, but he decided to return to his native town in Canada in 1926, where he spent his last years. He died there on July 8, 1928.

Mr. Macdonald was elected a Member of the American Society of Civil Engineers on September 15, 1869. He served as Director in 1871, and from 1874 to 1876; as Vice-President in 1893 and 1894; and as President in 1908.

<sup>\*</sup> "Proportions of the Heads of Eye-Bars," *Transactions*, Am. Soc. C. E., Vol. II (1872-73), p. 333; "The Failure of the Ashtabula Bridge," *Transactions*, Am. Soc. C. E., Vol. VI (1877), p. 74; "The Ocean Pier at Coney Island," *Transactions*, Am. Soc. C. E., Vol. VIII (1879), p. 227; "The Six-Hundred Ton Testing Machine at the Works of the Union Bridge Company at Athens, Pa.," *Transactions*, Am. Soc. C. E., Vol. XVI (1887), p. 1; and "Presidential Address at the 40th Annual Convention at Denver, Colorado, June 23d, 1908," *Transactions*, Am. Soc. C. E., Vol. LXI (1908), p. 544.

**FERDINAND FOCH, Hon. M. Am. Soc. C. E.\***

DIED MARCH 20, 1929.

Ferdinand Foch was born on October 2, 1851, at Tarbes in the Department of Hautes Pyrénées, France. Although his ancestry was not illustrious, he was sprung from the class of country gentry, a class that always forms the backbone and main strength of every people, and particularly of the French. His father was a practising lawyer, a calling which, however, did not appeal to the son, whose inclination was toward mathematical pursuits, although his strong religious sentiments at one time led him to consider taking Holy Orders. His brother did so, becoming a priest of the Jesuit Order, but Ferdinand was entered in 1869 at St. Clément's College, Metz, to study for the Ecole Polytechnique.

The Franco-German War broke out the year following and young Foch promptly volunteered, but by the irony of fate the future Maréchal of France and conqueror of the Teutonic armies saw no active service, being drafted into a unit that was held in Central France away from the fighting line.

The war ended; M. Foch, discharged from the army, took his examinations for the Ecole Polytechnique, from which he was graduated, commissioned, and assigned to the Artillery in 1873. After a short service with troops he was attached to the General Staff, and, in 1895, was appointed a professor at the Ecole de Guerre, when his military rank was that of a Lieutenant-Colonel. In 1901, he was named Director of the Ecole, serving until 1905.

There is a pretty story that M. Clemenceau, then President of the Council, appointed Colonel Foch to the post without any previous knowledge on his part that he was being at all considered. Unfortunately, this story lacks confirmation. Colonel Foch was a candidate, believing that his career lay in teaching, and he was given the post after long and careful consideration. This was one of M. Clemenceau's greater acts. Colonel Foch not only had no political influence, but had incurred the hostility of the radical party then in power on account of his strong religious views and devout practice. M. Clemenceau made the selection of Colonel Foch solely on the score of merit.

While a professor he delivered a series of lectures on the Art of War, which have been published in two volumes under the titles of "De la Conduite de la Guerre" and "De les Principes de la Guerre", and have been translated into many languages. In the latter volume he analyzed the campaigns of Napoleon, who was his military idol and inspiration; and in the former, the major battles and strategy of the Franco-German War of 1870. These lectures are particularly interesting as he shows that, with only slight improvement in French strategy, the German plan of campaign would have broken down. For these conclusions he gave full authority by quoting official German orders.

In 1911 he was given command of the 13th Division of Infantry, the first body of troops that he had commanded since as a Captain he had been at the head of a battery of artillery.

\* Memoir prepared by Wm. Barclay Parsons, Hon. M. Am. Soc. C. E.

When General Foch was 63 years old, or within a year of the time when an American army officer would be automatically retired "for age", the World War broke out. At that time he was commanding the Twentieth Army Corps with headquarters at Nancy, France. In July, 1914, he had been given leave and was visiting his country place, the Château de Transfécutenu, near Ploujean, on the Brittany Coast, to make ready against the enforced longer leave that he must soon take, when he received a peremptory order to return at once to his command. A few days later Europe was in ferment.

With the organization of the greatly enlarged French Army, following mobilization, there was a demand for officers to assume high and important rank. General Joffre had been made Commander-in-Chief of the French forces, and selected General Foch to command the Ninth Army. Thus, there was presented the extraordinary spectacle of an Army Commander, 63 years of age, whose military service had been almost exclusively confined to work on the General Staff, or in the lecture halls of the Ecole de Guerre. He had taken no part even in the small wars that France had carried on in the Colonies, nor had he ever handled large bodies of troops in the field. His experience had been wholly theoretical and didactic.

When General Joffre, while fighting masterly rearguard actions during August, 1914, in the retreat from Northern France, finally succeeded in placing his forces in such orderly arrangement along the Marne as would enable him to make a stand and by a counterstroke to attempt to seize the offensive, the Ninth Army occupied that portion of the line from Sezanne to Mailly le Camp with headquarters at Fère Champenoise. On the left was the Fifth Army commanded by General Franchet d'Esperey, and on the right the Fourth Army under General Langle de Cary. Opposed were parts of the Second and Third German Armies with Generals von Bülow and von Hausen.

On September 6, 1914, when the order was given to the whole line to stop retreating and to advance, no one saw more clearly than he, who had taught the theory of war, what the whole situation presented. If an advance could not be made, a further retreat with defeat was inevitable, while, on the other hand, an advance that did not completely dislocate the enemy's plan of attack would not suffice to avert impending disaster. For two days the German forces were thrown against the French and British line to break its resistance, and nowhere was the attack heavier than on the front of the Ninth Army. So violent was the pressure that General Foch had been forced to yield ground.

In his lectures he enunciated the principle that there was such a thing as the "Will to Victory", deducing from it that a battle is lost only when a commander believes himself beaten. On the afternoon of September 8, with his own resolve to win firmly fixed in spite of local reverses, he saw that the enemy forces had been drawn into an unfavorable position, which could be availed of by a rapid and daring shift of his own troops. It was then that he sent his famous dispatch, "My right heavily pressed, my center yields, situation excellent, I attack." It was the temporary faulty position of the forces in front of him that presented the excellent situation. This message was intended to cheer the drooping spirits of men who had been in continuous retreat for four weeks and who had but recently come under his command.

General Foch attacked with such vigor that the enemy, whose extreme right wing was in difficulty, saw that an immediate retirement along the whole front was necessary to avert a disaster. Paris and France were saved.

When time has removed all personal bias and an impartial study can be undertaken to apportion credit and evaluate effect between the genius of Joffre and Gallieni, the surprise pressure that developed on the enemy's right, the fact that the enemy had outrun his reserves and supplies, and other causes contributing to the victory on the Marne, there would seem to be no question that General Foch's brilliancy in discerning an "excellent situation" in the midst of what appeared to be a crushing defeat, and his alertness in seizing it, will be ranked as one of the most potent factors.

With any further advance temporarily stopped the Germans endeavored to correct an initial error which they had committed when they left the channel ports free. To assist in their defense by co-ordinating the efforts of the British, French, and Belgian forces, General Foch was sent to Northern France with the title of Commander of the group of Armies of the North. His authority was limited, however, to the French forces, and his relations with respect to the British and Belgian Allies were those of a liaison officer. In this double capacity he remained until the end of 1916, taking prominent part in the Artois and Somme offensives, during which there was some of the bloodiest fighting in the whole war.

Then, through one of those unfortunate developments in internal politics, which have no relation to the conduct of war, but which in a democratic government seem to be inseparable from it, General Foch was sent into temporary retirement, being ordered to Senlis "to rest", although later given nominal inspection duty and ordered to prepare a plan for resistance against a possible German invasion of Switzerland. In 1917, he was made Chief of the General Staff with headquarters in Paris, a position that carried no field command.

On March 21, 1918, the Germans began their last and great offensive. A wedge was driven between the British right and the French left just south of Peronne, involving the retirement of the British Fifth Army and the withdrawal of the French left. Not only was the whole area of the Somme, that had taken the Allies five months in 1916 to capture at appalling cost, regained in as many days, but additional territory was seized that had been held by the British or French since 1914. The enemy was in front of Arras and Amiens, and the main lines of communication from Paris northward were either cut or rendered useless as being under fire.

The situation was as desperate as it was on the Marne in 1914, and it was obvious that some drastic step must be taken to prevent a break-through to the Channel that would divide the Allies into two parts and involve disaster. As Field Marshal Haig put it, "We are fighting with our backs to the wall." There were three armies in the northern field co-operating but not correlated, French, British, and Belgian. There was a fourth, the American, just entering the field. These armies were under their own individual commanders, who conferred and acted jointly as best they could, while preserving their own

separate authority. They "loaned" each other troops and supplies, if sufficient emergency could be shown, but in accordance with the dictates of human nature, each commander reserved to himself the right to decide on the seriousness of the other's emergency and was reluctant to release reserves or material for fear that he might immediately find himself, in turn, in sore straits.

For three years it had been patent that this division of control was a serious handicap as opposed to the single will presented by the enemy, but as yet no nation was willing to accept an uncontrolled command vested in another national. Victory and defeat were now in the balance, and if the former were to be secured all personal antagonisms must be submerged into the greater consideration of the welfare of the common cause.

On March 26, 1918, a conference between the leading French and British military leaders and ministers representing the respective War Departments was held in the Hôtel de Ville, of Doullens, a small village about 20 miles north of Amiens and directly behind the front line, to determine a policy of joint action. It was at once agreed that complete unity in command could be postponed no longer, and the sole question was to find the man. Various names were proposed, even that of M. Clemenceau being brought forward, but after long discussion only General Foch had not been rejected. Sir Douglas Haig stated that he would accept Foch as Generalissimo and give him full support, an offer immediately repeated by General Pétain, then the French Commander-in-Chief. M. Clemenceau had General Foch waiting, because from the outset he was M. Clemenceau's candidate. He was called in and accepted the burden, so that finally after three and one-half years of blundering, a single directing force faced the common enemy. A few days later, General Pershing pledged the new Commander-in-Chief his support and that of the American Army, provided only that the latter should be used as a unit.

There is no parallel in history to the task that General Foch undertook that night in spite of his 67 years. The French, British, and Belgian Armies totaled nearly 10 000 000 men. They were wearied with almost four years of continuous fighting, during which time each had learned to think of itself as a separate unit working to some extent conjointly with others. Recently, they had received a blow that had sent them reeling and one that had nearly caused collapse. Guns in great number and material in huge quantities had been lost. Other blows were certain to follow. Could this great mass be welded into a single unit capable not only of withstanding the further attacks that were to come, but of assuming the offensive and striking back? That was General Foch's task, one that called for the stoutest "Will to Victory".

To-day is still too close to those great events when defeat was turned into victory, properly and fully to evaluate the service rendered by General Foch, and the manner in which he accomplished the task that had been assigned to him. To what extent he accepted and was guided by the advice of his Lieutenants, Haig, Pétain, and Pershing, is not as yet clear. Probably he left many details to each Commander, asking only that separate movements should conform to the general plan. His great accomplishment, as to which there will probably be no question, was his success in amalgamating four armies into

one, enabling him to treat reserves as one mass, which, whether in men or material, could be diverted or concentrated in such manner or place as he deemed most important. Yet that accomplishment meant victory, and alone justifies the enduring gratitude of the allied nations, of which America was one, and entitles General Foch to be accorded lasting fame. He has described himself as "No more than the conductor of the orchestra"; but what an orchestra!

The next attacks already planned by the enemy could not be averted, but by skillful handling of his forces, General Foch resisted them and gradually brought the offensive to a halt, with Arras, Amiens, and other strategic points safely held. Relieved of the pressure of defending, he set about building up a united army that would be capable of taking a successful offensive. By midsummer his preparations were complete, and he planned to strike the enemy on July 18, in the direction of Soissons.

German headquarters had learned of the proposed attack through their spy system and hoped to escape it by attacking first. This they did early in the morning of July 15, and succeeded in crossing the Marne between Château-Thierry and Dolmans, to a depth of five or six miles. At first, it looked as if the enemy had succeeded in his move, but General Foch, after a careful examination of the situation, decided that the result placed the Germans in a more difficult situation than it did the Allies and decided to continue with his own plan unaltered, leaving but a sufficient force to restrain the enemy from making a further advance. He saw that they had exposed a weak flank, and that his previously prepared plan would compel them to withdraw across the Marne, or have their advanced troops cut off, and this without any sacrifice on his part. This decision well illustrates his method of carefully weighing all the factors at the time of a crisis and not allowing his judgment to be warped either by an excess of caution or a disinclination to change a predetermined plan, and, having reached a decision, to act with firmness. In this particular case it took courage to leave the enemy in his advanced position. It was this ability to think clearly and then to execute without flinching or compromising, that gained for General Foch the unwavering confidence of all ranks.

General Foch's attack was successful and was quickly followed by others in succession until the offensive was general from the Channel to Metz. Steadily under the direction of the master mind the wave rolled on until at the end of October the enemy, realizing defeat, opened negotiations for an armistice, which was signed on November 11, 1918.

In fixing the terms of this armistice, General Foch resisted what must have been a severe temptation for a personal satisfaction. Great pressure was brought to bear on him to continue the war until every German soldier had been driven from France, to sign the treaty on German soil, and to lead a triumphal procession through Berlin. It would have been easy to find justification for such a course, especially as it was supported by popular clamor. The enemy was already in retreat, indicating that his power of resistance was broken, and his own recollection of the King of Prussia being crowned German Emperor at Versailles in 1870 and of the march of the victors down the Champs Elysées, must have been in his mind. He rejected all thought of

personal aggrandizement or unnecessary risk, however, arguing that there was no justification in prolonging the war one hour or shedding one drop of blood after the main objective had been gained, which, in this case, was the expulsion of the invader from France.

The war ended, General Foch made no effort to secure political advancement. He was a soldier fighting when his country needed his services and was not of the type of the "Man on Horseback" that France had always feared would come into being following a victorious war against Germany when the "stolen" Provinces would be returned. As soon as his military duties permitted, he withdrew to his estate of Transfeutenis.

All nations vied in heaping upon him every honor available. France made him a *Maréchal* and the Academy elected him as one of 40 "Immortals." Great Britain created him a Field Marshal and conferred on him the Grand Cross of the Order of the Bath and the Order of Merit. So it was with every nation associated with the Allied cause.

In 1921, he made his first and only visit to the United States. On December 6, he was received in the Engineering Societies' Building and was presented for Honorary Membership in all the Founder Societies, the only man who has ever received such distinction as a joint award.\*

During 1928, his health began to fail and, although he made the same determined fight against the one enemy who cannot be beaten, he was able only to postpone the inevitable. He died at his residence in Paris, on March 20, 1929. He was buried in the Invalides on March 26, 1929, close to his great hero, Napoleon.

Ferdinand Foch was married to Julia Bienvenue, by whom he had one son and two daughters. His son, an officer in the French Army, was killed at the outbreak of the war (August, 1914) in the Ardennes. It is related that when word of his son's death was brought to him he requested the members of his staff to withdraw and leave him alone for half an hour. When they returned they found him at his table studying his maps and prepared to carry on.

He was of medium height with a well-made frame. His face, although it showed energy and determination, had in repose a gentle, kind expression. His whole appearance suggested the man of action, but perhaps that of the man of affairs rather than the type of Roman conqueror that popular fancy has in mind for the military leader.

Marshal Foch was elected an Honorary Member of the American Society of Civil Engineers on December 6, 1921.

\* For an account of the presentation see *Proceedings, Am. Soc. C. E.*, January, 1922, Society Affairs, pp. 4-7.

## SAMUEL REA, Hon. M. Am. Soc. C. E.\*

DIED MARCH 24, 1929.

Samuel Rea was born in Hollidaysburg, Pa., on September 21, 1855, the son of James D. and Ruth (Moore) Rea, and the grandson of General John Rea, of Chambersburg, Pa., who was an Officer in the Revolutionary War.

Before reaching the age of sixteen, Mr. Rea entered the service of the Pennsylvania Railroad Company as a Rodman in one of its Engineering Corps. With the exception of a few short intervals, he served in that organization during the remainder of his life as Engineer, Principal Assistant Engineer, Assistant Second Vice-President, Assistant to the President, First Assistant to the President, Fourth Vice-President, Third Vice-President, Second Vice-President, First Vice-President, Vice-President and, finally, President from January 1, 1913, to September 30, 1925. On the latter date he retired as President under the Pension Regulations. Mr. Rea was the only President to attain the age of 70 years in active service, none of his predecessors in that office having lived beyond 63 years.

His employment with the Pennsylvania Railroad Company and his active and vigorous interest in it through the period of its ever-increasing development and importance as the leading transportation system of the country, were the heart and soul of his existence—in fine, he lived the Pennsylvania Railroad.

His quick grasp of difficult questions, his exceptional memory, his natural ability to analyze and solve railroad problems, and the opportunity of growing up in close touch with the development of the large area served by the Pennsylvania System, all welded together in him an amazing knowledge of the property and the territory it serves. It may truthfully be said that he knew more about the physical and financial characteristics of the Pennsylvania Railroad, its history and problems, than any of his contemporaries.

The range of Mr. Rea's activities in the service of the railroad was extensive and diverse. Early in his career he centered his attention on the numerous branch lines of the Pennsylvania System which, in his case, meant not only their construction and operation, but also their corporate formation, financing, etc.

More than thirty years ago he foresaw the desirability and need of railroad consolidations as a factor that would contribute toward more efficient and economical operation of the railroads. The Pennsylvania System originally consisted of more than 600 constituent transportation companies, which at the close of Mr. Rea's administration in 1925, and largely through his intensive efforts, had been reduced through consolidations and acquisitions to 127 companies. His activities in this direction gave him the nickname among his associates of "Consolidation Sam."

He was connected with practically all these subsidiaries in the capacity of President or Vice-President, or as a Director. The acquisition of an inter-

\* Memoir prepared by W. W. Atterbury, M. Am. Soc. C. E.

est in a large number of lines, such as the Long Island Railroad, the Norfolk and Western Railway, and others, was carried out under his direction.

His close association with former Presidents Roberts and Cassatt, and former Financial Vice-President John P. Green, served to broaden his outlook and increase his knowledge in many directions in the railroad field.

In the course of his work, Mr. Rea made the acquaintance of Gustav Lindenthal, M. Am. Soc. C. E., the noted bridge engineer, with whom his activities brought him in close association for many years. Mr. Rea took a deep interest in the organization of the North River Bridge Company, of which he was one of the incorporators. The construction of this bridge would have provided an all-rail entrance into the heart of New York City. Failing to secure needed co-operation of other rail lines to assure the success of such a large project, the Pennsylvania Railroad Company proceeded independently to make its own plans for such an entrance by means of tunnels under the Hudson and East Rivers, and Mr. Rea was given direct charge of this work by former President Cassatt. This was most appropriate because, upon his appointment as Assistant to the President in 1892, he had been sent to London, England, to make an examination of the underground railroads then constructed and proposed in that city, and subsequently made a report thereon. Before this, in 1887, he had written a book entitled, "The Railways Terminating in London", a comprehensive study of the physical and financial condition of the English railroads. The success of this great tunnel extension, including the erection of the Pennsylvania Station in New York, N. Y., will always be classed as one of his greatest monuments.

He was also the Executive Engineering Head in the construction of the New York Connecting Railroad, including the Hell Gate Bridge, the longest arch span in the world, which connects the Pennsylvania and New Haven Systems and furnishes an all-rail connection for the Pennsylvania Railroad Company from the South and West with New England and Canadian points.

Mr. Rea took a keen interest in civic and welfare work, making liberal contributions of money and personal effort to worthy causes. He favored regional planning for the Metropolitan Area in and around Philadelphia, Pa., and was Chairman of the Regional Planning Federation of Philadelphia Tri-State District. He not only was Chairman of the Committee to raise funds to carry on this work, but also devoted a great deal of time and study to comprehensive planning for the future of this important section of the country. He was a member of the Board of Trustees of Bryn Mawr Hospital and headed the work of securing a large building fund for that institution. He was for many years President of the Board of Trustees of the Bryn Mawr Presbyterian Church and took a prominent part in building its new edifice, giving a great deal of time to the raising of the necessary money and actual construction work. He contributed the cost of the new organ with the understanding that it would contain no mark or plate showing the name of the donor. Fortunately, he lived to see the Church building completed.

He was also a Trustee of the Pennsylvania Museum and, during his life, contributed a valuable collection of old English silver to the Art Museum in

Fairmount Park, Philadelphia. This is one of the most important private benefactions the Museum has received.

Mr. Rea's interest in railroad transportation was not confined to the Pennsylvania System. His frequent trips throughout the country gave him the opportunity to observe methods of construction and operation on other roads, and the knowledge thus gained was of great value to the Government immediately after the United States entered the World War and before the railroads were taken over at the end of 1917. For eight months prior to that time Mr. Rea and the executives of five other roads constituted what was known as the "Railroads' War Board," under the direction of which the competitive activities of all the important railroads of the United States were submerged, and their properties operated as a continental railway system so as to produce the maximum of National transportation efficiency.

At the time of his death Mr. Rea was a Director of the Pennsylvania Railroad Company and of several of its subsidiaries; also a Director of the Southern Pacific Company, the Philadelphia National Bank, the Bank of North America and Trust Company, the Equitable Life Assurance Society of the United States, the Philadelphia Saving Fund Society, the Bell Telephone Company of Pennsylvania, the Norfolk and Western Railway Company, and a member of the Philadelphia Gas Commission.

Although Mr. Rea did not go to college, having secured his knowledge of engineering through actual experience supplemented by keen observation and study at night, and by extensive travel at home and abroad, in later years he received several honorary degrees, including that of Doctor of Science, from the University of Pennsylvania in 1910; Doctor of Laws from Lafayette College in 1916; and Doctor of Science from Princeton University in 1916.

Mr. Rea was elected a Member of the Institution of Civil Engineers of Great Britain in 1891 and an Honorary Member in 1928, and, at his death, was the only American Member so honored.

On May 12, 1926, the Franklin Institute of Philadelphia awarded him the Franklin Medal, "in recognition of his outstanding work in the conception and construction of railroads, their terminals, tunnels, and bridges, and of his eminently successful application of the principles of science, economics and human relations to railway engineering and administration, in which he displayed vision, imagination and courage of high order".

He was married on September 11, 1879, to Mary M. Black, of Pittsburgh, Pa., and was looking forward to celebrating his Fiftieth Wedding Anniversary in 1929. They had two children, George Black Rea, who died in 1908 at the age of 27 years, and Ruth Rea, who is married to George B. Junkin.

Mr. Rea was a man of simple tastes, one who avoided ostentation and was beloved by all. He was devoted to his family and his life's work; he was a great reader and intensely interested in the growth of the country and its industries—a loyal friend and a great man.

The following is an abstract from the minutes adopted by the Board of Directors of the Pennsylvania Railroad Company at its meeting on March 27, 1929:

"Three years and a half ago, this Board recorded the termination of the active service of Samuel Rea, President of the Company, and paid tribute to his distinguished service. To-day we come, in the sorrow of bereavement, to record the termination of his life,—a life of accomplishment and distinction.

"Though, after his retirement from the Presidency, Mr. Rea continued, as a member of this Board, to devote much of his time, and to give the benefit of his extensive experience and fund of knowledge of its history and traditions, to the management of the Company's affairs, he found, in relief from the exactions of executive office, leisure to devote his talents to the solution of problems of civic welfare, the betterment of his fellow men and the advancement of art.

"Mr. Rea's connection with the Company covered half a century. Innate talent, unusual intellectual endowments, industry, and an indomitable determination to know and to be ever of greater service, developed from the roddman of less than seventeen years the finished engineer and the master of railroad science. Each step in that development was characterized by devotion to the Company's interest and a single purpose to promote its welfare.

"This Company's foothold on Manhattan Island, and the welding of its lines to those in New England, have been called a monument to the vision and courage of Alexander J. Cassatt. The realization of that vision was committed to the hands of Samuel Rea, and its accomplishment stands as the most conspicuous monument to his professional skill and administrative ability. In the corporate and economic structure of the now vast system are other memorials, which, though unseen, are of no less importance to its welfare.

"In recognition of his intellectual attainments, institutions of learning have conferred honorary degrees, and scientific bodies decorations and honorary membership. Worthy tributes all to the man of genius and achievement, but dearer to those who mourn his loss is the willing bestowal of the greatest decoration which man can receive of man—that he was honored, respected and beloved as well for what he was, as for his culture and the fruits of his notable talents.

"The name of Samuel Rea is enrolled on history's pages with those of the distinguished men who have wrought the fabric of, and builded, each in his turn, on the great highway of the nation's progress.

"It is difficult in this record to pay just tribute to the genius and worth of so accomplished a man, and to adequately express the measure of our sorrow and loss in his death.

"His works are his enduring monument; the affectionate regard of those with whom he was associated, a tribute, more eloquent than words, to his worth."

Mr. Rea was elected a Member of the American Society of Civil Engineers on June 4, 1884, and an Honorary Member on June 6, 1921.

**EUGENE HILARIAN ABADIE, M. Am. Soc. C. E.\***

---

DIED APRIL 27, 1929.

---

Eugene Hilarian Abadie was born in St. Louis, Mo., on March 1, 1872, the son of Eugene S. and Mary (Snow) Abadie. He was educated in the public and private schools of St. Louis, and at Washington University.

From 1891 to 1892, Mr. Abadie was employed in the Shop and Engineering Department of the Wagner Electric Manufacturing Company assembling and testing electrical apparatus, and from 1893 to 1900 he was Secretary and Manager of Sales, as well as a member of the Executive Board of this Company. From 1901 to 1903, he was Manager of the Sales Organization of the Bullock Electrical Manufacturing Company, of Cincinnati, Ohio, and of the Wagner Electric Manufacturing Company, of St. Louis, directing and supervising the acquisition of engineering contracts.

From 1903 to 1908, he was a member of the firm of E. H. Abadie and Company, Engineers and Contractors, during which time he designed and constructed the heating plant and power house for the State Buildings at Jefferson City, Mo. In 1904, he designed and built the central heating plant for the Pana, Ill., Gas and Electric Company, and, in 1905, he served as Engineer for the Southern Kansas Railway, Light, and Power Company, developed the project, and furnished a report for underwriters.

In 1906, Mr. Abadie designed and built all the underground conduits in Louisville, Ky., for the various public utilities. At that time he was associated with the late Arsene Perrilliat, M. Am. Soc. C. E., in the location of the New Orleans and Baton Rouge Electric Railroad, supervised the engineering, and wrote the engineering report. In 1907, he rehabilitated the Moberly, Mo., Gas and Electric Company and increased the connected load 300 per cent. He also designed and built the municipal power plant at Little Rock, Ark. In 1908, he designed a plant for stripping earth with steam shovels from a coal bed of the Lilly Jellico Coal Company, at Lilly, Ky., and, in a similar manner, mined the coal.

As a Constructing Engineer, Mr. Abadie designed the electric power generating plant for the Consumers Light and Power Company, at Fort Worth, Tex. As a Contractor, he built for the United States War Department, the sewer and water-works at Jefferson Barracks, Missouri. He also designed and installed a number of isolated and industrial steam and electric power plants in St. Louis and in the Central and Southern States. As a general or sub-contractor, he contracted to supply mechanical equipment, comprising heating, ventilating, and lighting systems and steam and electrical power plants in shops, department stores, and other large buildings. From 1908 to 1917, he was a practicing Consulting Engineer, and was associated with Dr. George S. Hessenbruch, of St. Louis, during the last five years of this period. In addition, he was Secretary and Treasurer of the Industrial Engineers Corporation of St. Louis. In 1910, he was Consulting Engineer and acted in an

---

\* Memoir prepared by D. H. Sawyer, M. Am. Soc. C. E.

advisory capacity to the Public Service Commission in matters connected with the valuation of public utilities of St. Louis.

In 1917, Mr. Abadie joined the United States Army, first as a Major of Engineers in the United States Reserve Corps. In July, 1917, he was assigned to the Construction Division of the Army as Supervising Constructing Quartermaster, having personal charge of National Army Cantonments and National Guard Camps (Camps Funston, Dodge, and Lee). In September, 1917, Major Abadie took charge of the construction of Camp Lee as Constructing Quartermaster, later going to Washington, D. C., as Supervising Constructing Quartermaster in charge of Camps Holabird, Jessup, and Normoyle, and the Army Tubercular Hospitals, at Denver and Azalea, Colo., as well as several smaller projects. In 1918, he took charge of construction matters connected with shops, camps, etc., of the Motor Transport Corps. In August, 1918, he was commissioned Lieutenant Colonel and served in that capacity until after the World War. In 1919, Colonel Abadie served as General Comptroller for the United States Shipping Board and Emergency Fleet Corporation. On May 1, 1920, he was appointed General Agent, in Washington, for the International Maritime Corporation, Tropical Steamship Corporation, and other shipping concerns. For several years previous to his death, he had been engaged in practice as a Consulting Engineer, with offices in Washington.

Colonel Abadie, due to the wide spread of the engineering field which he served, while maintaining headquarters in St. Louis, acquired an extremely wide circle of friends and business acquaintances. His Army experience and association with the Shipping Board, together with his experience as a Consulting Engineer in Washington, also contributed to his remarkable popularity. He was of a disposition to hold this. He concerned himself in public and organization affairs and was a forceful advocate of policies destined to better his profession, as well as raise the plane of his community.

Colonel Abadie was a member of the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, the Society of American Military Engineers, the Engineers' Club of St. Louis, the Western Society of Engineers, the Society of Colonial Wars, the Military Order of Foreign Wars, the American Legion, the Congressional Country Club, and St. Margaret's Protestant Episcopal Church, in Washington, D. C.

Colonel Abadie was elected a Member of the American Society of Civil Engineers on June 1, 1920.

**JOHN JARRETT ALBERTSON, M. Am. Soc. C. E.\***

DIED NOVEMBER 23, 1928.

John Jarrett Albertson was born in Magnolia, N. J., on August 16, 1858, the son of Chalkley and Annie (Stokes) Albertson. He was descended from old Quaker pioneer stock and the estate on which he lived has been continuously in the Albertson family since 1687, when it was first settled by William Albertson and his wife, Hannah (Druit) Albertson.

John Jarrett Albertson was graduated from the Friends Central High School, at Philadelphia, Pa., in 1876, and for a year, following his graduation, taught school in his home district.

In 1878, he began his life work as an engineer. He was employed by the Philadelphia and Atlantic City Railroad Company on preliminary surveys and, later, on the construction of this railroad to the Jersey Coast. On the completion of this project, he was associated with Judge John Clement, an eminent jurist, and at that time the leading surveyor of South Jersey.

Mr. Albertson took particular interest in road building and was one of the early authorities in New Jersey on Telford, macadam, and gravel roads, writing many of the original specifications governing these types for various State Highway Commissioners. Prior to 1898, he was Engineer for Camden, Gloucester, and Atlantic Counties, New Jersey, engaged on State Aid road work exclusively. At this time, the law required that the County Engineer reside in the county that he represented. Accordingly, Mr. Albertson gave up his work for Atlantic and Gloucester Counties, retaining only his position as Engineer of Camden County, to which he had been appointed in 1892. He held this position until his death.

In 1893, he went to Europe to study road building. After traveling for a year, he returned with much valuable information which he proceeded to utilize in his own work. The location of many of the principal highways of Camden, Atlantic, and Gloucester Counties, remain as they were originally laid out by him, with very minor subsequent deviations.

Probably his foremost contributions to South Jersey were the Meadow Boulevard at Atlantic City, N. J., in the construction of which he introduced hydraulic dredging for road work; the White Horse Pike which has world-wide fame; and the very fine road system of Camden County. He served as Engineer of the Commission in the construction of the Camden County Court House, one of the finest public buildings of its time, and also was influential in the construction of the Camden County Institutions at Lakeland, N. J., where expenditures in recent years have exceeded \$4 000 000. He also served with distinction on the Advisory Board for the New Jersey Approaches to the Delaware River Bridge and as a member of the Technical Advisory Committee of the Philadelphia Regional Planning Federation. In addition, he acted as Engineer for many municipalities in Camden County, particularly the Boroughs of Hadden Heights and Audubon which he served from their inception until his death.

---

\* Memoir prepared by Beale M. Schmucker, Assoc. M. Am. Soc. C. E.

Mr. Albertson was a Mason of high standing, having been a member of Cyrene Commandery and Crescent Temple. He was also a member of the Camden Lodge of the Benevolent and Protective Order of Elks.

He was a man of varied interests. With his brother, he owned and cultivated the homestead farm. He was President\* and principal owner of the Defiance Fruit Company and also of the Atlantic Cranberry Company, the latter being one of the largest in the State. His home at Magnolia is a horticultural Paradise and here he raised beautiful and rare plants and trees from all climes. His love of horticulture was carried to the County Institutions at Lakeland where former swamp and waste land has been drained and replaced by beautiful shrubbery and flowered gardens.

Mr. Albertson was also active in the line of finance, having been a Director of the First Camden National Bank and Trust Company which is the largest bank in Southern New Jersey and also a Director in the Woodbury Trust Company.

In 1886, he was married to Elizabeth Swift Wills, of Poughkeepsie, N. Y. They had one child, a daughter, Anna Mary, now Mrs. Lester Collins, of Moorestown, N. J.

Mr. Albertson was a forceful man of high character and great energy, whose absolute integrity was never questioned throughout a long and active public life. He was loved and respected by those with whom he came in contact, and his death was a great loss, not only to the community, but to all South Jersey, as he was one of the foremost citizens of the State.

Mr. Albertson was elected a Member of the American Society of Civil Engineers on March 14, 1916.

## WILLIAM STUART AUCHINCLOSS, M. Am. Soc. C. E.\*

---

DIED APRIL 10, 1928.

---

William Stuart Auchincloss, the son of John and Elizabeth Auchincloss, was born in New York, N. Y., on March 19, 1842. His primary education was obtained at the Bacon School and at Lyons School, both in New York. Because of his decided mechanical turn of mind he then entered Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated in 1862, at the head of his class, with the degree of Civil Engineer.

In order to secure the advantage of being well grounded in shop work, Mr. Auchincloss began his career as an employee of the Novelty Iron Works, of New York, where large marine engines were built. At the time, the Company was engaged on the construction of a steamer for the Pacific Mail Route and the iron-clad, *Roanoke*, for the United States Navy.

In 1867, he was appointed by the Government as Commissioner to the Paris Exposition. While abroad on this important errand, he visited Great Britain, France, Germany, Austria, Italy, Egypt, and Palestine. He spent several months at the Exposition and made a complete report to the Government on his return to the United States.

For several years Mr. Auchincloss was connected with the Jersey City Locomotive Works, the Atlantic and Great Western Railway Company, and the Ramapo Car and Foundry Company. After conducting the sale of the Jersey City Locomotive Works, he bought an interest in the Delaware Car Works, of Wilmington, Del., and became Vice-President of the Company.

In 1874, Mr. Auchincloss visited Brazil and built the rolling stock of the São Paulo and Rio de Janeiro Railway. In 1876, subsequent to his return to Wilmington, the Emperor, Don Pedro II, of Brazil visited the United States and was entertained at the home of Mr. and Mrs. Auchincloss. While the Emperor was in this country he ordered a private car built by the Delaware Car Works, which was designed and built under the supervision of Mr. Auchincloss. This car was exhibited at the Philadelphia Centennial Exposition in 1876 and received first prize.

Mr. Auchincloss moved from Wilmington to Philadelphia, Pa., in 1879, and organized the firm of Bates and Auchincloss, Agents of Messrs. J. and P. Coats, Thread Manufacturers, of Paisley, Scotland. After Mr. Bates died, Mr. Auchincloss carried on the business in his own name, establishing his family, and building a home, in Bryn Mawr, Pa., which he called "Hillcrest".

In 1903, having retired from business, he moved to Atlantic Highlands, N. J., where he built another home, "Rest Haven", on the shore of Sandy Hook Bay. Here, he lived until his death on April 10, 1928.

Mr. Auchincloss' tastes were decidedly mechanical, but, in later years, he devoted much of his time to literary work. He was the author of the following books and booklets: "Report to U. S. Government, as Honorary Commissioner to the Paris Exposition" (1867); "Standard Work on Link and Valve

---

\* Memoir prepared by William K. Auchincloss, Esq., New York, N. Y.

Motions" (1869); "90 Days in the Tropics" (1874); "Schieber und Contisendteurungen" ("Link and Valve Motions", published in Germany, 1884); "Yearly Tides" (1892); "Waters within the Earth and Laws of Rainflow" (1897); "Stoomschief-en Schaarbewegingen" ("Link and Valve Motions", published in Holland, 1899); "St. Peter, the Apostle of Asia" (1901); "The Book of Daniel Unlocked" (1905); "The Mask of Eddyism" (1907); "Standard Chronology of the Holy Bible" (1908); "Wonders of God's Universe" (1912); "Seaside Astronomy" (1920); "Christianity and the Britons" (1920); "The Greatest Man of the Ages" (1921); and the final edition of the "Standard Chronology of the Holy Bible" (1924).

Mr. Auchincloss also directed his genius to the invention of an averaging machine in 1882. This machine had a capacity of 110 business accounts per hour, which equalled the customary task of six skilled accountants. A paper describing the machine, entitled "Averaging Machine",\* was presented by its inventor before the Society. Relative to his mechanical work, Mr. Auchincloss had received six patents.

In 1870, he was married to Martha Tuthill Kent, the daughter of William Campfield Kent, a noted merchant of the firm of James Kent Santee and Company, of Philadelphia. They had three children, James Stuart, Jane Kent, and William Kent.

He was most kindly, upright, and honorable in all his dealings—a devoted father, and a Christian gentleman.

Mr. Auchincloss was elected a Member of the American Society of Civil Engineers on February 7, 1869.

---

\* *Transactions, Am. Soc. C. E.*, Vol. XI (1882), p. 121.

## WILLIAM AUSTIN BASSETT, M. Am. Soc. C. E.\*

---

DIED MAY 16, 1929.

---

William Austin Bassett was born on September 29, 1876, at Roxbury, Mass. His New England ancestry dates back to 1621. His father was Isaac Austin Bassett and his mother, Annie (Tuson) Bassett.

Mr. Bassett attended the Lawrence Scientific School at Harvard University, from which he was graduated in 1901, with the degree of Civil Engineer. From August, 1901, to October, 1904, he was with the Pittsburgh Division of the Pennsylvania Railroad Company, in the Altoona, Pa., Office, in charge of construction of two main-line bridges, double-tracking the Southwest Branch, and miscellaneous yard and terminal work. From October, 1904, to June, 1906, he was with the Pittsburgh, Pa., Bureau of Filtration, engaged in the construction of a filtration plant, filtration galleries, and settling basins of reinforced concrete design. In June, 1906, he was appointed Assistant Professor of Civil Engineering at Carnegie Technical School, at Pittsburgh, and also was engaged in special work for the Department of Water Supply of the City of Pittsburgh.

From June to November, 1909, Professor Bassett was with the New York City Board of Water Supply as Assistant Engineer on the construction of the Rondout Tunnel at High Falls, N. Y., and from November, 1909, to November, 1910, he was Designing Engineer in charge of the drafting-room at the Cambridge Office of the Boston Elevated Railroad Company, engaged in the construction of the Cambridge-Boston Subway. From November, 1910, to November, 1911, he was Engineer in charge of construction, costs, and cost investigations, at the Donora, Pa., Steel Works, of the American Steel and Wire Company. From November, 1911, to April, 1913, he served as Associate Editor of *The Engineering Record*.

From April, 1913 to December, 1926, Professor Bassett was Chief of the Division of Engineering and Public Works of the New York Bureau of Municipal Research and National Institute of Public Administration, engaged in miscellaneous professional and consultant service to municipalities, counties, and States in the United States and Canada. On December 1, 1926, he joined the Faculty of the Massachusetts Institute of Technology to organize a Division of Municipal and Industrial Research, of which he was Director until his death. Some of the accomplishments under his direction were a comprehensive survey of industrial conditions and possibilities in and about Providence, R. I., an industrial survey of Bangor, Me., and civic surveys of Meriden, Conn., and Norwood, Mass.

He served on the Hoover Committee for the Simplification of Building Codes and Practices, and on the Advisory Board for Highway Research of the National Research Council. He was a Trustee of the Village of Scarsdale, N. Y., from 1922 to 1926, and a Supervisor of Westchester County, New York, from 1923 to 1926. He was the author of "Problems of Road Administration",

---

\* Memoir prepared by William W. Brush, M. Am. Soc. C. E.

published in 1917, and contributed to the technical press on engineering matters related to municipal and State problems.

Professor Bassett was intensely interested in establishing higher and more efficient standards in carrying on municipal and other Governmental activities, and devoted a great deal of his time to this phase of engineering work. His criticisms were always constructive and the methods he adopted, together with his pleasant personality, added greatly in securing the co-operation of those with whom he came in contact. His death at a comparatively early age is a distinct loss to the community.

He was a member of the Harvard Society of Engineers, the American Society for Municipal Improvements, and the Harvard Club.

His widow, Grace Loring Bassett, to whom he was married on March 30, 1908, and a son, John Austin Bassett, survive him.

Professor Bassett was elected a Member of the American Society of Civil Engineers on August 9, 1920.

## SAMUEL GIVENS BENNETT, M. Am. Soc. C. E.\*

DIED APRIL 4, 1929.

Samuel Givens Bennett, the son of John W. and Agnes (Givens) Bennett, was born at Taylorsville, Ky., on July 12, 1863. He was educated in the public schools at Owensboro and Hartford, Ky., and later studied for two and one-half years at Georgetown College, Georgetown, Ky.

In 1886, Mr. Bennett went to California where he commenced his life work, the practice of land surveying and civil engineering. His first employment was with the late E. T. Wright, M. Am. Soc. C. E., of Los Angeles, Calif., in the capacity of Chainman, Rodman, and Draftsman.

In subsequent years he was engaged in the following positions: From September, 1889, to September, 1890, as Draftsman and Instrumentman with L. Friel, Civil Engineer; from September, 1890, to September, 1891, as Assistant Engineer with the Redondo Railway Company; from September, 1891, to October, 1893, as Draftsman with the Pacific Coast Abstract Company, of Los Angeles, Calif.; from October, 1893, to December, 1896, in conducting general engineering business in Los Angeles and vicinity, in partnership with Frank H. Olmsted, M. Am. Soc. C. E., and the late Burr Bassell, M. Am. Soc. C. E.; from May, 1897, to April, 1898, as Engineer with the Chicala Water Company, of Rialto, Calif.; from April to October, 1898, as Superintendent of the construction of a pumping plant and a riveted steel pipe line for the Azusa Glendora Water Company; from October, 1898, to April, 1899, in association with J. B. Lippincott, M. Am. Soc. C. E., in connection with the Pasadena, Calif., Water Supply System; from April, 1899, to January, 1903 as Assistant Resident Hydrographer for the United States Geological Survey in California; from January, 1903, to June, 1906, as Engineer in the United States Reclamation Service, having charge of the Sacramento Valley Project for almost two years of this period; in 1907, as Locating Engineer for the Los Angeles and Owens Valley Railroad Company; from 1908 to 1909, in private practice; and during 1910, as Engineer for the United Sugar Company in the State of Sinaloa, Mexico. In 1911, Mr. Bennett again returned to private practice, but was soon appointed City Engineer of Oxnard, Calif., which position he held until his death.

On March 22, 1899, Mr. Bennett was married at Redlands, Calif., to Mable J. Randall, of Minneapolis, Minn., who, with their four children, Harman R., S. Gerald, Mable Rose, and John Newton, survives him. Mr. Bennett was a member of the Baptist Church, and was greatly beloved among a wide circle of friends.

Of a retiring, modest disposition, he was a great student along scientific and religious lines. His hydrographic work in the High Sierras in California for the U. S. Geological Survey brought him conspicuous success. As City Engineer of Oxnard, "Sam" Bennett enjoyed the esteem and respect of the Trustees of that city during the long period of years in which he held that office.

Mr. Bennett was elected a Member of the American Society of Civil Engineers on October 3, 1906.

\* Memoir prepared by Frank H. Olmsted, M. Am. Soc. C. E.

## EDWARD AUSTIN BOND, M. Am. Soc. C. E.\*

DIED DECEMBER 10, 1929.

Edward Austin Bond was born on April 22, 1849, at Dexter, Mich., the son of Hollis and Emily Faxon Bond. His ancestor, William Bond, came to the United States from England about 1620 and settled at Watertown, Mass.

Mr. Bond was educated in the public schools of Michigan and in a business college at Utica, N. Y. His first engineering work was for the Utica, Chenango and Susquehanna Railroad Company in 1868. In 1869, he served as Assistant Engineer on the Chicago, Pekin, and South Western Railroad, near Pekin, Ill., and on the Utica, Chenango and Susquehanna Valley Railroad, near Norwich, N. Y.

In 1870, he became Assistant Engineer on the Utica and Black River Railroad from Lowville to Carthage, N. Y., and also on the Black River and Morristown Railroad, near Philadelphia, N. Y. From late in 1870 to November, 1873, he was Chief Engineer of the Clayton and Theresa Railroad, from Clayton to Theresa Junction, N. Y. During part of 1874, Mr. Bond served as Resident Engineer, and between August, 1874, and April, 1886, as Chief Engineer, of the Utica and Black River Railroad and during that time the line between Morristown and Ogdensburg, N. Y., was built. From May, 1886, to May 1, 1889, he was Chief Engineer and General Superintendent of the Carthage and Adirondack Railroad, on the portion between Carthage and Benson Mines, N. Y. Several railroads on which Mr. Bond was employed are now included in the New York Central Lines.

Mr. Bond was a member of the engineering firm of Hinds and Bond, of Watertown, N. Y., from 1889 to 1896, and during those years this firm designed or constructed water-works in Cape Vincent, Antwerp, Theresa, West Carthage, and Philadelphia, N. Y., and Barrie, Chatham, and Napanee, Ont., Canada. Mr. Bond had personal charge of the location of the Gouverneur and Edwards Railroad and of the surveys for the proposed Mohawk and St. Lawrence Railroad in Jefferson, Lewis, and St. Lawrence Counties, New York.

He was engaged in private practice from July, 1896, to November, 1898, as Consulting Engineer on various works. In November, 1898, he was elected State Engineer for New York and served as such until May 1, 1904. While Mr. Bond held this position many questions on canal and highway matters were considered. He served on the Committee on Canals that thoroughly investigated different projects in this field and reported to the Governor thereon in January, 1900. As State Engineer he had charge of a detailed survey of the canal routes through the State, known as the Barge Canal Survey, and reported thereon to the Governor early in 1901. The report gives in detail the various canal routes, estimates of cost, reports of the engineers in charge of the various parts of the work, and, in all, is a record of great engineering value. The studies covered by the report were so thorough and the methods used so exact that they received the confidence of the people of the State and enabled them to form a careful judgment on the matters con-

\* Memoir prepared by William B. Landreth, M. Am. Soc. C. E.

sidered. As State Engineer, Mr. Bond also had charge of the State's improved roads—then in their infancy—and many of his designs have since come into general use.

Mr. Bond resigned as State Engineer on May 1, 1904, to become Chairman of the Advisory Board of Consulting Engineers on the Barge Canal, and served as such until that Board was abolished by the State Legislature, in July, 1911. While the duties of the Advisory Board varied somewhat from time to time, it had a general oversight of the design and construction of the Barge Canal. Mr. Bond visited Europe as a member of the Barge Canal Terminal Commission that made an exhaustive study of terminals and, in the main, the report of that Commission has been followed on State Terminals.

After 1911, Mr. Bond was in private practice on canal and harbor works. He visited Uruguay on a harbor project in 1914, and was a member of the Advisory Board of the Trans-Alaska and Siberia Railroad.

He had the faculty of choosing competent and experienced men to work with him, and he showed much tact and wisdom in such choice. He quickly realized the essential points of a project and his decisions showed a full knowledge of the questions involved and their solution. He was a good judge of men and their work, and his associates showed their confidence in him by giving of their best efforts.

Mr. Bond was a Thirty-third Degree Mason, and a Republican in his political affiliations. He was an officer in several water-works companies in the United States and Canada.

He was married to Gertrude Hollenbeck in 1873; after her death to Clara E. Ellis, in 1904; and subsequent to her death to Mrs. Elizabeth Parsons, in 1908, who survives him.

Mr. Bond was elected a Member of the American Society of Civil Engineers on September 6, 1899.

## WILLIAM LEWIS BRECKINRIDGE, M. Am. Soc. C. E.\*

DIED JULY 11, 1929.

William Lewis Breckinridge, the son of Marcus Prevost Breckinridge, M. D., and Lucy (Long) Breckinridge, was born at Louisville, Ky., on June 29, 1857.

He was a direct descendant on his paternal side of a family noted for its patriotism, oratory, and statesmanship. After first settling in Virginia in 1730, John Breckinridge, his great-grandfather, migrated to Kentucky in 1780. One of his grandsons, John C. Breckinridge, became famous in political circles, being Vice-President of the United States from 1856 to 1860, and, later, running for President of the United States in opposition to Abraham Lincoln. He afterward became a General in the Confederacy and Secretary of War under Jefferson Davis.

His grandfather, the Rev. William Lewis Breckinridge II, was a Presbyterian Minister, and, at one time, served as Moderator of the combined Presbyterian Churches of the United States. While many of the Breckinridge family espoused the Southern cause, Marcus Prevost Breckinridge and his descendants allied themselves with the Union in the controversies leading up to the Civil War.

On his maternal side, the Long family was quite as prominent; his grandfather, Stephen Harriman Long, was one of the foremost engineers of his day. From 1818 to 1826, he supervised explorations between the Mississippi River and the Rocky Mountains, Long's Peak, the highest summit in those mountains, being named after him. In 1829, he published a "Railroad Manual", the first book of its kind in the United States. From 1827 to 1830, he was Chief Engineer of Surveys, in connection with the building of the Baltimore and Ohio Railroad; later, he became Engineer in Chief of the Western and Atlantic Railroad, in Georgia, during which time he introduced a system of curves on location work. He served for a time on the Board for Improvements of the Mississippi River, and was made Colonel of Engineers in 1861, shortly before his retirement in 1863.

William Lewis Breckinridge spent his boyhood days in Alton, Ill., attending the public schools. After graduating from High School, he went to the Worcester Military Academy, Worcester, Mass., and from there to Washington University, St. Louis, Mo., from which he was graduated with the degree of Civil Engineer in 1879. In June, 1907, Washington University conferred upon him the Honorary Degree of Master of Arts.

He entered the service of the Chicago, Burlington, and Quincy Railroad Company on July 15, 1879. Beginning as an Assistant Engineer, he was subsequently made a Division Engineer in 1880; Engineer of Iowa Lines in 1890; Assistant Superintendent of Iowa Lines in 1898; Chief Engineer in 1899; Chief Engineer of Maintenance in 1904; and Chief Engineer of the Chicago, Burlington, and Quincy System, then under Federal Control, in 1918. He con-

\* Memoir prepared by a Joint Committee of the Society, the Western Society of Engineers, and the Chicago Engineers Club, consisting of A. W. Newton and Elmer T. Howson. Members, Am. Soc. C. E., and Charles W. Melcher, M. W. S. E.

tinued in this capacity until the end of Federal Control in 1920, when he was appointed Assistant Chief Engineer of the System, which position he held until his retirement in April, 1923.

In his service with the Burlington Railroad, extending over a period of nearly half a century, Mr. Breckinridge saw the Lines East of the Missouri River grow by construction and by acquisition from a group of loosely knit light traffic lines, comprising a total of 1 857 miles in 1880, to a highly developed system of 4 410 miles in 1923. This period was one of intensive, as well as extensive, development, much of which was under Mr. Breckinridge's supervision. He was in charge of the re-alignment and revision of grades on the Burlington's main line across Iowa from 1898 to 1902, which comprised some of the heaviest work of its kind up to that time.

Under his administration, the Burlington extended its line into the Southern Illinois coal fields, and then rebuilt existing lines from Centralia, Ill., north to St. Paul, Minn., providing a maximum grade of 0.3% for this distance of more than 600 miles. Coincident with this program, numerous large terminals were built, including the gravity classification yards at Galesburg and Hawthorne, Ill., and the new locomotive shops at West Burlington. Particularly outstanding for its day was the track-elevation work between Chicago and Clyde, Ill., one of the earliest projects of this magnitude to be undertaken.

Mr. Breckinridge was a man of unusual personality, possessing a dignity of bearing, yet with a friendliness that inspired respect and admiration. He was a gentleman in every sense of the word, considerate of others to an unusual degree—a trait which won for him the unreserved loyalty and friendship of all those with whom he came in contact. Naturally of a retiring disposition, his ability and personality were known only to those with whom he was associated, but by them he was held in the highest esteem.

On October 15, 1891, he was married to Irene Waples, of Alton, Ill., who, with two sons, William Lewis and Frank Prevost, survives him. His religious affiliations were with the Protestant Episcopal Church.

He became a member of the Western Society of Engineers and of the American Railway Engineering Association in 1899, and of the Chicago Engineers' Club in 1906.

Mr. Breckinridge was elected a Member of the American Society of Civil Engineers on October 7, 1903.

## WILLIAM WALLACE BRIER, M. Am. Soc. C. E.\*

DIED DECEMBER 28, 1928.

William Wallace Brier, the son of the Rev. William Wallace Brier, a Presbyterian home missionary, and Elizabeth Ann (Naylor) Brier, was born near Centerville, Calif., on August 7, 1858. He was a great-grandson of Lieutenant Benjamin Lodge, of the Pennsylvania Continental Line, one of the original members of the Society of the Cincinnati. His father was of Scotch-English-Quaker ancestry, some of his forebears having settled in Pennsylvania after buying large tracts of land from William Penn in 1682. His mother was of Irish-English descent.

Mr. Brier attended the public school near his father's farm, and, under his tutorship, prepared for the University of California, from which he was graduated in 1882 with the Degree of Bachelor of Philosophy in Civil Engineering.

In 1882 and 1883, Mr. Brier was employed on maintenance of way and water supply work as an Assistant to the Division Engineer of the Galveston, Harrisburg and San Antonio Railway Company, a subsidiary of the Southern Pacific Railroad.

From 1884 to 1890, he taught school in San Luis Obispo and Los Angeles Counties, California, and conducted a book business in San Francisco, Calif. He returned to engineering in 1891, and was in private practice until 1897, in which year he was appointed Civil Engineer of the Alameda Sugar Company, at Alvarado, Calif., and, later, of the Union Sugar Company, at Betteravia, Calif., in charge of railway, irrigation, drainage, and reclamation work.

Mr. Brier remained in these positions until March, 1901, at which time he became Chief Engineer of the E. B. and A. L. Stone Company, General Contractors, at San Francisco. During his connection with this firm, which continued until the end of 1905, he superintended the construction of the plant of the Standard Portland Cement Company at Napa Junction, Calif., the erection of the Los Angeles and Salt Lake Railroad Company's concrete bridge across the Santa Ana River, in California, and also had charge of numerous other contracts which the firm was executing.

While he was superintending construction, Mr. Brier had made a study of contractors' methods and, after leaving the Stone Company, he decided to make use of his acquired experience. In March, 1906, he organized the Occidental Construction Company, of Los Angeles, Calif., which specialized in railroad construction, and of which he was President and Engineer. In 1917, he founded the Western Reinforced Concrete Pipe Company, of Los Angeles, which was engaged in the design, manufacture, and installation of this class of pipe, and of which he was also President and Engineer. Early in 1923, he disposed of his interests in Los Angeles and moved to San Francisco, where he maintained an office as a Consulting Engineer until a few months before his death.

\* Memoir prepared by the following Committee of the San Francisco Section: Bernard Benfield and Jerome Newman, Members, Am. Soc. C. E.

Mr. Brier was married on March 27, 1889, to Helen Maria Blake who, with four children, William Wallace III, Edward Blake, Helen Naylor, and Isabel Presbrey Brier, M. D., and two sisters, Mrs. Mary Brier Moores and Mrs. Carrie Brier Schorr, survives him.

In all the relations of life, as a dutiful son, husband, and father, as a friend, engineer, contractor, and citizen, William Wallace Brier was a modest, kindly, sterling character. Firm in his beliefs, yet wholly tolerant and considerate of the views of others; loyal to those whom he served and appreciative of those who served under him; public-spirited, and deeply interested in all matters affecting the Commonwealth; faithful to every promise and every obligation; he gave freely and efficiently of the best that was in him in everything that he undertook. The world can ill afford to lose a man such as he was; his passing left a deep sense of loss in the hearts and memories of those who were privileged to be associated with him in any phase of his long and active career.

Mr. Brier was a member of the Commonwealth Club of California, the Engineers Club of San Francisco, the Astronomical Society of the Pacific, the Seismological Society of America, the American Association of Engineers, and the American Association for the Advancement of Science. He was also a member of the Masonic Order and of Phi Gamma Delta Fraternity.

Mr. Brier was elected a Member of the American Society of Civil Engineers on October 21, 1924.

## WALDO CLAYTON BRIGGS, M. Am. Soc. C. E.\*

DIED DECEMBER 13, 1926.

Waldo Clayton Briggs was born in New Haven, Conn., on March 14, 1870. He was the son of the late William Alexander Briggs, a merchant of New Haven, and Sarah Maria (Baldwin) Briggs, both of whom traced their ancestry back to the Colonial days of New England. His forebears fought on the patriot side in the American Revolution.

Mr. Briggs attended the public schools of New Haven and was graduated from the Hillhouse High School in 1889. The following three years he spent in the Sheffield Scientific School of Yale University, from which he was graduated in 1892 with the degree of Bachelor of Philosophy.

During his vacation periods, while he was in college, Mr. Briggs worked on surveying and drafting for the City Engineer of New Haven, and, in 1892, following his graduation, he continued in the same type of work with the City Engineer of Hartford, Conn. In 1893, he returned to New Haven as Resident Engineer on the construction of a masonry dam, about 1 000 ft. long, for the New Haven Water Company.

From 1894 to 1897, he served as City Engineer and Street Commissioner for South Norwalk, Conn. His next engagement, covering the period from 1898 to 1900, was as a Civilian Engineer with the Corps of Engineers, United States Army, on computing, drafting, and superintending the construction of fortifications at the eastern entrance to Long Island Sound. This connection was severed when the appropriation for the work was exhausted.

Mr. Briggs went to New York City in 1900 and, thereafter, until the time of his death, he was engaged on the construction of important engineering projects in and about the city. From October, 1900, to March, 1901, when he resigned, he was an Assistant Engineer on the First Division, Rapid Transit Railroad Commissioners, supervising the construction of a part of the first rapid transit subway. Subsequently, until 1904, he was employed with the Degnon-McLean Contracting Company, as Assistant Engineer, later as Engineer in Charge, under the Chief Engineer of the Company, on its contract for the building of that part of the first rapid transit subway which extended from 41st Street and Park Avenue, through 42d Street and Broadway, to 47th Street. At that time, subway construction was of the nature of pioneer work in New York City, and experience in working out the problems involved, by which those who built the later subways benefited, was then lacking. Those, like Mr. Briggs, who so successfully accomplished their difficult task under such conditions, deserve commendation for the ingenuity, foresight, and skill they displayed.

In 1905, when the Pennsylvania Railroad Company began its construction of the great project for a passenger terminal in New York City with all the appurtenant work, including tunnels under the Hudson and East Rivers, Mr. Briggs became the Resident Engineer for the New York Contracting and Trucking Company on its contract for excavating the site of the passenger

\* Memoir prepared by Robert Ridgway, Past-President, Am. Soc. C. E.

terminal in the blocks bounded by 31st and 33d Streets and Seventh and Ninth Avenues, and for constructing the retaining walls and viaducts in connection with this project.

In 1907, he accepted a position with the Degnon Contracting Company, and, at first, was engaged on the preparation of bids and the supervision of various contracts. The following year he was made Chief Engineer of the Degnon Realty and Terminal Improvement Company, and was in charge of the contract for the construction of the large Sunnyside Yards of the Pennsylvania Railroad and of the real estate development in Long Island City, N. Y., continuing in this capacity to the end of 1912. The successful completion of the construction of the Sunnyside Yards, in low-lying marsh land, gave him much satisfaction.

From 1913 to 1916, Mr. Briggs was Chief Engineer for Carpenter and Boxley and Herrick on the construction of Sections 11-B-1 and 11-B-2 of the rapid transit subway from 40th Street to 86th Street, in Fourth Avenue, Brooklyn, N. Y., at a cost of \$3 725 000. On the completion of this work, he returned to the Degnon Contracting Company, for the period, 1917 to 1920, as Engineer and Superintendent on two other Brooklyn subway contracts, one a deep tunnel in sand, 4 300 ft. long, known as Section 2-A of Route 12, the other, a subway station, directly under the existing Flatbush Avenue Terminal of the Long Island Railroad, known as Section 1-B of Route 12. These contracts involved a cost of about \$2 000 000. Although Section 1-B was of relatively short length, the construction was so involved as to require careful planning and execution. Mr. Briggs brought both contracts to successful completion, after which he severed his connection with the Degnon Contracting Company, as that Company had decided to discontinue its contracting activities.

During 1922, the Thomas Crimmins Contracting Company of New York City employed Mr. Briggs as Superintendent on a \$2 000 000 contract in Westchester County for installing additional steel pipes in certain siphons on the Catskill Aqueduct of the New York City Water Supply. From 1923 to the time of his death in 1926 he was employed by Henry Steers, Incorporated, of New York City, as Engineer and Superintendent. For the major part of these four years he was engaged on the difficult task of installing foundations for the large plant of the Western Electric Company at Kearney, N. J., on the marshy ground of the Passaic River meadows. The contract involved the expenditure of about \$4 000 000, and, in the words of a member of Henry Steers, Incorporated:

"Not only by his engineering ability as shown by the efficient and able handling of this intricate work, but by his experience, his personality, and the many sterling qualities of his character, which we came to know, he established himself as a permanent and valued member of our staff. He acted in an advisory capacity to Mr. Steers on the various projects in which we were interested, and at the time of his death, he had an assured and brilliant future in this Company. By his untimely end, we feel deeply the loss of a valued business associate and a friend."

Death came to Mr. Briggs suddenly, without warning. On the morning of December 13, 1926, while leaving the City Hall of Jersey City, N. J., where

he had gone on business connected with plans for work in progress in that city, he had a heart attack and died almost instantly.

Waldo Briggs was a man of positive characteristics—one to whom right was right and wrong was wrong. He was intolerant of anything that was not direct and open and drove straight to the conclusion that, in his judgment, was the correct one. Absolutely loyal to a friend and a cause, he was indefatigable in his attention to any work he had in hand, studying its particular problems, never satisfied until he had mastered its details and thought out ways of overcoming its difficulties. His success was due, in large measure, to his straightforward and courageous way of looking at his problems and to his courage in acting as his judgment directed. One remembers long, and appreciates deeply, the friendship of such a man. He was of the army of constructive men who leave the world better than they found it.

Mr. Briggs enjoyed country life and out-of-doors sports. He was fond of dogs and on his long rambles, one, and sometimes two, were his companions. Biographies of noted men always interested him, and he read many, making copious notes of his impressions. In line with this, his interest in civic affairs was deep and he took the active part of a good citizen in the local affairs of his community.

He was married on September 2, 1897, to Belle Ferris, of South Norwalk, Conn., who, with a son, Ferris Briggs and a daughter, Amy Ferris Briggs, survives him. He was a member of the Scarsdale Golf Club, the Carteret Club of Jersey City, and the Yale and Quill Clubs of New York City.

Mr. Briggs was elected a Junior of the American Society of Civil Engineers on December 5, 1893, and a Member on July 10, 1907.

## ALEXANDER BROCINER, M. Am. Soc. C. E.\*

DIED NOVEMBER 16, 1928.

Alexander Brociner was born at Galatz, Roumania, on April 21, 1880, the son of André and Rosalie Brociner. His early life was spent in his native city, where he obtained his elementary and higher education, receiving his Bachelor's degree in 1898. Five years later the Royal Technical College at Bucharest, Roumania, from which he was graduated with highest honors, conferred on him the degree of Civil Engineer. He then served for a time as Second Lieutenant of Heavy Artillery in the Roumanian Army.

While he was still a student, Mr. Brociner had visualized the United States as the country offering the widest scope for his activities. Accordingly, shortly after his graduation, he came to America.

His practical engineering experience began with the firm of Bradford Lee Gilbert, in New York, N. Y., for which he soon became Chief Engineer, serving in this capacity from 1904 to 1907. At this time Mr. Brociner began his independent practice as Consulting Engineer, on building and heavy construction. He was soon rewarded with success. For more than twenty years, he had an extensive practice, during which he greatly increased the scope of his work, having to his credit apartment houses, hotels, loft buildings, churches, school buildings, railroad stations, water-front structures, bridges, etc. Among the buildings for which he was Consulting Engineer are the Windsor Hotel, Montreal, Que., Canada, the Chateau Laurier and the Terminal Station, Ottawa, Ont., Canada, Lawrence College, Yonkers, N. Y., the King Cotton Hotel, Greensboro, N. C., and the Proctor Memorial Bridge, at Proctor, Vt.

At various times Mr. Brociner contributed technical articles to *Engineering News-Record*, *Insurance Press*, *Safety Engineering*, and its predecessor, *Insurance Engineering*, the *Real Estate Magazine*, and also to the New York daily press.

He was an untiring worker who never spared himself when his time and energy were needed. His work was especially marked by a thorough conscientiousness in the interest of his clients. In his particular field of structural engineering, he was a close student of new developments, and his thorough knowledge of good practice and legal requirements made his services of great value. The high regard in which he was held by his profession is expressed in a memorial resolution of the Structural Engineers' Society of New York, of which he was a member, in the following terms, as

"An engineer of ability and highly respected both for his accomplishments and also for his high standard of professional ethics.

"He deserves high credit for his labors in the Society and in an effort to create a better understanding and bond of fellowship among his co-workers."

He is survived by his widow, Jolanthe, to whom he was married in 1909, and by a son, Victor.

Mr. Brociner was elected a Member of the American Society of Civil Engineers on August 28, 1922.

\* Memoir prepared by Jacques S. Negru, Esq., New York, N. Y., and Rudolph P. Miller, M. Am. Soc. C. E.

## WILLIAM BROWN, M. Am. Soc. C. E.\*

DIED DECEMBER 24, 1929.

William Brown was born in Glasgow, Scotland, in 1850, and was educated at Renfrew and Paisley Grammar Schools and at the University of his native town. He was the son of Andrew Brown, who invented and patented the type of vessel now known as a "hopper dredge". This design was improved in later years by the introduction of the "stern well type" which also was patented by Mr. Andrew Brown.

Beginning his apprenticeship in 1866 in the Engineering Department of Messrs. William Simons and Company of Renfrew, William Brown was assumed with his brother, Col. Walter Brown, as a partner by his father. He was associated with this firm, which was converted into a Limited Liability Company in 1900, until his death on December 24, 1929.

Mr. Brown was appointed Assistant Manager of the Engineering Department in 1872 and Manager in 1876. He was taken into partnership in 1888, and was elected a Director in the Company when it was floated. He then became Chairman and Managing Director in 1907, which position he held until his death.

He identified himself very closely with the development of all types of marine dredging plant, particularly suction dredges and in the adaptation of this type of dredge for working in clay or similar materials. He patented a number of devices calculated to increase the efficiency of such machinery. The large fleet of dredging plant originally used at Durban, Natal, for the improvement of the depths in the bar and harbor there, and a large number of very powerful dredges which are in use at various ports in India, were designed under his direction.

Mr. Brown was a Member of the Institution of Civil Engineers, the Institution of Naval Architects, the Institution of Mechanical Engineers, and the Institution of Engineers and Shipbuilders in Scotland. At various times, he contributed to the *Proceedings* of the first and last named. He also found time to devote himself very largely to the public interests of Renfrew, and he represented the Renfrew Town Council on the Clyde Navigation Trust for a great number of years.

In 1918 Mr. Brown had the honor of Commander of the British Empire conferred on him in recognition of his services during the World War; and, in 1923, the Burgh of Renfrew further honored him by presenting him with the Freedom of the Burgh.

Mr. Brown was elected a Member of the American Society of Civil Engineers on October 3, 1911.

---

\* Memoir prepared by Wm. Simons & Co., Ltd., Glasgow, Scotland.

**RALPH ELIJAH BROWNELL, M. Am. Soc. C. E.\***

---

**DIED JANUARY 29, 1928.**

---

Ralph Elijah Brownell was born in Filmore County, Minnesota, on January 5, 1857. He received his primary education in the public schools, and was graduated from the Englewood, Ill., High School in June, 1874.

Mr. Brownell then entered the Department of Public Works of the Town of Lake (now a part of Chicago), Ill., with which he was connected in every branch of municipal work until January, 1880. During four years of this period he received instruction in Mathematics and Civil Engineering under the private tutelage of the Principal of the Englewood High School. From January, 1880, to January, 1882, Mr. Brownell was Assistant Engineer with the South Park Commission of Chicago and from January, 1882, to March, 1883, he held a similar position with the Grand Trunk Railway Company on reconstruction work throughout Michigan, which was followed by his acceptance of the position of Chief Engineer and Superintendent of Public Works of the Town of Lake.

In March, 1886, Mr. Brownell became a member of the firm of Eggleston, Mallette, and Brownell, which firm was engaged in general contracting for public improvements. He was the responsible head of this organization in the development of property in the suburbs of Chicago and in this capacity had charge of all engineering work and its various resultant problems. In September, 1894, he organized the Brownell Improvement Company of Chicago, of which he was, successively, Vice-President, President, and again, Vice-President. This Company was engaged in subdividing and improving vacant property in the suburbs of Chicago. In January, 1902, he was made Consulting Engineer for the City of Chicago, and in this position was engaged particularly in the design of stone-crushing plants and in public works.

In June, 1904, Mr. Brownell moved to Oklahoma City, Okla., where he organized and operated the O. K. Building and Construction Company, Contractors, engaged in public improvements, principally in concrete construction. From November, 1907, to May, 1909, he served as Consulting Engineer for Oklahoma City; from May, 1909, to May, 1911, as Chief Engineer of the Park Department, designing the Park System and constructing a 28-mile boulevard around the city; and from May, 1911, to November, 1914, he again served as Consulting Engineer for Oklahoma City. In November, 1914, he was appointed County Engineer for Greer, McIntosh, and Pottawatomie Counties in the State of Oklahoma, which position he retained until August, 1916, when he became District Engineer of the Portland Cement Association for Oklahoma, and was thus engaged until August, 1922. In this connection, Mr. Brownell was primarily instrumental in promoting the building of concrete roads throughout the State.

Mr. Brownell first went to Los Angeles, Calif., in 1922, with the Rotary Club of Oklahoma City, and immediately became interested in the development of The Palos Verdes Estates, near Redondo Beach, Calif., planning and

---

\* Memoir prepared from information on file at the Headquarters of the Society.

building the water-works for that organization. His death occurred while he was actively engaged on this construction.

He was a member of the American Association of Engineers, having served as President of the Oklahoma City Chapter. He was also a member of the Redondo Beach Rotary Club, and a Trustee of the Methodist Episcopal Church at that place, actively associated in its Sunday School work.

A man of impeccable character and of true fineness of nature, Mr. Brownell was loved and respected by all those of the Engineering Profession by whom or with whom he had been employed or associated.

On October 31, 1878, Mr. Brownell was married to Lucy T. Adams, who, with four daughters, survives him.

Mr. Brownell was elected a Member of the American Society of Civil Engineers on November 9, 1920.

**STEPHEN SANS BUNKER, M. Am. Soc. C. E.\***

---

DIED DECEMBER 15, 1928.

---

Stephen Sans Bunker, the son of David A. and Jeannette (Higgins) Bunker, was born at Bar Harbor, Me., on August 20, 1876. His education was obtained in the Bar Harbor schools and at the University of Maine in Orono. He was graduated from the latter institution in the Class of 1897, receiving the degree of Civil Engineer. He was a Member of Phi Gamma Delta Fraternity.

Immediately on the completion of his college course Mr. Bunker went to Rockland, Me., where for several months he held a position in the City Engineer's Department. He then accepted a position as Transitman on railroad construction with the James T. McDonald Company of New York, N. Y., remaining with that firm for three years. During this period he was employed in the construction of the Washington County Railroad, now a branch of the Maine Central Lines, and on the Seaboard Air Line in Virginia.

In 1900, he returned to Bar Harbor, where he opened an engineering office and was actively engaged in building an addition to the water-works of the town. From 1901 to 1902 he was employed with the W. G. Wilkins Engineering Company, of Pittsburgh, Pa., holding the position of Resident Engineer in street railway and paving construction. In the fall of 1902 he became connected with the Jersey City, N. J., Water Supply Company in the building of a 6-ft., steel, water main for that city. From 1902 to 1904 he was Chief of Party and Resident Engineer on railroad construction in Oklahoma with the William Kenefich Construction Company.

In 1904 and 1905 Mr. Bunker was in Bolivia, South America, as Chief of Party on preliminary surveys, for the Bolivian Government, in the Andes Mountains. In 1905, he returned to the United States and for three years was employed in the South as Chief of Party and Resident Engineer on railroad work for the Louisville and Nashville, and Chesapeake and Ohio Railroad Companies. In the fall of 1908, he again went to South America, this time to Brazil, where as Division Engineer he assisted in the building of 250 miles of railroad in the Amazon Valley. The road commenced at the head of navigation in the Madeira River, 1 600 miles from the sea, and ended in the wilderness on the banks of the Mamoré River, the boundary between Brazil and Bolivia. This work was completed in 1912, at which time Mr. Bunker returned to the United States, going to Toledo, Ohio, where, for several months, he was engaged in street railway surveys.

In the fall of 1913 he accepted a position with the Maine State Highway Commission as Assistant Engineer. He was engaged in this work when the United States entered the World War. He immediately volunteered for service and was sent to the first Plattsburgh Camp in June, 1917. He was not without "peace-time" military experience as he had been Captain of the Color Company at the University of Maine and, later, a member of the National Guard of the State of Maine. Mr. Bunker was soon given a com-

---

\* Memoir prepared by Oliver L. Hall, Esq., Bangor, Me.

mission as Captain and sent to Fort Sheridan, Illinois, where he was a Drill Master.

He went to France in November, 1917, as Captain of the 503d Engineer Regiment. His first service was in forestry work near the Swiss border, his company being engaged in manufacturing lumber for the trenches. He was then, during a period of several months, in charge of grading and steam shovel work in the Montoir Railroad Yards near St. Nazaire, the principal port of debarkation.

During his service in France Captain Bunker was also in charge of pouring the concrete for several of the immense warehouses constructed at St. Nazaire. Following the signing of the Armistice he was placed in charge of rebuilding the roads in this district, which were severely worn by army trucks.

Captain Bunker spent twenty months in war service in France, returning to the United States in July, 1919, in command of a detachment of the 72d Engineer Regiment. He proved himself an excellent officer, extremely efficient, and was held in the highest regard by his men. That his services were appreciated by his superiors is attested by the fact that he was recommended for promotion to the rank of Major, but unfortunately promotions were stopped by the Armistice. He later, however, received a commission as Major in the Reserve Officers' Corps.

Following his return from France Captain Bunker resumed his position with the Maine State Highway Department in charge of the construction of several concrete and gravel bituminous roads in various sections of the State. In January, 1923, by unanimous vote of the Board of Public Works, he was elected City Engineer of Bangor, Me., in which capacity he had charge of the street and highway, park, and sewer departments, with power to appoint his own subordinates. In his six years in this position, Captain Bunker was given credit for valued services. During this period the City constructed 10 miles of cement concrete roadway, 3 miles of cement concrete sidewalks, and 4½ miles of new sewers. In these years, 190 000 cu. yd. of gravel were used by the Municipal Government. This gravel was obtained on very advantageous terms through the purchase of a large gravel bank.

During his service as City Engineer, the Department was motorized from two pieces of apparatus in 1922 to twenty-five pieces of equipment in 1928, and, to-day, it is rated as one of the most competently equipped municipal departments in New England.

Captain Bunker always will be remembered in Maine as a pioneer in keeping adjacent highways free from snow during the winter. The movement spread by the co-operation of neighboring towns with the City of Bangor until the highways in that section were available for motor use all the year around. The effort was so successful that it was copied by other Maine communities until now there are few main highways in the State which are not cleared following heavy snows.

He was ever ready to extend aid and assistance to other City Departments as well as to local engineers and contractors who found the knowledge attained by him of vast help. Always courteous and kindly, he was held in high

regard by the employees of the Engineer Department and by the citizens generally.

Captain Bunker died after an illness of several months in Bangor. The funeral services were held on December 17, 1928, at All Souls Congregational Church in that city. The interment was at Bar Harbor. He is survived by his widow, Euna (Sanford) Bunker, a native of Bath, Me., two daughters, Jeannette Mary, of Boston, Mass., and Ruth Elizabeth, and one son, Paul, in the employ of the Maine State Highway Department. He is also survived by his mother, Mrs. Jeannette Bunker, of Bar Harbor, and two sisters, Mrs. Maurice C. Rumsey, of New York City, and Mrs. Oliver L. Hall, of Hampden, Me.

Fitting testimonial to the worth of Captain Bunker as a public official was given by the following public announcement of his death made by the Hon. John Wilson, Mayor of Bangor:

"Stephen S. Bunker, City Engineer of Bangor for seven years, after several months of failing health, died in Bangor, on Saturday, December 15, 1928. Mr. Bunker had served the city with faithfulness, honesty, and ability, and has left as his lasting memorial, a system of concrete roads on the main arteries of the city, of which the city is justly proud, and which establishes clearly his reputation as one of the great road engineers of New England. He was a loyal soldier in the Great War, a good citizen, and a man of high character with an exceptionally lovable disposition. The City of Bangor has met a great loss and will officially and sadly pay proper respect to his memory on the day of his funeral."

Captain Bunker was elected an Associate Member of the American Society of Civil Engineers on October 4, 1910, and a Member on June 2, 1920.

**JAMES BURDEN, M. Am. Soc. C. E.\***

---

DIED MARCH 1, 1928.

---

James Burden was born at Glasgow, Scotland on January 12, 1864, the son of John and Janet (Duncanson) Burden. When he was very young his parents came to the United States. He received his preliminary education in the public schools of Troy, N. Y., and at the Sterling, Scotland, High School; he was graduated from the Rensselaer Polytechnic Institute at Troy, in 1892, with the degree of Civil Engineer.

After his graduation from college, Mr. Burden made a specialty of construction work on dams, canals, and water-works. He was engaged for a time as Draftsman for the Metropolitan (Boston) Water-Works in connection with the Wachusett Aqueduct and Reservoir. In 1897 and 1898, he had charge of the New York State improvements on the Minetto Dam and on the canal at Manlius Center, N. Y. In 1899 he entered the employ of the Sharon Steel Company of Sharon, Pa., for which he designed and installed the sewers, water supply, and railroad yards at its new plant.

From 1900 to 1904, Mr. Burden served as Principal Assistant Engineer on the construction of the Troy Water-Works, in charge of the surveys and construction of the pipe lines and dams. From 1904 to 1908, he was Assistant Engineer in the main office of the New York State Barge Canal, at Albany, N. Y., where he made studies of back-water above proposed dams across the Mohawk River as well as of the design of locks and movable dams. In 1908 Mr. Burden was appointed Resident Engineer on various sections of the New York State Barge Canal, at Mechanicsville, Oswego, and Utica, N. Y., which position he retained until 1918. From 1919 to 1921, he was employed with the Emergency Fleet Corporation at Washington, D. C., and Philadelphia, Pa., in connection with dry docks and marine railways. The following year he was appointed City Engineer of Oswego, which position he held until his death.

Mr. Burden was a member of Grace Presbyterian Church of Oswego, and took an active part in church work, serving as President of the Board of Trustees. He was also a member of the Permanent International Association of Congresses of Navigation, the Fortnightly Club, and the Oswego Country Club. He was sincere in all his undertakings, giving his best to everything with which he was connected.

On December 5, 1912, Mr. Burden was married to Edith Sloan, the daughter of the late James and Mary Sloan, of Oswego, who survived him. Mrs. Burden died on October 23, 1928.

Mr. Burden was elected an Associate Member of the American Society of Civil Engineers on February 5, 1902, and a Member on January 5, 1904.

---

\* Memoir prepared by Morton Burden, Assoc. M. Am. Soc. C. E.

**LUTHER HAROLD BURT, M. Am. Soc. C. E.\***

---

DIED JANUARY 29, 1929.

---

Luther Harold Burt was born on February 29, 1876, in Hartford, Conn., the eldest of seven children. His father, Luther W. Burt, was for many years in private practice as a Surveyor in Hartford, and for some time served as City Surveyor, so that the boy grew up in an engineering atmosphere. His mother, Mary A. Greene, of Middletown, Conn., and all his ancestors were of pure New England stock.

After receiving the usual preliminary education, principally in the Hartford Public Schools, he was graduated in 1900 from Trinity College, Hartford, with the degree of Bachelor of Science.

Following vacation work which began in 1895 with his father's field parties on various surveys and on the construction of the Springfield Branch of the Central New England Railway, Mr. Burt, in August, 1900, entered the employ of the Central Railway Company of New Jersey. He was, successively, Draftsman and in charge of a field party on maintenance of way for this Company, the Lehigh Valley, the Greenwich and Johnsonville, and the Pittsburgh and Lake Erie Railway Companies. For the latter, he was Draftsman and Designer in the office of the Chief Engineer on various structures connected with double- and four-tracking.

From March, 1903, to October, 1908, Mr. Burt was Draftsman and in charge of design under the Division Engineer of maintenance-of-way work for the Pennsylvania Railroad Company, at Philadelphia, Pa. The masonry design for the Delaware River Bridge above Easton, Pa., and the design of the West Morrisville Yard for the Pennsylvania Lines were among the larger items of his work during this period. Through the winter of 1905-06, he was Draftsman on the Electric Zone Improvements for the New York Central and Hudson River Railroad Company, and from March, 1906, until April, 1911, he was an Assistant Engineer for the Bronx Valley Sewer Commission, at White Plains, N. Y., in charge of important parts of the design and construction of large trunk sewers and other structures connected with the improvement of the Bronx Valley.

In April, 1911, Mr. Burt returned to Hartford and associated himself with his father, under the firm name of L. W. Burt and Son. After his father's death in 1921, he continued alone in the practice of surveying and general engineering.

He designed and supervised the erection of the Brazos Dam at Middletown, as well as the Baldwin-Ives Dam, and was in charge of many of the real estate sub-divisions in and about Hartford. He had systematized the records of his father's early work, and not only made great use of them in his work of re-establishing old land lines, but was generous in allowing others to use them.

Mr. Burt was a regular attendant at the meetings of the local engineering societies and was well liked by his associates and by all with whom he came in

---

\* Memoir prepared by Henry R. Buck and Robert J. Ross, Members, Am. Soc. C. E.

contact. His death removes an engineer who was a credit to the profession and a worthy citizen.

He was married on April 7, 1903 to Claudia La Seur, of Schuylerville, N. Y., who survives him. Their only son, Richard White Burt, was associated with his father for some time and now carries on the work of the office under the old firm name.

Mr. Burt was elected an Associate Member of the American Society of Civil Engineers on November 1, 1910, and a Member on April 2, 1913.

## CHARLES LINCOLN CARPENTER, M. Am. Soc. C. E.\*

---

DIED SEPTEMBER 28, 1929.

---

Charles Lincoln Carpenter, the son of the Rev. Charles Carrol and Feronia (Rice) Carpenter, was born at Amherst, Mass., on June 17, 1867. On both sides of the family there was a background of sturdy New England stock, identified with the civil, religious, and martial life of the Colonies from their beginning. The first of the name in this country was William Carpenter, an English Puritan, who settled in Weymouth, Mass., in 1638. On the maternal side he was descended from Deacon Edmund Rice, an early settler (1638) of Worcester, Mass., and on the same side he was allied to the Knowlton and Pomeroy families.

Mr. Carpenter was graduated from Dartmouth College in 1887 and from the Thayer School of Civil Engineering in 1889. The funds for this college education were largely earned by himself in doing odd jobs around the campus and in working during the summer vacations.

After his graduation, Mr. Carpenter went to Nicaragua where he was engaged for two years for the Canal Construction Company as Leveler and Transitman on preliminary and railroad location surveys. He was in charge of 30 miles of telegraph line construction; detail surveys for locks and embankment of canal; and also of surveys on construction and improvements of Greytown Harbor.

In July, 1891, he returned to Massachusetts where he was employed with the Boston Board of Survey and the Street Commission of Boston for seven years, one year as Transitman and six years as Engineer in charge of surveys, calculations, and the laying out of a new street system in Boston.

In May, 1898, Mr. Carpenter went to Alaska on a prospecting and mining trip. On his return in November, 1900, he spent several months on preliminary and location surveys for the Boston and Worcester Electric Railroad Company, and then accepted a position in Cuba on railroad location and construction with the Cuba Central Railroad Company as Transitman and Assistant Division Engineer. At the expiration of a year in Cuba, he returned to the United States and was engaged for about three months as Assistant to the City Engineer of Gloucester, Mass. In September, 1902, however, he entered the employ of the Federal Government as U. S. Junior Engineer on river and harbor work at Boston.

When work on the Panama Canal was begun, Mr. Carpenter took one of the first parties to Panama in June, 1904, and the necessary surveys of the Great Gatun Lake Basin were started. Possible dam sites at Gamboa and Althajucta on the Chagres River, were investigated and reported on; and surveys for the relocation of the Panama Railroad at Bas Obispo, the location of the center line of the Canal on the Atlantic end, with the necessary borings, and the

---

\* Memoir prepared by E. F. Sinz, Assoc. M. Am. Soc. C. E.

location of the Canal Zone boundary line, were all done under his supervision during the first two years.

In July, 1906, Mr. Carpenter was made Resident Engineer of the Gatun Dam and in July, 1907, Resident Engineer of the Gatun Locks, which position he held until July, 1908. All clearing of the site of this huge earth dam and these locks, surveys, borings for foundation, and preliminary excavations were made while he was in charge, and his work as an organizer was outstanding. The Porto Bello Quarry, where all the rock for the immense concrete structures on the "Atlantic end" was quarried and crushed, was put in operation under his direction.

In September, 1908, Mr. Carpenter again went to Cuba, this time for J. G. White and Company, in charge of the reconstruction of the Cuban Eastern Railroad. During the year of this contract, the road-bed was rebuilt so that it would stand up under traffic during the tropical rains and floods. He continued with this railroad, which was re-organized and named the Guantanamo and Western Railroad, as General Manager and built up the property into a prosperous organization.

In December, 1911, Mr. Carpenter went to Porto Rico as Superintendent of the Ponce and Guayama Railroad. In June, 1912, he was appointed to fill the vacancy of General Manager of the Central Aguirre Sugar Company and of the Ponce and Guayama Railroad Company. Later, the duties of Vice-President of these two companies were added as well as those of Vice-President and General Manager of The Central Machete Company and of the Santa Isabel Sugar Company. In 1919, he became one of the Managing Partners of Luce and Company, a land-holding organization in Porto Rico. He held all these positions until his death.

The professional career of Mr. Carpenter was a varied one and took him to many parts of the North American Continent—from Alaska to Panama. He was an outstanding administrator, as the progress of the works that he directed will testify. He demanded results, but he never asked his men to go where he would not go himself. During his work in the tropical jungles, he never spared himself, and this willingness to share all hardships won for him the loyalty and friendship of his associates, many of whom were always glad to work under him, wherever he happened to be. He was a great lover of the outdoors and his favorite form of vacation was a tramp through the New England mountains or a canoe trip along the rivers of Canada.

Death came to Mr. Carpenter very suddenly, while he was on one of these canoe trips in one of the wildest parts of the Upper Gatineau River region of Canada. A few days of hard paddling with several difficult portages were too much for his strength, and he died of heart failure on September 28, 1929. He will long be remembered by his associates as an able, beloved executive and by the poor as a generous giver when help was needed.

Mr. Carpenter was a Mason, and a member of various geographical and historical societies and of the Appalachian Mountain Club. He had contributed to the Byrd Antarctic Expedition and to many associations for the preservation of forests and of wild life. He cheerfully gave to the poor and

distressed, particularly to children. Those who knew him well loved him for his whole-hearted friendship and kindness.

Mr. Carpenter was married on December 15, 1892, to Charlotte Florence Sullivan, of Boston, Mass., who, with three children, James Sullivan, Thomas Rice, and Charles Carrol, survives him.

Mr. Carpenter was elected a Member of the American Society of Civil Engineers on December 6, 1905.

## JAMES FRANCIS CASE, M. Am. Soc. C. E.\*

DIED DECEMBER 14, 1929.

James Francis Case was born at Columbus, Wis., on September 22, 1868, the son of the Rev. George Wilkinson Case and Nina (Nash) Case.

He was graduated from the University of Wisconsin in 1890. There followed a few years of railroad work in the Middle West; then came the Spanish-American War when he left Oregon as the Captain of a Company of Militia—was made a Major for gallantry and distinguished service in the Philippines; served as City Engineer of Manila; and, in 1908, was made Director of Public Works. During this period he did important work in the construction of harbors, roads, water-works, and sewers. He became proficient in the Spanish language and, later, a master of French, both of which were to be very helpful to him.

Major Case then became the Havana Representative of the Cuban Engineering and Contracting Company and, as its Vice-President, carried out the largest sanitary project the world had yet seen, building several hundred miles of sewers and drains and a very novel turbo-electric pumping station for that city.

In 1916 he joined the staff of the American International Corporation. He reported upon engineering projects of magnitude in Spain, Greece, Mexico, and South America, and also served as contact between his Company and the United States Government in the vast construction enterprises carried out by that Company during the World War.

For Ulen and Company Major Case negotiated many contracts in foreign countries, notably that for the construction of the water-works in Athens, Greece.

In 1928 he was appointed Paris Representative of Stone and Webster, Incorporated, which position he held at the time of his death. Taken ill with pneumonia while on a business trip in this country, he died in New York, N. Y., of heart failure, on December 14, 1929. He is survived by his widow, Helen (Smith) Case.

Born in a small town in the Middle West, this son of religious parents, with but little help, save his own indomitable will power, secured for himself an education, and, later, made for himself fame as an engineer, a reputation for kindness to his fellowmen, and an acquaintanceship which circled the globe. He was loved by bootblacks and bank presidents and was the friend of two Presidents of the United States, the Presidents of many Central American and South American countries, and of several of the crowned heads of Europe.

Major Case was chosen by the League of Nations to report on the transportation system of Poland. In 1918, he headed a delegation of American engineers that attended a Reconstruction Congress in France, at the invitation of the French Society of Civil Engineers.

---

\* Memoir prepared by Paul G. Brown, M. Am. Soc. C. E.

In 1929 he was awarded the James Laurie Prize by the Society for his paper "The Ancient Roman Aqueduct at Athens," which has been published\* and is an outstanding contribution to engineering literature.

Major Case was a member of many clubs and societies, among which were: Western Society of Engineers, The Engineers' Club of New York, American Club of Havana, Havana Country Club, Havana Yacht Club, Vice-President, Società Italo Americana di Studi e Lavori Pubblici, Membre d'Honneur, Société des Ingénieurs Civils de France, Bankers Club of America, Sleepy Hollow Country Club, Army and Navy Club of Washington, D. C., and the Four Square Club, New York.

His life was a busy and a useful one, yet he was fond of sports and was helpful to his clubs. He served as a Governor of The Engineers' Club of New York for several years.

Major Case was elected a Member of the American Society of Civil Engineers on January 6, 1904.

---

**EDWARD BERTIE CODWISE, M. Am. Soc. C. E.\***

---

**DIED FEBRUARY 11, 1927.**

---

Edward Bertie Codwise, the son of Elisha Rogers and Harriette M. S. (Salter) Codwise, was born at Elizabeth, N. J., on May 9, 1849. His ancestors came to the United States from Holland in 1624, and settled in Massachusetts. In 1664 the family moved to Elizabeth. His great-grandfather, Christopher Codwise, was a field officer in the Continental Army and a member of the Society of the Cincinnati.

Mr. Codwise received his education at the Baldwin Academy, in New York, N. Y., from which he was graduated. Later, he attended the Brooklyn Collegiate and Polytechnic Institute and was graduated with the Class of 1865. Subsequently, he was for two years a student at the L'Institution Davaux, at Amiens, France.

On his return to the United States in 1868, Mr. Codwise accepted a position as Assistant Engineer with the Erie Railroad Company on the construction of the Newburgh and New York Railroad, the Fort Lee Railroad, and the Weehawken, N. J., Cattle Yards. From 1869 to 1870 he served as Assistant Engineer with the New Jersey Southern Railroad Company, and from 1870 to 1872 he was engaged as Principal Assistant Engineer for the Wallkill Valley Railroad Company on construction work from Gardner to Kingston, N. Y.

Mr. Codwise spent a brief period from March, 1872, to April, 1873, in Peru, South America, where he was Assistant Engineer on the Callao, Lima, and Oroya Railroad. He was engaged for part of this time on the design and construction of what proved to be, for many years, the longest and highest railroad bridge in the world.

After his return to this country, he held for a short period the position of Principal Assistant Engineer for the New Jersey Southern Railroad Company. In 1874, he opened a private office in Rosendale, N. Y., and also served as Engineer for the Rosendale Cement Company. In 1876 he gave up this occupation to accept the position of Assistant Engineer in charge of inventory surveys, etc., for the Erie Railroad Company.

From 1879 until his retirement in 1923, Mr. Codwise held the following positions: Assistant Engineer in charge of the construction of the New York City Elevated Railroad on Ninth Avenue between 30th and 59th Streets; Division Engineer for the Albany and Jersey City Railroad (now the West Shore Railroad) Company on location surveys; Assistant Engineer in charge of the construction of extensions of the Wallkill Valley Railroad; Resident Engineer of the West Shore Company in charge of construction from Newburgh to Kingston, N. Y.; Chief Engineer of the Ulster and Delaware Railroad Company; and City Engineer of Kingston, where he was also engaged in private practice. During this time, Mr. Codwise designed the present water supply system of Kingston. His choice for the location of the reservoir

---

\* Memoir prepared from information on file at the Headquarters of the Society.

was between two sites, one of which contemplated that a dam be placed across Esopus Creek only a few hundred feet down stream from the site of the present Ashokan Dam of the New York Water Supply. The reservoir, however, was constructed at the other location on Sawkill Creek, which was much nearer Kingston and more economical.

Because of a complete collection of original maps of Central and Eastern New York, which date back to the land grants from European rulers, Mr. Codwise was called upon to compile the location of the lands and boundaries of the State Forest Preserve.

He was married on March 28, 1872, to Emma Snyder, of Rosendale, who died in 1924. After his wife's death, he resided with his daughter, Mrs. R. H. Edmondson, of Morgantown, W. Va., who, with his two sons, Henry R. Codwise, M. Am. Soc. C. E., and George Wallace Codwise, also a Civil Engineer, of Kingston, survives him.

Mr. Codwise was exceedingly fond of his family, preferring his home to clubs and social life. He was of a happy, likeable disposition, admired by all his employees and honored by his business associates. His reputation for honesty and integrity was well demonstrated by the confidence that was placed upon his testimony when he appeared as an expert witness in Court cases. He was a member of the Kingston Club and of Kingston Lodge No. 10, F. and A. M.

Mr. Codwise was elected a Member of the American Society of Civil Engineers on September 5, 1888.

## EDWARD ZANE COLLINGS, M. Am. Soc. C. E.\*

DIED NOVEMBER 19, 1928.

Edward Zane Collings was born on a ranch near Beaver City, Nebr., on December 12, 1885. He was graduated from the High School of Beaver City in 1902 and entered the State University of Nebraska the same year, taking a course in Civil Engineering. Circumstances prevented his completing the course, however, and, in 1905, he moved to California.

Mr. Collings began his practical engineering experience with the City Engineer of Santa Monica, Calif., following a short period spent with the Los Angeles and Salt Lake Railroad Company. In 1906 he moved to Los Angeles, Calif., where he entered private practice with Mr. F. D. Lanterman on subdivision work. This engagement was not of long duration.

Subsequently, he entered the service of the City of Los Angeles and, with the exception of a short period of absence, he remained in this service until the beginning of the World War in 1917. During this association Mr. Collings advanced rapidly through the stages of Draftsman and Grade Computer in the office, and of Instrumentman, Chief of Party, and Assistant Engineer in the field. He had charge of the surveys for the annexation of the Towns of San Pedro and Wilmington to the City of Los Angeles, and was the first Harbor Chief Surveyor when the initial parties were put in the field by the Harbor Department after the annexation. The field surveys of the present triangulation system covering the Harbor District were made under his supervision. In fact, he was one of the first of the City's engineers to pioneer in the development of Los Angeles Harbor. Many of the present pier-head lines, wharfs, and municipal docks were established during his service as Harbor Surveyor. He was greatly interested in water-front work of all kinds and during his leisure he studied navigation and obtained a navigator's license.

As Civil Service Assistant Engineer, Mr. Collings established and operated a rock quarry on Catalina Island for the Los Angeles Harbor Department, the quarried rock being transported and used in jetty construction.

While in college Mr. Collings had had military training which stood him in good stead when the United States entered the World War. Being an officer in the Reserve Corps, he was one of the first to register at the Presidio at San Francisco, Calif., and to become a Captain in the 316th Engineers, 91st Division, stationed at Camp Lewis, Washington. It was in the Battle of the Argonne, and while in command of his Company, that he was severely wounded. Eventually, he lost one of his legs after spending three years of suffering in a hospital in an attempt to save it. Captain Collings was cited for bravery in action and recommended for a Majority. After the Battle of the Argonne, his wound resulted in disablement as far as the Army was concerned.

Army hospital experience cost Mr. Collings dearly, necessitating inactivity in his profession. Returning to Los Angeles, in 1921, he was reinstated with

\* Memoir prepared by Sherman A. Jubb, M. Am. Soc. C. E., and W. T. Collings, Jr., Assoc. M. Am. Soc. C. E.

the City of Los Angeles as a Designing Engineer in the Street Planning Division. In this capacity he remained until the summer of 1923. Being recognized as proficient in this class of work, the Strong and Dickinson Syndicate of Los Angeles employed him as Chief Engineer on municipal subdivision and street improvements, and as such he served that Company under a Deputyship of the City Engineer's Office. The subdivision, planning, and improvement of the Morena Highlands and Silver Lake Terrace Tracts are monuments to his engineering ability. Engaged for a period of more than six years with the same firm, he became recognized as an authority on city planning and development.

For three years previous to his death, Mr. Collings served as President of the Northwest Chamber of Commerce in the City of Los Angeles. In this capacity, he was most active in the development of the northwest section of the city and in addition was a leader in civic affairs. Mr. Collings' death resulted directly from an operation which he underwent with the hope of being restored to better health.

Mr. Collings was married, in 1906, to Elsie Verna Dakan, formerly of Beaver City, Nebr., whom he had known from childhood. His widow, one son, and two daughters survive him.

The achievements of Mr. Collings, particularly for the time dating from his discharge from the Army, are noteworthy, considering his physical handicap. During those years and until the time of his death, although suffering almost constant pain, he was ever active. Civic, political, and military organizations demanded much of his time. He was active among World War Veterans, and was Commander of the Disabled Emergency Officers of the World War and a member of the Sunshine Post of the American Legion. He was also a member of the First Presbyterian Church of Glendale, Calif., and keenly interested in all its affairs. Genial in disposition, a loving father and friend, he will be missed by all who ever knew him or worked with him.

Mr. Collings was elected a Member of the American Society of Civil Engineers on March 7, 1921.

**GEORGE BIRDSALL CORNELL, M. Am. Soc. C. E.\*****DIED MARCH 14, 1929.**

George Birdsall Cornell was born in New York, N. Y., on October 17, 1855, the son of Birdsall Cornell who founded the old Cornell Iron Works and served as its head for a number of years. His family came to America in 1638 from England and first settled on Long Island.

Mr. Cornell received his early education abroad, attending private schools in Switzerland and France, and preparing for college at Anthem's School in New York. He was graduated from Columbia College, New York, in the School of Mines, in 1877, with the degrees of Engineer of Mines and Civil Engineer.

Mr. Cornell began his professional career as Rodman with the Engineer Corps of the Manhattan Elevated Railway Company, and in 1879 was Assistant Engineer on the construction of the Brooklyn Elevated Railway. From 1880 to 1882 he served as Engineer on the location and construction of the Buffalo, Rochester, and Pittsburgh Railway in Pennsylvania. Subsequently, he was engaged for two years as Bridge Engineer with the late Walter Katté, M. Am. Soc. C. E., during the construction of the New York, West Shore, and Buffalo Railway.

In 1884 he became Chief Engineer for the Brooklyn Elevated Railway Company, during the time of the construction and equipment of its lines for operation. Mr. Cornell was then employed as Chief Engineer of Construction for the Union Elevated Railway Company, Brooklyn, N. Y., until 1889, when he went to Chicago, Ill., as Chief Engineer on the construction of the Chicago South Side Elevated Railway. He returned to New York in 1892, as Chief Engineer of the J. B. and J. M. Cornell Iron Works, engaged on what was, at that time, high building construction.

During the period extending from 1893 to 1895, Mr. Cornell was Chief Engineer for the East River Bridge Company and prepared the plans for a bridge on the site of the present Williamsburgh Bridge, obtaining the approval for this undertaking from the War Department. In 1895, he again took up the duties of Chief Engineer for the Brooklyn Elevated Railway Company and of Chief Engineer and General Manager for the New York and Brooklyn Bridge Railway Company, in which capacity he was in charge of the operation of bridge trains. He prepared and obtained the approval of plans for the elevated railway to cross the East River Bridge, and put these lines in operation. He also installed the first electric train service on the Brooklyn Elevated Railway. In 1898, Mr. Cornell went to Europe to investigate automobile designs for New York capitalists.

He was engaged on consulting work, from 1899 to 1903, reporting on water power, railway, and electrical developments in the United States and abroad. Among other projects was one for building an elevated railway along the route of Regents Canal in London, England. In 1904, he again was called abroad to report on electrical problems in France and Germany for international bankers.

---

\* Memoir prepared by H. J. Cornell, Esq., New York, N. Y.

Returning to the United States, Mr. Cornell, in 1905, made a reconnaissance for a railroad from Quebec, Que., Canada, to the French River, covering the entire route in winter on snowshoes. In 1906, he went to Cuba, to report on electrical and power properties for Cuban bankers and sugar interests and from 1906 to 1907 he was employed as Chief Engineer with the Memphis Street Railway Company, and as Resident Engineer for Ford, Bacon, and Davis, covering construction and reconstruction of railway, power plant, and overhead lines. In 1908 he became Chief Engineer for Meikleham and Dinsmore which firm he served until 1914 in charge of the design and construction of steam and hydro-electric plants, high-tension transmission lines, and electric railways in New York, New Jersey, and Pennsylvania.

From 1914 to 1918, Mr. Cornell was engaged in the supervision of power plants and distribution systems and was also associated with J. C. Brackenridge, M. Am. Soc. C. E., on the valuation of public utilities and steam railroad properties for the Cities of New York, Jersey City, N. J., Hoboken, N. J., Buffalo, N. Y., Little Falls, N. Y., and others. From 1918 to 1921 he served with Ford, Bacon, and Davis, first as Resident Engineer on a marine boiler plant at Richmond, Va., for the U. S. Shipping Board. He later acted as Engineer of Design of the factory and laboratory for the Pathé Company and as Valuation Engineer on properties of the Public Service Corporation of New Jersey and of other public utilities.

From 1921 to 1924, Mr. Cornell was again associated with Mr. Brackenridge on plans for the station of the Hudson and Manhattan Railway Company at West Side Avenue, Jersey City, and on testimony before the Public Utilities Board of New Jersey for Jersey City. He also designed the station at Ridgefield Park, N. J., for the New York, Susquehanna, and Western Railway Company, and offered testimony before the Public Utility Commission of New Jersey for the Town of Ridgefield Park. In behalf of adjacent property owners, he assisted in the valuation of the 42d Street Spur of the New York Elevated Railways, looking to its removal, and from 1924 to 1926 was engaged in the valuation of the Yonkers Electric Light and Power Company, and of the New York Edison Company for Murray and Company. The following year he was employed on the valuation of the property of the Philadelphia Electric Company for Gillette and Malcomson.

Mr. Cornell retired from active practice in 1928 after fifty-one years of varied and successful achievements in the Engineering Profession. He was a member of Psi Upsilon Fraternity and a Thirty-second Degree Scottish Rite Mason.

On January 31, 1882, he was married to Eleanor Jackson, of Ridgway, Pa. He is survived by a daughter, Mrs. James B. Tailer and five sons, George B., Jr., Harold Jackson, Robert Leslie, Thomas Whilehead, and Francis Shepard Cornell.

Mr. Cornell was elected a Junior of the American Society of Civil Engineers on August 6, 1879, and a Member on October 6, 1886.

## ALFRED CRAVEN, M. Am. Soc. C. E.\*

DIED SEPTEMBER 30, 1926.

Alfred Craven was born in Bound Brook, N. J., on September 16, 1846, the son of the late Rear-Admiral Thomas Tingey Craven, U. S. N., and Emily (Henderson) Craven.

His forebears served in the Navy in every generation since and including the American Revolution. He was a descendant of Thomas Tingey, a Captain of the Continental Navy. His father commanded the Sloop of War, *Brooklyn*, of Farragut's Fleet in the passage of Forts Jackson and St. Philip on the Lower Mississippi on April 24, 1862. An uncle, Tunis Augustus Macdonough Craven, was in command of the monitor, *Tecumseh*, of Farragut's Fleet at the Battle of Mobile Bay, on August 5, 1864. The *Tecumseh* struck a torpedo and sank in 30 sec. with most of her crew. Commander Craven was in the pilot-house with the pilot when the ship struck. The opening from the pilot-house would permit but one at a time to pass. While realizing that every second counted, Commander Craven turned to the pilot and said, "You first, Sir." The pilot was saved and the Commander was drowned.

Following the traditions of the family, Alfred Craven entered the United States Naval Academy at Annapolis, Md., during the Civil War and was graduated in 1867, remaining in the Service until 1871 when he retired with the rank of Master. In 1871, he joined the California Geological Survey which did such notable work for the State. He was a member of the famous Whitney Survey and was one of the party of three under Mr. C. F. Hoffman who were the first to climb to the summit of Tower Peak. Later, he was engaged on irrigation work in the Sacramento and San Joaquin Valleys and then went into private practice in Virginia City, Nev., where he was connected with the development of the famous Comstock Lode. On this work, he was associated with Adolph Sutro in the construction of the well-known Sutro Tunnel designed to drain some of the deep mines.

Mr. Craven returned East in 1884 and became an Assistant Engineer on the surveys for, and the construction of, the New Croton Aqueduct of the New York Water Supply, serving under the Aqueduct Commissioners. This was a work of great magnitude for those days. The aqueduct was more than 30 miles long, constructed almost entirely in rock tunnel, and lined with brick. It was designed for a capacity of about 300 000 000 gal. daily. When the work was placed under contract in the early part of 1885, Mr. Craven was made Division Engineer of the Fourth Division.

On this work he established an enviable record for ability, courage, and rugged honesty. He stood firmly against practices resulting in dishonest work. After some straightforward and unimpeachable testimony before an investigating committee, an incensed politician is said to have told Mr. Craven: "You have done the last piece of work you will ever do on this job"; whereat, Mr. Craven quietly replied, "I will be here when you are gone."

\* Memoir prepared by Robert Ridgway, Past-President, Am. Soc. C. E.

This proved to be correct, for the agitation led to a legislative investigation and the passage of an act which permitted Mayor Hewitt to re-organize the Aqueduct Commission and to appoint men of a caliber to appreciate honest service. Because of his fine record and his ability as an engineering executive, Mr. Craven was given increased responsibility and he assisted in completing the aqueduct in a manner that reflected credit on himself and others concerned.

For more than fifteen years Mr. Craven was a Division Engineer on the construction of this aqueduct and additional reservoirs of the Croton System. He was in charge of the construction of Reservoir "D" on the West Branch of the Croton, near Carmel, N. Y. (capacity about 9 000 000 000 gal.) and of the completion of Reservoir "M" on the Titicus River, near Purdys, N. Y. (capacity more than 7 000 000 000 gal.). These are two of the chain of storage reservoirs built before and since in the Croton Basin, and they are still in service. Between 1895 and 1900, he was in charge of the building of the Jerome Park Reservoir, a storage or equalizing reservoir of the Croton System, located in the Borough of The Bronx, New York City. During the progress of this work, material changes were made in the plans, of which he did not approve, and early in 1900 he resigned.

In May of the same year, when the first New York City Rapid Transit Subway work was begun, Mr. Craven was appointed Division Engineer on the Staff of the Rapid Transit Railroad Commission of New York City, and was given charge of the construction of that part of the four-track subway from 41st Street and Park Avenue to Broadway and 104th Street, known as the Second Division. He was appointed Deputy Chief Engineer of the Commission in 1904; Deputy Engineer of Subway Construction of the Public Service Commission (the successor of the Rapid Transit Railroad Commission) in 1907; Acting Chief Engineer of the same Commission in 1910; and Chief Engineer in 1911.

Under Mr. Craven's administration as Chief Engineer, the great so-called "Dual Subway System", costing for construction and equipment more than \$500 000 000, was planned and, in a great part, built. At that time this was one of the greatest municipally constructed projects ever undertaken, comparable in magnitude with, and greater in cost than, the Panama Canal, and presenting great difficulties in planning and construction. That work may fittingly be regarded as a monument to Mr. Craven. He resigned as Chief Engineer in 1916, and was immediately made Consulting Engineer of the Commission holding that position under the Commission, and its successor the Transit Construction Commissioner, until he retired from service on December 31, 1920.

Mr. Craven was one of those men who, with no apparent effort on his own part, won the respect and affection of all who served under him or were otherwise associated with him. He never sought popularity. He had but to request that a thing be done and his Staff would work cheerfully day and night to accomplish the result. His fairness and straightforward way of thinking appealed to those who had business with him, and his decisions were generally accepted, whether they were for or against the claimants.

In commenting on his death, former Transit Commissioner Le Roy T. Harkness said:

"Mr. Craven was one of those really great men whose outstanding work was only thoroughly appreciated by the Engineering Profession and by those who had the rare pleasure of being associated with him. The people of New York use the magnificent subway system designed and built by Mr. Craven, but only a handful know of him. For this Mr. Craven's modest and retiring disposition was, of course, responsible. He was blunt and straightforward with a courage and integrity that matched his great ability. It has been said of him that he had no hinge in his moral backbone. Engineers generally realize that, while the Panama Canal is comparable with the New York Subway System in the matter of cost, there is no comparison in the matter of difficult and perplexing engineering problems. In the minds of those who knew and worked with Mr. Craven, the great Dual Subway System will always be regarded as a great monument to him. I had the rare privilege of serving with Mr. Craven for nearly ten years, and during that time came to have the same admiration and affection for him that was universal among all those who ever worked with or for him."

The Memorial Resolution passed by the Board of Transportation of the City of New York on October 5, 1926, reads, in part, as follows:

"This Board has learned with deep regret of the death of Alfred Craven on September 30th, 1926.

\* \* \* \* \*

"His memory will be a bright spot in the hearts of all who knew him. His sound judgment and absolute fairness, combined with his kindliness and modesty, won for him the respect and admiration of commissioners and contractors alike. His subordinates gave him the willing, loyal, and unstinted services that such a character inspires.

"His work is his monument."

Mr. Craven was survived by his widow, Nina Florence Browne Craven, to whom he was married in California in 1871, and who died in 1928. He is survived by three daughters, Mrs. Lucy Edgerton Bruce, Mrs. Emily Henderson Whittlesey, and Mrs. Nina C. Jones.

Mr. Craven was fond of fishing and golf. He was one of the first to take up the latter game in this country, and was a member of the St. Andrew's Golf Club. He was a member of the Society of Municipal Engineers of the City of New York, the Navy Athletic Association, and the Senior Golf Association. In 1915, he was appointed one of the two representatives of the Society on the Naval Consulting Board and served on it until his death. In 1908, he was awarded, under an Act of Congress, the Civil War Medal.

Mr. Craven was elected a Member of the American Society of Civil Engineers on December 5, 1888. He served as Director from 1903 to 1905 and as Vice-President in 1916 and 1917.

## CARLTON ROLLIN DART, M. Am. Soc. C. E.\*

DIED JUNE 23, 1929.

Carlton Rollin Dart, the son of Rollin C. and Sarah E. (Darling) Dart, was born at Lansing, Mich., on February 1, 1862. He was graduated from the Michigan Agricultural College in 1881 with the degree of Bachelor of Science. He began his professional career in 1881 as Assistant to the City Engineer of Lansing, but entered the University of Michigan in September, 1882, for the autumn and winter semesters.

In May, 1883, Mr. Dart again took up engineering work as a Surveyor and Draftsman on construction for the Marquette and Western Railway Company, at Marquette, Mich., making plans for a 50-pocket ore dock which was built at that place. From June, 1885, to September, 1886, he was Draftsman for the Grand Rapids and Indiana Railroad Company, at Grand Rapids, Mich.; and from September, 1886, to May, 1887, he was Assistant Engineer on construction for the Kansas City and Omaha Railroad Company, in Nebraska. He then entered the service of the St. Joseph and Grand Island Railroad Company, at St. Joseph, Mo., and was in charge of the construction of the railroad shops and terminal yards built for the St. Joseph Terminal Railway Company. In March, 1889, he entered the employ of the Union Pacific Railroad Company and was engaged on the work of building shops and terminal yards at Cheyenne, Wyo., and from May, 1890, to February, 1891, he designed and built railroad terminals for the Oregon Short Line and Utah Northern Railroad Companies, at Salt Lake City, Utah.

In February, 1891, Mr. Dart located in Chicago, Ill., and served until June of that year on building work in that city, after which he joined the Engineering Corps on construction work for the World's Columbian Exposition and was thus engaged until June, 1893. In July, 1893, he began the practice of general engineering with an office in Chicago and made complete plans for a large power station for the North Chicago Street Railway Company. In March and April, 1896, he was engaged on the structural work on the bear-trap dam at Lockport, Ill., collaborating with the late Alfred Noble, Past-President, Am. Soc. C. E., in this work. From May to December, 1896, he represented the late George S. Morison, Past-President, Am. Soc. C. E., in making surveys for a water-power project in East Tennessee, and from February, 1897, to January, 1898, he served as Draftsman in the office of Mr. Morison in Chicago. He then entered the service of the Lassig Bridge and Iron Works of Chicago, as Structural Draftsman and Checker, which position he retained until July, 1900, from which time until February, 1901, he was engaged in making drawings under the direction of Mr. Noble for compensating works in St. Mary's River at Sault Ste. Marie, Mich.

In February, 1901, Mr. Dart entered the service of the Sanitary District of Chicago as Assistant Engineer in charge of the Bridge Division. In December, 1903, he was promoted to be Bridge Engineer and served in that capacity until

\* Memoir prepared by Joint Committee of the Illinois Section and the Western Society of Engineers, consisting of Langdon Pearse, Albert F. Reichmann, and George M. Wisner, Members, Am. Soc. C. E.

March, 1921, when he was appointed Consulting Bridge Engineer, which position he held until his death.

Under Mr. Dart's direction were built many of the larger bridges over the Chicago River and practically all the bridges over the Drainage Canal, among which were the State Street Bridge, the Dearborn Street Bridge, the Jackson Boulevard Bridge, the Twenty-Second Street Bridge, the Western Avenue Bridge, the Eight-Track Bridge, etc. He also designed the butterfly dam at Lockport, the controlling works for the Calumet-Sag Channel, as well as all bridges over the North Shore Channel and the Calumet-Sag Channel. He was also engaged as a Consultant on the structural work carried on at the various pumping stations and other buildings of the Sanitary District, and took a keen interest in the development of the proposed controlling works suggested for the Chicago River.

Personally, Mr. Dart was a very kindly man, extremely modest as to his own accomplishments, and very considerate of his associates, as well as helpful in emergencies. During his later years, he had taken an interest in gardening.

He was a member of the Western Society of Engineers, of which he served for many years as Treasurer, the American Association of Engineers, the American Association for the Advancement of Science, the Structural Engineers' Association of Illinois, the American Railway Engineers' Association, and the Geographic Society of Chicago. He was also a member of the Engineers' Club.

In 1908, he was married to Ella Weinland, who died several years before him.

Mr. Dart was elected a Member of the American Society of Civil Engineers on May 6, 1903.

**FREDERICK AUSBERT DELAVAU, M. Am. Soc. C. E.\***

---

**DIED MAY 28, 1929.**

---

Frederick Ausbert Delavau was born on August 25, 1871, in Rochester, N. Y., the son of Joseph Stansbury Delavau and Margaret (Clements) Delavau.

Mr. Delavau's entire life was spent in Rochester, where he likewise attended school. In 1889, he was employed by Gray and Storey, Civil Engineers, and subsequently, with William R. Storey, Civil Engineer, and with Mr. William G. Gray, on surveys and in private practice.

In 1898 he was employed by the City Engineer of Rochester as Draftsman and Transitman, from which positions he rose steadily through the various grades of Assistant Engineer and Office Engineer. In 1926, Mr. Delavau became Deputy City Engineer and, in 1928, Supervising Engineer in Charge of Local Improvements. He retired on a disability pension on April 16, 1929, after thirty-one years of service. After a year's illness he died at the Strong Memorial Hospital on May 28, 1929.

Mr. Delavau was a conscientious worker and led an exemplary life. In 1903, he was married to Sallie E. Williamson, of Skaneateles, N. Y., and is survived by his widow and one son, Robert W. Delavau, both residing in Rochester.

He was a member of the Masonic Order and the Shrine, the Rochester Engineering Society, and the American Society for Municipal Improvements.

Mr. Delavau was elected a Member of the American Society of Civil Engineers on January 17, 1927.

---

\* Memoir prepared by C. A. Poole and John F. Skinner, Members, Am. Soc. C. E.

**EUGENE FRANK DELÉRY, M. Am. Soc. C. E.\***

DIED NOVEMBER 24, 1929.

Eugene Frank Deléry, the son of Frank F. and Cora (Hall) Deléry was born in New Orleans, La., on November 26, 1877. Educated in New Orleans at Farde's Private School, and, later, at Tulane High School and Tulane University, Mr. Deléry was graduated from the latter in Civil Engineering in 1899, and in Mechanical Engineering in 1900.

From July to September, 1899, Mr. Deléry served as Rodman and Computer with the Mississippi River Commission on levee surveys and erection; during April and May, 1901, on design and irrigation plant and boiler settings, for A. M. Lockett and Company, New Orleans; and from May to December, 1901, as Draftsman for the Johnson Iron Works, New Orleans, on steel hull construction of the Southern Pacific tugs, *El Vivo* and *El Listo*, boiler piping, and general machinery design.

From December, 1901, to September, 1903, Mr. Deléry was engaged in private design work, chiefly for the following firms: The Shakespeare Iron Works, the John N. Murphy Iron Works, and with Frank Paul Barber, New Orleans. From September, 1903, to June, 1904, he served as Manager of the St. Louis Rice Mill. In July, 1904, he entered into private design practice and general machinery design. From January, 1905, to August, 1908, he was Surveyor and Construction Engineer at the U. S. Naval Station, New Orleans.

From 1908 to the date of his death, Mr. Deléry served as Assistant Engineer of the Sewerage and Water Board of New Orleans. His most important piece of work done in this connection was in the capacity of Designing Engineer on the Purification Plant Extension.

His contemporaneous private practice covered irrigation plant design, settling tanks for settling out by-products, and miscellaneous machinery design. He had acted as Consulting Engineer for the architectural firm of Emile Weil, Incorporated, on the construction of the new Saenger Theatre and the Tulane University Stadium. At the time of his death he was associated with the J. F. Coleman Engineering Company on the design of filter plants. He was also associated as Consulting Engineer for A. Merrick Blamphin, Assoc. M. Am. Soc. C. E., on drainage work in St. Bernard Parish, Louisiana, and with Henry A. Mentz and Company, Consulting Engineers, of Hammond, La., on the design of plants for water filtration.

Mr. Deléry's mechanical and engineering ability resulted in the invention of the rotary flow pump and impact strainer system. He also had patents on the following appliances: Axial flow pump, the hydraulic thrust bearing, and a machine for forming the depressed orifices in the impact strainer tubes, with other patents on hydraulic appliances pending in the Patent Office.

The impact system of filter underdrains, of which he was the inventor, has proved very successful and is in use in the 72 000 000-gal. addition to the New Orleans Filtration Plant, and has been installed in the 24 000 000-gal. addition to the Tulsa, Okla., Filtration Plant. They have also been installed at

\* Memoir prepared by Henry A. Mentz, President, Henry A. Mentz, Inc., Hammond, La.

Franklin, Donaldsonville, Monroe, and Lafayette, La., and Wemoka, Okla., and at the time of Mr. Deléry's death, were being considered for several large cities.

Mr. Deléry was a member of the American Society of Mechanical Engineers, and the Louisiana Engineering Society. He was also a devout member of the Roman Catholic Church, and of the Society of the Blessed Virgin of the Church of the Immaculate Conception, New Orleans.

Stricken in the prime of life, he died on November 24, 1929, of a cerebral hemorrhage, due to high blood pressure and heart trouble, in the chapel of the Ursuline Convent, where he had stopped for a moment in prayer.

On July 9, 1918, Mr. Deléry was married to Edna Marie Fuselier. He is survived by his widow, and two small children, R. de la Claire and E. Marie Yvonne, also by two brothers, Clarence H. and Frank B. Deléry, and five sisters, the Misses Caro, Edna, and Cora Deléry, and Mrs. C. A. Shaw and Mrs. Freret.

A man of charming personality and lovable character, Mr. Deléry was admired by all who came in contact with him, for his great ability as an engineer, and for his many endearing qualities as a man.

His professional work was marked by a high degree of integrity. His death is deeply deplored by all his associates, by whom he was held in the highest esteem and who hold his memory in affectionate regard.

Mr. Deléry was elected an Associate Member of the American Society of Civil Engineers on May 7, 1913, and a Member on March 16, 1925.

## FREDERIC LESLIE DUDLEY, M. Am. Soc. C. E.\*

DIED MARCH 26, 1929.

Frederic Leslie Dudley was born in Templeton, Mass., on August 16, 1858. He attended the public schools of Templeton and studied Civil Engineering at the Worcester Polytechnic Institute, at Worcester, Mass., from which he was graduated in 1879.

After leaving the Institute, Mr. Dudley spent more than a year as Draftsman with Edward P. Adams, Landscape Architect and Civil Engineer, of Boston, Mass.

This was the period of railroad expansion in the West and in February, 1881, Mr. Dudley went to Kansas, where he was engaged in railroad construction for a number of years, first with the Engineering Corps of the Atchison, Topeka, and Santa Fé Railroad Company and the St. Louis, Iron Mountain, and Southern Railway Company; and, later, as Division Engineer of the Burlington and Missouri River Railroad Company on construction work in Nebraska and Colorado.

In 1888, Mr. Dudley returned to the East and entered the employ of the Edge Moor (Del.) Bridge Company. In this new line of work he started as Draftsman, then became Checker, and, in two years, was in charge of design as a Squad Leader. He supervised the detailing of all classes of structures; bridges, however, became his chosen specialty. At this time he began his work on swing bridges which later developed into all classes of movable bridges, in which field he became well known. He contributed much valuable information of a permanent nature to this branch of the Engineering Profession.

In 1901, the Edge Moor Bridge Company became a part of the American Bridge Company and in January, 1904, Mr. Dudley was transferred to the new Ambridge, Pa., Plant of this Company, in charge of the detailing of movable bridges. In 1905, he became Engineer of the Drawing Room for Railroad Bridges, including the design of machinery for movable bridges. For a number of years previous to his death his work also included the development of self-contained, power-driven railroad turn-tables and machinery for special movable structures, such as transfer-tables, ore and coal-handling bridges, etc. Until his retirement on January 1, 1929, just three months before his death, he continued in charge of this special work at the Ambridge Plant and as Consultant in the design of machinery for many movable structures.

During his twenty-five years at the Ambridge Plant, Mr. Dudley supervised the detailing of more than one hundred movable bridges of all types, including many of the larger swing and lift bridges, built by the American Bridge Company, in the United States. While in charge of the Drawing-Room for Railroad Bridges he supervised the detailing of many large structures, among which were the Mobile River Bridge, for the Louisville and Nashville Railroad Company (330-ft. draw span); the Hackensack River Bridge, for the Delaware, Lackawanna, and Western Railroad Company (a three-track, 198-ft. vertical lift bridge at Jersey City, N. J.); the Tombigbee River Bridge, for the

\* Memoir prepared by R. G. Manning, M. Am. Soc. C. E.

Southern Railroad Company (184-ft. vertical lift span); the Rigolets Bridge, for the Louisville and Nashville Railroad Company (414-ft. draw span); the coal-handling bridge for the Carnegie Steel Company, at Clairton, Pa. (a double trolley, 400 ft. between shear leg and tower, 630 ft. over all, including the mechanical and electrical equipment).

The fixed long-span bridges on which Mr. Dudley was engaged, included a bridge for the Kentucky and Indiana Terminal Railroad Company, at Louisville, Ky. (two 615-ft. spans and one 400-ft. draw-span erected as cantilevers from adjoining spans, respectively, 275 and 373 ft.); the Ohio Connecting Railway Bridge, for the Pennsylvania Railroad Company, over the Ohio River, at Pittsburgh, Pa. (spans, 416 and 525 ft., respectively, each half of the latter erected as a cantilever using one-half of the former erected temporarily at each end as anchor arm); the suspension bridge over the Ohio River between Parkersburg, W. Va., and Belpre, Ohio (three spans, 775, 375, and 275 ft., and approaches); the 977½-ft. arch span for Hell Gate Bridge (six tracks) over the East River from Long Island to Ward's Island, New York, for the New York Connecting Railroad Company; and the single-track cantilever bridge over the Ohio River at Steubenville, Ohio (660-ft. channel span and 230-ft. anchor arms). Many of these bridges involved very special and difficult erection features, the details of which had to be developed in connection with the steel work.

While Mr. Dudley never entered the field as an author of technical books, he contributed valuable information to technical students, draftsmen, and engineers, in the form of a set of blue-print notes (54 pages) entitled, "Notes on Engineering Bridge Details." This pamphlet was widely distributed to college students and instructors in structural courses and to employees in the structural drawing-rooms all over the United States and Canada.

In the course of his practice, Mr. Dudley acquired a large amount of valuable information relating to the designing and detailing of machinery for movable bridges. This information, together with some added material, developed, through a committee of the American Bridge Company composed of Mr. Dudley, as Chairman, Mr. R. A. Mather, and P. J. Reich, M. Am. Soc. C. E., into a set of notes entitled, "Notes on Designing Machinery for Movable Bridges." These notes laid the foundation for an enlarged copy of nearly 200 pages developed under the supervision of O. E. Hovey, M. Am. Soc. C. E., Assistant Chief Engineer of the American Bridge Company. In his valuable two-volume work on "Movable Bridges," Mr. Hovey acknowledges the assistance and co-operation given by Mr. Dudley in its preparation.

In the death of Mr. Dudley, the Engineering Profession lost one of the most versatile men in the practical design and detail of movable bridges, inasmuch as the last thirty years of his life were intimately associated with the development of this class of structures, from the early types of the simple hand-operated swing bridge to the largest and most varied types of power-operated swing, bascule, and rolling bridges. He was also well versed in the detailing and designing of all types of steel structures and had an exceptionally keen insight into the fundamentals of engineering.

In acknowledging the worth of a member to the Society and the profession, one should not overlook his value to the community. Sterling in character, Mr. Dudley was of gentle and kindly disposition. He was a devoted husband and father and is survived by his widow, Clara Garvey Dudley, and a daughter, Ruth Dudley Daniells.

Mr. Dudley took an active part in the community life and devoted much time to the advancement of things worth while. He was a delightful companion, and much loved by his fellow citizens and co-workers.

Mr. Dudley was elected a Member of the American Society of Civil Engineers on October 10, 1916.

## LOUIS HYDE EVANS, M. Am. Soc. C. E.\*

---

DIED JUNE 5, 1929.

---

Louis Hyde Evans, the son of Enoch W. and Caroline Hyde Evans, was born at Kenosha, Wis., on January 21, 1851. He was the second oldest of a family of four children, two sons and two daughters. His father was a prominent attorney in Kenosha, and Chicago, Ill., to which city the family moved during the Sixties.

After preparation in the public schools of Chicago, Mr. Evans commenced his railroad work, in 1871, first as Rodman, then as Instrumentman, with the Chicago and Northwestern Railway Company on the location and construction of its lines in the Northern Peninsula of Michigan. In the fall of 1872 he resigned to enter Rensselaer Polytechnic Institute, at Troy, N. Y., in the Class of 1876. He left the Institute, however, after six months, and entered the University of Michigan at Ann Arbor, Mich., as a special student in Engineering in the Class of 1875. In July, 1873, he obtained a leave of absence from the University to accept a position with the Erie Railroad Company as Assistant Engineer on the construction of double track on the Delaware Division of that road, grading and bridging 25 miles between Lackawaxen, Pa., and Calicoon, N. Y. He then returned to the University at Ann Arbor in the fall of 1874.

Following his graduation Mr. Evans was again employed with the Chicago and Northwestern Railway Company, and from June, 1876, to 1879, was Assistant Engineer on location and construction of its lines in Minnesota, on the completion of which, in 1879, he was employed on the Central Branch of the Union Pacific Railroad. In the latter part of 1879 he again returned to the Chicago and Northwestern Railway Company and served as Division Engineer and Engineer of Track Elevation in Chicago until 1900, when he resigned to accept the position of Assistant Chief Engineer with the Delaware, Lackawanna and Western Railroad Company at Hoboken, N. J. About 1904 he resigned that position to become a member of a firm of contractors who were making grade reductions on the Delaware, Lackawanna and Western Railroad in Northern New Jersey; after the completion of this work he returned to Chicago as Consulting Engineer for the Union Stock Yards and Transit Company, on its track elevation.

When this work was finished, Mr. Evans became associated with the late Horace G. Burt, Civil Engineer, formerly Chief Engineer and Vice-President of the Chicago and Northwestern Railway Company, and President of the Union Pacific Railroad Company, as a Consulting Engineer on the Chicago Smoke Abatement and Electrification Commission. He then became Consulting Engineer for the Southern and Frisco Railway Systems on the construc-

\* Memoir prepared by a Joint Committee of the Society and the Western Society of Engineers, consisting of Lincoln Bush, Past-President, Am. Soc. C. E., E. C. Carter, M. Am. Soc. C. E., and J. S. Robinson, M. W. S. E.

tion of the Chalmette Slip, a deep waterway and terminal at New Orleans, La. On the completion of this work in 1915 he retired from active practice, and devoted the remainder of his life to his personal interests in Chicago, and his country home on the Delaware River, in Pennsylvania.

Mr. Evans was a member of the Western Society of Engineers and of the Zeta Psi Fraternity.

He was married on June 2, 1879, to Frances Helen Robinson, at Mast Hope, Pa., and is survived by his widow and two children, Mrs. E. T. Hiscox, of Tyringham, Mass., and Major E. Webster Evans, of Detroit, Mich.

Mr. and Mrs. Evans celebrated their Golden Wedding Anniversary on Sunday, June 2, 1929, at Mast Hope. Mr. Evans was apparently in fine health at that time, but a sudden heart attack in his sleep, early on Wednesday morning, June 5, caused his death.

His sterling character, his love of justice to all, his enthusiasm in his work, and his encouragement to others under trying circumstances, endeared him to the many who worked with him, or came in contact with him.

Mr. Evans was elected a Member of the American Society of Civil Engineers on July 3, 1889.

**JAMES EDWARD FULTON, M. Am. Soc. C. E.\***

---

**DIED DECEMBER 6, 1928.**

---

James Edward Fulton, the son of the late Hon. James Fulton, who represented the Taieri, New Zealand, Constituency in the House of Representatives many years prior to his elevation to the Legislative Council, was born at West Taieri, Otago, New Zealand, on December 11, 1854. His preliminary training was received in the District School at West Taieri which, together with intervals spent under private tutelage, completed his education.

When Mr. Fulton was still a very young man, he showed a special aptitude for engineering and in the early Seventies had sole charge of the machinery of a large flax mill for a period of nine months.

In January, 1874, he was articled to Mr. John Carruthers, of Wellington, who was then the New Zealand Government Engineer-in-Chief in the Colony in charge of railways. After Mr. Fulton had served for four years as a Cadet, he passed the Junior and Senior Civil Service examinations, and also one required for the diploma of New Zealand Authorized and Licensed Surveyor. He was then appointed an Assistant Engineer of the Public Works Department, in principal charge of some railway location through heavily forested and rough country. He also served as First Assistant on the construction of 60 miles of railways, permanent way, and bridges, and had charge of the location and survey of 80 miles of additional railways.

In November, 1880, he resigned his position in the Government service to engage in private practice, but before doing so he was sent by the Department to the Bay of Islands, where he took soundings of the Harbor of Auckland and made a re-survey of part of the railway reserve lands there. During the period that Mr. Fulton was in private practice he went to Hawkes Bay to make some city re-surveys and, in 1882, to Auckland where he made a preliminary survey and estimate of the cost of the proposed line of the Kaihu Valley Railway Company.

From August, 1882, to 1897, Mr. Fulton was connected with the Wellington and Manawatu Railway Company, first as Resident Engineer under H. P. Higginson, Chief Engineer, in charge of the construction of the Palmerston-Waikanae Section. As Referee he also reviewed the various plans for the water supply and drainage of Palmerston North. In August, 1889, Mr. Fulton was promoted to the positions of Manager and Locomotive Superintendent to succeed his brother, the late A. R. W. Fulton. Mr. Fulton took a keen interest in his profession and was ever on the alert to give his Company the benefit of his inventions and improvements. It was while he was in the employ of the Wellington and Manawatu Railway Company that he invented and used in his office a telephone switchboard which was an attractive piece of mechanism, simple in manipulation, although of intricate appearance. He was associated with the movement to introduce from America the first compound locomotives that were used in New Zealand and that are still running with high efficiency on the Manawatu Railway.

---

\* Memoir prepared by M. Crompton-Smith, Esq., Wellington, New Zealand.

Mr. Fulton retired from service with the Railway Company in 1897 and again entered private practice, undertaking the work of designing and building the Kelburne Cable Tramway in Wellington, which consisted of tunnels, viaducts, and retaining walls, amounting in value to more than £30 000. He also designed a great many bridges for County Councils and the New Zealand Government, and was the Designer and Engineer of a light railway for the Taupo-Totara Timber Company, 50 miles in length, which includes the longest wooden arch span (234 ft.) of any bridge in New Zealand. He served as Engineer for the construction of the railway for the Tongariro Timber Company.

Mr. Fulton's death occurred on December 6, 1928, after almost a year of failing health. As a man of high attainments in his profession and of estimable qualities in other respects, his passing was greatly regretted among a wide circle of friends, professional and otherwise, throughout the Dominion.

He was a member of the Institution of Civil Engineers of London, England, and of its Advisory Committee in New Zealand. He was also a member of the New Zealand Institute of Surveyors, of which he had served as President.

He is survived by his widow, Mrs. C. F. Fulton, of Wellington, and one daughter, who is the wife of Professor Horton, of Holloway College, in England.

Mr. Fulton was elected a Member of the American Society of Civil Engineers on October 4, 1910.

**DANIEL WINGERD GROSS, M. Am. Soc. C. E.\***

**DIED JANUARY 23, 1930.**

Daniel Wingerd Gross was born at Harrisburg, Pa., on September 25, 1871. He was the son of George A. Gross and Mary A. (Wingerd) Gross. Mr. Gross received his technical education at Pennsylvania State College and was graduated therefrom with the degree of Bachelor of Science in Civil Engineering in 1893.

He began work in 1893 as Rodman for the Beech Creek Railroad Company and his professional services before entering the employ of the Atlantic Coast Line Railroad Company were, as follows: In 1893, Rodman, the Beech Creek Railroad Company; 1894, Rodman, the Clearfield, Conemaugh and Western Railroad Company; 1895 to 1899, drafting and designing, Frog, Switch and Signal Department, the Pennsylvania Steel Company; 1899 to 1901, Division Engineer on construction and maintenance, the International Traction Company; 1901 to 1902, Chief Engineer, the Lake Shore Electric Railway Company; 1902 to 1904, Division Engineer on the construction of the Ballston Line, Schenectady Railway Company; 1904, Plant and Mine Engineer for Queens Run Fire Brick Company, Lock Haven, Pa.; 1905 to 1906, with J. G. White and Company, designing special work for electrification of the Sociedad Commercial Lines of Montevideo, Uruguay.

In March, 1906, Mr. Gross went to the Atlantic Coast Line Railroad Company as Engineer in charge of maintenance of way for its Florida Lines, with an office at Jacksonville, Fla. These lines had been acquired by purchase and merger a few years before and, consequently, there was need for definite constructive work by the engineer in charge of maintenance in order that they might conform to the standards of the Atlantic Coast Line System. So excellent were the plans of Mr. Gross for the improvement and so good was the work accomplished that he was soon promoted to the position of Engineer of Construction for the entire System, which position was created for him; his office was established at Wilmington, N. C. During the period in which he held this position the capital account expenditure for extension and improvement of the System for roadway, track, and structures aggregated more than \$15 000 000.

When the Act of Congress was passed in 1913 to cover the valuation of the railways in the United States, Mr. Gross was put in charge of the work for the Atlantic Coast Line System and some of its subsidiaries, first, with the title of Chairman of Valuation Committee and, later, as Valuation Engineer. In this capacity, he directed the work of the valuation on the System until the period of Federal Control of railways, in August, 1918, when he was appointed Corporate Engineer. When the railways were released from Federal Control, Mr. Gross was promoted to the newly created position of Assistant to the President. In addition to the work then required of him as Executive he continued to give advice and attention to many of the valuation matters and was serving at the time of his death as a member of the Engi-

\* Memoir prepared by J. E. Willoughby, M. Am. Soc. C. E.

neering Committee for the Southern Group of Railways in the Presidents' Conference Committee.

The work which Mr. Gross performed for the Atlantic Coast Line System during the twenty-four years of his service was of definite value to the property. By that work he established his reputation as a careful, intelligent engineer with such vision for the future as makes for economy. His personality was of a kind to win for himself a host of friends both in and out of railway service.

He died on January 23, 1930, and is survived by three sisters, Miss Helen Gross, of Wilmington, N. C., Mrs. J. M. T. Finney, of Baltimore, Md., and Mrs. John L. Yates, of Milwaukee, Wis. He never was married.

Mr. Gross was elected an Associate Member of the American Society of Civil Engineers on May 1, 1901, and a Member on June 24, 1916.

## RICHARD AUGUSTUS HALE, M. Am. Soc. C. E.\*

---

DIED DECEMBER 17, 1928.

---

Richard Augustus Hale, the son of Bernice Sargent Hale and Sophia Kidder Hale was born on December 3, 1852, at Lowell, Mass.

After graduating from the Lowell High School, Mr. Hale entered the office of the late Hiram F. Mills, Hon. M. Am. Soc. C. E., Hydraulic Engineer, in Boston, Mass. A few months later Mr. Mills was appointed Engineer of the Essex Company in Lawrence, Mass. Young Hale went with him as his Assistant and remained in this office until he entered the Massachusetts Institute of Technology in 1873.

He was graduated from the Massachusetts Institute of Technology in 1877 with the degree of Bachelor of Science in the Department of Civil Engineering. During his four-year course at "Tech", Mr. Hale continued to work during the summer months with the Essex Company, and after receiving his degree he returned to that Company with which he remained associated continuously. In 1886 Mr. Hale was made Chief Assistant Engineer of the Company; when Mr. Mills died on October 4, 1921, he was made Engineer, in which capacity he served until his death.

Mr. Hale was an outstanding authority on water power and made several hundred reports on water-power sources in New England, New York, and Delaware. He served as Chairman of the Commission appointed by the Court to investigate and define the water rights of various parties at Hinsdale, N. H., and made measurements for the proper sub-division of the rights involved in that controversy. He also served as an expert in many cases of water diversion where hearings were held before commissions and masters.

In 1894 he was appointed a member of the Lawrence Park Commission and served in that capacity for twelve years, being Chairman of the Commission during the latter half of his tenure of office. He was a pronounced golf enthusiast and traveled about the United States, taking part in many tournaments on different courses.

Mr. Hale was a member of numerous clubs and organizations, including the Appalachian Mountain Club, the American Forestry Association, the Boston Society of Civil Engineers, which he served as President in 1916, the New England Water Works Association, the National Geographic Society, the American Civic League, the Massachusetts Civic League, the Merrimack Valley Technology Club, the Technology Club of Boston, the Merrimack Valley Country Club, the Lawrence Canoe Club, the Lawrence Boys' Club, and the Monday Night Club.

He was not merely a member of this long list of clubs, but one to whom membership meant service. His constant attendance at meetings of the different societies and his willingness to serve on committees, made him always outstanding. For this and his other winning qualities, Mr. Hale will long be remembered by his engineering associates, his neighbors, and his friends.

---

\* Memoir prepared by Charles T. Main and Arthur T. Safford, Members, Am. Soc. C. E.

His was the unusual distinction of having worked for only one employer during his entire professional career, and that a long one. This includes not only his undergraduate days, but afterward, a single noteworthy service of more than fifty-one years. Few engineers can boast such a remarkable record.

On October 28, 1880, he was married to Arabella Johnson Plummer. Mrs. Hale, three sons, Frank B., Elliot K., and Richard A., Jr., and two daughters, Helen P. Hale and Mrs. Ernest A. Nordon, survive him.

Mr. Hale was elected a Junior of the American Society of Civil Engineers on February 8, 1884, and a Member on July 1, 1891.

**ROBERT JOHN HARDING, M. Am. Soc. C. E.\***

---

**DIED JULY 31, 1929.**

---

Robert John Harding, the son of Albert G. and Mary A. (Peck) Harding, was born on February 16, 1880, at Allegan, Mich. Soon afterward, however, his people moved to Chatham, N. Y., and this town was his early home.

Mr. Harding was graduated from Cornell University at Ithaca, N. Y., in the Class of 1903. After serving as an Instructor at the University of Pennsylvania, and as Recorder on the United States Lake Survey, he became Superintendent of Public Works in Hudson, N. Y., in 1905. In 1908, he accepted a similar position in the larger city of Poughkeepsie, N. Y., where he rendered distinguished service until 1912. During the latter year he was engaged in private practice in Poughkeepsie.

In 1913, he went to San Antonio, Tex., as Manager of the Water Supply System which was owned by Belgian interests. He managed the extensive property for the foreign owners with ability and fidelity during the troublesome years of the World War.

After the war, the Belgian stockholders desired to realize on their investment and Mr. Harding formed a group among neighbors to purchase the stock and take over the property. As Chief Engineer and Vice-President, he continued to manage and extend the property, known as the San Antonio Water Supply Company, until it was sold to the City of San Antonio in 1925.

After the sale of the water-works, Mr. Harding was engaged principally in the development of several small water companies, but he made a professional trip to South America and, later, assisted in the investigation of sewers in the Borough of Queens in the City of New York.

Mr. Harding was interested in Red Cross work and was Chairman of the San Antonio Committee during the war period. He had a keen insight and was rarely wrong in his judgment of the men and conditions with which he had to contend. He was quiet and unassuming, but forceful withal—a competent executive and a loyal friend.

He was fond of hunting and fishing and was a most delightful companion on camping expeditions in search of wild ducks and turkeys. One of the writer's most cherished memories is of a long automobile trip from Texas to Arizona, with visits to all the most important dams along the route.

Mr. Harding was a member of the American Water Works Association, the New England Water Works Association, and the American Public Health Association. In the prime of his active manhood, and with much to look forward to, he was killed in an automobile accident for which he was in no way responsible.

He was married on December 25, 1903, to Louise E. Swick, of Mecklenburgh, N. Y., who survives him, with three sons, two daughters, and one grandchild.

Mr. Harding was elected an Associate Member of the American Society of Civil Engineers on November 4, 1908, and a Member on September 3, 1912.

---

\* Memoir prepared by the late Allen Hazen, M. Am. Soc. C. E.

## WILLIAM WALLACE HAYDEN, M. Am. Soc. C. E.\*

DIED JANUARY 7, 1929.

William Wallace Hayden, the son of James Francis and Catherine (McKittrick) Hayden, was born on August 7, 1861, at Baton Rouge, La.

Mr. Hayden's professional career began at a very early age, as he served as a Rodman in 1877 and 1878 on the New Orleans, Texas and Pacific Railroad (now the Texas and Pacific Railway). In 1879 and 1880, he was an Assistant Engineer on the location and construction of the Southern Pacific Extension from Lafayette to Cheneyville, La., and, in 1880 and 1881, he was engaged as Assistant Engineer on the Louisville and Nashville Railroad, from New Orleans, La., to Montgomery, Ala.

At various periods during 1877, 1879, and 1880, he pursued studies at the Louisiana State University in Baton Rouge. From 1882 to 1885, Mr. Hayden was in the employ of the Yazoo and Mississippi Valley Railroad Company (now a part of the Illinois Central Lines), which was then known by other names. During this period he was Transitman on surveys and Resident Engineer in charge of bridging and track-laying. In 1886, he served as Division Engineer on the Burlington and Missouri River Railroad for a time and subsequently was employed by the Kansas City, Memphis and Birmingham Railroad Company, first on location and then as Resident Engineer.

Mr. Hayden then returned to the Yazoo and Mississippi Valley Railroad and the Illinois Central Railroad Companies with which he remained for many years. He resurveyed the Yazoo and Mississippi Valley Railroad from Memphis, Tenn., to New Orleans; located and built the Bayou Sara Branch; and also located many other lines, including that from Centreville to Woodville, Miss., and one from Wilczinski, to Dahomey, Miss. The lines from Jackson to Ethel, La., and from Jackson to McManus, La., and the line from Minter City to Parsons, Miss., were also included in his construction work. He had charge of all construction from the Ohio River southward on the Illinois Central Railroad and from Memphis south on the Yazoo and Mississippi Valley Railroad until about 1905.

He was later appointed Chief Engineer and afterward Assistant to the President of the Mobile, Jackson and Kansas City Railroad Company, after which he entered the employ of the Missouri Pacific Railroad Company, locating the Hickman Branch. In 1906 and 1907, he was Locating Engineer and then Principal Assistant Engineer on the New Orleans, Great Northern Railroad. He next located and built the Lakeview Traction Company Line extending out of Memphis, and was subsequently Chief Engineer of the proposed Memphis and Pensacola Railroad. He was afterward employed by the New Orleans and Northeastern Railroad Company on maintenance of way. After a brief period, however, he left that Company to serve as Pilot Engineer, first on the Gulf Coast Lines and, later, on the Missouri, Kansas and Texas Lines.

---

\* Memoir prepared by J. F. Coleman, President, Am. Soc. C. E.

Mr. Hayden's health could no longer stand the strain of such an active life. In consequence, he forsook the railways which he had served long and faithfully and in 1924 accepted employment with the Louisiana State Highway Commission. He remained in this position until shortly before his death, which was caused by a severe heart attack.

He was a most genial man who made and kept many friends. He had a keen sense of humor and was ever ready for a joke. He was active and energetic, and devoted to the work of railway location in which he was especially proficient. Indoor occupations were irksome to him, and many of his changes of business were made primarily to escape work which kept him indoors.

He was married on December 16, 1891, to Ruth Davenport, of Port Gibson, Miss., who survives him. He also leaves two daughters, Mrs. C. R. Bostick, of Wauchula, Fla., and Mrs. Talmadge Kinnebrew, of Homer, La.

Mr. Hayden was elected a Member of the American Society of Civil Engineers on November 6, 1895.

**HARRY FOOTE HODGES, M. Am. Soc. C. E.\***

---

DIED SEPTEMBER 24, 1929.

---

Harry Foote Hodges was born in Boston, Mass., on February 25, 1860, the son of Edward Fuller and Anne Frances (Hammatt) Hodges. Both his parents belonged to families well known and respected. His father, Edward Fuller Hodges, was one of the most prominent and successful members of the Suffolk County Bar. Harry Foote Hodges traced his descent directly from William Hodges, the founder of the Taunton Branch of the family, who emigrated from England to Taunton, Mass. and died there in 1654. Others of his paternal grandparents were George Hodges who served with distinction in the French and Indian War, and Silas Hodges, a Surgeon in the Continental Army and many times in personal attendance on General Washington.

As a boy, Harry Foote Hodges prepared for college at the Boston Latin School and the Adams Academy, at Quincy, Mass. He entered the United States Military Academy at West Point, N. Y., in 1877, and as a cadet he early began to show the qualities which were later to distinguish him. One of the youngest members of the graduating class of 1881, he stood fourth in the Class. As a First Classman he was Cadet Lieutenant and Quartermaster. On being graduated, he received a commission as Additional Second Lieutenant in the Corps of Engineers of the Army.

After serving for four years at the Engineer School and as Adjutant of the Battalion of Engineers at Willets Point, N. Y., Lieutenant Hodges was assigned as Assistant to the District Engineer in charge of works on the Great Lakes, with headquarters at Detroit, Mich. He remained on this duty until 1888, principally engaged on the design of parts for the Poe Lock at the Sault Ste. Marie Canal, for which he also designed the steel lock-gates.

Lieutenant Hodges then returned to the U. S. Military Academy as Assistant Professor of Civil and Military Engineering. After this tour of duty he was appointed as Assistant to the late Col. Amos Stickney, Corps of Engineers, U. S. A., at Cincinnati, Ohio, on the improvement of the Ohio and tributary rivers. In 1893, he was promoted to the grade of Captain and placed in charge of improvements of the Upper Missouri and other rivers. This work included dike construction, snagging, and extensive surveys. On his relief from this detail, Captain Hodges served as a member of the Engineer Board, and originated the design of many features for mounting modern sea-coast guns.

At the outbreak of the Spanish War, he was appointed Lieutenant-Colonel and then Colonel of the 1st U. S. Volunteer Engineers, Porto Rican Expedition. During the war he remained in Porto Rico making roads and surveys and constructing defensive works, reservoirs, refrigerating plants, and bridges. Returning to the United States in 1899, he was placed in charge

---

\* Memoir prepared by Duncan Hodges, Esq., Lake Forest, Ill.

of river improvements at Cincinnati, until 1901, when he became Chief Engineer under General Wood, in the Department of Cuba, in charge of the works of the Port of Havana and other military and civil projects. On his return from Cuba, he was assigned to the Office of the Chief of Engineers in Washington, D. C. He was promoted to the grade of Major shortly after surrendering his commission as a Colonel of Volunteers.

In 1907, while Major Hodges was still on duty in the Office of the Chief of Engineers, the late George W. Goethals, Major-General, U. S. A., M. Am. Soc. C. E.—who had been appointed to succeed John F. Stevens, Past-President Am. Soc. C. E., as Chief Engineer of the Panama Canal—expressed his desire to the President to have an officer of the Canal Commission who was thoroughly familiar with lock structures and competent to design them. He suggested Major Hodges, explaining to the President his connection with the Sault Ste. Marie Canal and the design of the gates for the Poe Lock. However, the late Gen. Alexander MacKenzie, U. S. A. (*Retired*), Hon. M. Am. Soc. C. E., then Chief of Engineers, objected to the relief of Major Hodges on the ground that his departure would cripple the work of the Department. Shortly after, however, Major Hodges was assigned as General Purchasing Officer for the Isthmian Canal Commission, with headquarters in Washington. As such he supervised the purchase of immense quantities of materials required for the construction of the Panama Canal.

In August, 1907, President Roosevelt appointed Lieutenant-Colonel Hodges a member of the Panama Canal Commission. On the Commission he ranked next to General (then Colonel) Goethals, and was Acting Chairman in the latter's absences. As Assistant Chief Engineer of Canal Construction, he was given general supervision of the design and construction of the locks, dams, and control works. A number of the most valuable features of the Canal are the direct results of his engineering skill.

In Joseph Bucklin Bishop's book entitled "The Panama Gateway", there appears the following paragraph in which General Goethals estimates Colonel Hodges' services:

"He took over the designing work for the Panama Canal at a time when definite plans had to be adopted and the work carried to completion. Comprised in that work were designs for the dams, locks, gates, spillways, valves, operating machinery, hydro-electric station, and aids to navigation. He was placed in charge subsequently of the erection of the gates and the installation of valves and operating machinery. Charged with the solution of the most important engineering problems of the canal, it can be said of him truthfully that *the canal could not have been built without him.*"

It must not be supposed that Colonel Hodges completed the design and construction of the locks and dams of the Panama Canal without much technical criticism by engineers in the United States. During construction days on the Canal, it was often heard that certain of the designs of the locks were faulty. It was even rumored that the methods of suspending the 730-ton lock-gates were inadequate to the loads imposed. In view of the magnitude and uniqueness of the task assigned to Colonel Hodges, it is not surprising that such criticism existed. Nearly eighteen years have passed since the first gate was swung into position. Constant operation of the lock machinery

without essential modification has proved its soundness beyond all doubt. The fact that able engineers at one time criticized the design now shows how difficult the project was technically, and how great the feat accomplished.

Shortly after the first steamer passed through the Canal on August 15, 1914, Colonel Hodges returned to the United States. In March, 1915, he was promoted to the grade of Brigadier General of the Line of the Army and received the distinguished honor of the Thanks of Congress for his services. He remained in Washington in charge of the Washington Engineer District until May, 1915, when he assumed command of the North Atlantic Coast Artillery District, with headquarters at Fort Totten, N. Y.

In August, 1917, promoted to the grade of Major General (National Army), he assumed command of the 76th Division, Camp Devens, Massachusetts. The supervision of the building of the Cantonment and the organization and training of the Division were entrusted to him. On December 10, 1917, he was ordered overseas on an observation tour of the Allied Forces in France, returning in February, 1918. While in France, he was with the New Zealand Division, 2d British Army, in the Ypres Sector, and the 4th Division, French 2d Army, in the Avescourt Sector. On returning to the United States he again took command of the 76th Division. In July, 1918, he sailed with his Division for France, where he remained until after the signing of the Armistice. Among his awards was the Distinguished Service Medal, with the following citation:

"For exceptionally meritorious and distinguished services in a position of great responsibility. As Commanding General, Camp Devens, Massachusetts, he displayed unusual administrative and executive ability, sound judgment and high professional skill. He established a model system of schools and training, organized and trained the 76th Division, and in addition thereto trained for overseas service more than 40 000 men of other units. His untiring energy, devotion to duty, coupled with other outstanding soldierly qualities, contributed markedly to the successful operations of the American Forces during the World War."

After the war, General Hodges commanded, successively, the 20th Division at Camp Sevier, South Carolina, Camp Travis, Texas, and the North Pacific Coast Artillery District, retiring in the grade of Major General on December 22, 1921, after more than forty years' continuous and conspicuous duty in the service of his country.

General Hodges possessed, to an unusual degree, all the qualities of the successful engineer, combining with high mental alertness a great power of concentration. He was able to deal successfully with a multitude of details without losing sight of the end to which he strived. He prepared himself painstakingly for each task assigned him. One of his foremost characteristics was his mental integrity; he could not bring himself to countenance either carelessness or inaccuracy. A man of such energy and driving power, he required his subordinates to live up to the standard he set for himself. He contrived to accomplish this without nagging or undue pressure. Quiet and self-possessed, he never resorted to the tactics of the slave driver. By his own example he was able to gain and keep the respect and loyal support of those under him. In later years, when he held positions of high command,

he never permitted himself to hide behind his rank; he faced all issues squarely as they were presented to him. He was exceedingly astute in grasping the details of plans submitted to him. In whatever capacity, or wherever he served, men soon learned that he quickly got to the bottom of any problem and, having determined all the facts to his satisfaction, took action promptly and efficiently.

After his retirement from active service, General Hodges made his home in Lake Forest, Ill. He devoted his time to reading, studying, and his favorite outdoor sports, shooting and golf. In September, 1926, he suffered the loss of his wife, Alma L'Hommedieu Reynolds, to whom he was married in December, 1887. The attachment between the two was such that it could not be supposed that he would long survive her. General Hodges died at his home in Lake Forest on September 24, 1929, and is survived by his daughters, Mrs. A. H. Acher and Mrs. G. L. Dickson, and his son, Duncan Hodges.

General Hodges' death brought many tributes from all parts of the United States showing the great respect and high regard in which he was held. Gen. Charles P. Summerall, U. S. A., Chief of Staff, wrote in part that:

"From the date of his appointment as Second Lieutenant in the Corps of Engineers until his retirement as a Major General more than forty years later, General Hodges had undertaken the performance of every duty assigned him with characteristic zeal and energy. His successful accomplishments were only limited by the number and variety of the responsibilities entrusted to him. In his death, which is deeply regretted, the Army loses one of its most brilliant and successful officers."

General Hodges was elected a Member of the American Society of Civil Engineers on March 4, 1903.

## CAREY VANDERVORT HODGSON, M. Am. Soc. C. E.\*

DIED MAY 19, 1929.

Carey Vandervort Hodgson, the son of Lorenzo and Clara Emma (Hyatt) Hodgson, was born on July 11, 1880, at Wilmington, Ohio. He was educated in the public schools, at Wilmington College, and at Haverford College, Haverford, Pa. He received the degree of Bachelor of Science from Wilmington College in 1902, and from Haverford College in 1903.

On March 31, 1904, he entered the field force of the United States Coast and Geodetic Survey with which he remained, except for two short periods, until his death. He was successively promoted to Assistant and then to Hydrographic and Geodetic Engineer, with the relative rank of Lieutenant Commander in the Navy (May 18, 1920). From December 18, 1905, to October 20, 1906, he was in commercial employment, and during the World War he served in the United States Army.

Under Executive Order of September 24, 1917, he was transferred to the Army with the rank of Captain in the Engineers Reserve Corps. His military service included the following: 1918, Topographical Officer (about 4 months) and commanding Company B (about 4 months), 104th Pioneer (sapper) Engineers, United States and France; Topographical Officer, 29th Division, and Assistant Division Engineer, France (more than 1 month); October, 1918, became Major, and for about 4 months commanded 2d Battalion 104th Engineers, France. By Executive Order of February 26, 1919, he returned to duty in the Coast and Geodetic Survey, reporting on March 19 of that year.

Major Hodgson had a very wide experience in charting and mapping work with the United States Coast and Geodetic Survey, during the twenty-five years he was connected with that Bureau. When he first entered the Survey he was assigned to one of its vessels, the *Matchless*, engaged on the hydrographic survey of the Potomac River; later, he was assigned to the *Blake*, operating on the New England Coast. He then had a season of topographic work along the Potomac River and, subsequently, returned to ship duty. This work carried him to many points on the Atlantic and Pacific Coasts and along the coasts of Alaska, as well as to the Philippine Islands. During the earlier period of his duty in the Islands, he was in charge of a launch party surveying along the coasts of Bohol, Cebu, Leyte, and Samar. The work included the original survey of the San Juanico Straits. Later, he commanded the Coast and Geodetic Survey Steamer, *Research*, which was engaged on surveys on the southern coast of Masbate.

After serving three years in the Philippines (1908-11), he returned to the United States and was assigned to the determination of telegraphic longitudes in the United States and in Alaska, in co-operation with the late Edwin Smith, M. Am. Soc. C. E., then an Assistant in the Coast and Geodetic Survey.

In 1912, the Director of that Bureau decided that an attempt should be made to complete in a single season an arc of first-order triangulation, running approximately along the 104th Meridian from the vicinity of Pike's Peak,

\* Memoir prepared by William Bowie, M. Am. Soc. C. E.

Colorado, to the Canadian boundary. This triangulation was needed to furnish strong geographic positions at the international border on which the boundary surveys could be based. Major Hodgson was chosen as Chief of one of the two triangulation parties engaged on that work. He had had previous experience on second-order triangulation in the Philippines, and the reports of his superiors showed that he had accomplished the work assigned to him in an efficient manner. It was for this reason that he was selected for work on the 104th Meridian.

Plans were perfected in the Washington Office and the two Chiefs of Party took the field early in the summer. During a period of seven months they completed an arc of triangulation 720 miles in length. This was rapid progress, but the work was done with standard accuracy and at low unit cost.

Major Hodgson's next assignment consisted of first-order triangulation and astronomic determinations of latitudes. In 1914, he was engaged for more than seven months in the determination of such latitude in Texas, New Mexico, Arizona, California, and Nevada. During the season of 1913, he used a 1½-ton automobile truck to transport his party from station to station while on astronomical work. This was the first time that the Coast and Geodetic Survey had used an automobile truck in its surveying operations. During 1912, an engineer of the Bureau had hired a truck for use while measuring some base lines along the 49th Parallel, in connection with the United States-Canada Boundary Survey. That officer had been assigned to the Boundary Commission to carry on base-line operations. The truck proved so successful on the boundary work that it was decided to use it as an experiment on the work that Major Hodgson had under his direction in 1913. The test was so successful that the truck became the standard means of transportation for geodetic surveying parties.

From 1914, until he entered the Army in 1917, he was engaged on various triangulation and traverse projects. On his return to the Survey, at the close of the World War, he was placed in charge of the first-order triangulation party working on what was called the El Reno (Okla.)-Needles (Calif.) arc of triangulation. This arc crosses the States of Oklahoma, Texas, New Mexico, and Arizona. After one season on this work, he was given, in May, 1920, the assignment of Assistant Chief of the Division of Geodesy, on duty at the Washington Office of the Survey. He occupied this position at the time of his death.

While serving as Assistant Chief of the Division of Geodesy, Major Hodgson had direct charge of the field force of the Geodetic Branch of the Survey. He made annual inspections of the geodetic parties in the field and prepared the instructions under which the work was done. He studied carefully the practices of other countries as shown in the official reports received from geodetic organizations abroad. He prepared the copy for two manuals of the United States Coast and Geodetic Survey, "Manual of First-Order Triangulation",\* which appeared in 1926, and the other, "A Manual of Second and Third-Order Triangulation and Traverse",† which was issued about the time of his death.

\* Special Publication, No. 120, U. S. Coast and Geodetic Survey.

† Special Publication, No. 145, U. S. Coast and Geodetic Survey.

While at the Washington Office, Major Hodgson took an active part in engineering matters. In addition to his official duties, he became a member of the American Military Engineers, and the Washington Society of Civil Engineers. He was also a member of the American Geographical Society, the Washington Academy of Sciences, the Philosophical Society of Washington, and a Fellow of the American Association for the Advancement of Science. He was a Director of the Washington Society of Engineers in 1927 and 1928, and also a Director, from 1927 to 1929, of the Society of American Military Engineers. Since March 2, 1914, he had been a member of the Cosmos Club, of Washington, which may be called the scientific headquarters of the city.

On the organization, in December, 1926, of the Division of Surveying and Mapping of the Society and the election of an Executive Committee of that Division, Major Hodgson was appointed Secretary to the Committee. He served in that capacity until his death. He took an intense interest in the affairs of the new Division and helped to organize a number of standing and special committees formed to report on different phases of surveying and mapping. It may well be said that the success of the Division of Surveying and Mapping is due, in a great extent, to the efforts and ability of Major Hodgson. He represented the Chairman of the Division at the meeting of the Committees on Technical Procedure of the Society, held in Dallas, Tex., in April, 1929.

Major Hodgson and his 10-year old son, William Hockett, an only child, were drowned Sunday, May 19, 1929, while canoeing along the shore of Chesapeake Bay, in the vicinity of Annapolis, Md. He and his wife and son were spending the week-end at their cottage at Bay Ridge, about four miles south of Annapolis. He decided to test his canoe under sail during the forenoon of the day of his death. The canoe had been used by him and his son for the last two years, but had never before been equipped with a sail. No one saw the accident, but it is believed that the rather fresh wind carried the canoe from smooth water out into the increasingly rough waters offshore and made return from the capsized craft impossible, against the rising wind and sea.

In the early afternoon a search was made for the canoe and its occupants by an airplane, a submarine chaser, and launches stationed at the Naval Academy at Annapolis. The search was continued until dark and was resumed at daybreak, Monday. No trace whatever was discovered until the canoe was found, the following Wednesday, floating upside down, Major Hodgson's body under it, with the painter of the boat wrapped around his arm several times. His son's body was not recovered until June 2, 1929 (two weeks after the accident). It was found across the Severn River from Annapolis, twenty miles or so from where Major Hodgson and the canoe were found. Major Hodgson was buried, with full military honors, in Arlington National Cemetery, on May 25, and on June 3 the boy's body was buried beside that of his father.

Major Hodgson was married on April 17, 1916, to Edith Hockett, of Westboro, near Wilmington, Ohio, who survives him.

Due to his writings, his activities in engineering societies, and his administrative duties in the Coast and Geodetic Survey, Major Hodgson was recog-

nized as one of the leading engineers of the United States in the field of surveying and mapping. He was considered an outstanding authority in these lines. In addition to his high professional qualifications, he possessed a personality and character that impressed most favorably all with whom he came in contact and endeared him to many. His untimely death is a great loss not only to the Government Service, but to the entire Engineering Profession.

Major Hodgson was elected a Member of the American Society of Civil Engineers on November 25, 1919.

**HOWARD KINGSBURY HOLLAND, M. Am. Soc. C. E.\***

---

DIED OCTOBER 29, 1927.

---

Howard Kingsbury Holland was born in Edwardsburgh, Mich., on March 24, 1884. He was the second son of Dr. Marion Holland and Harriet (Kingsbury) Holland. His father was a physician and druggist and his paternal grandfather, Dr. Samuel Ward Holland, was one of the pioneer physicians of Eastern Michigan. His maternal grandfather was Asa Kingsbury, a banker and merchant of Western Michigan.

In 1894, Mr. Holland's parents moved to Cassopolis, Mich., and he was graduated from the Cassopolis High School in 1901. The following summer he entered the employ of the Page Wire Fence Company, at Monessen, Pa., in which position he was engaged at first in the drafting-room and, later, as a helper on the open-hearth furnace.

In the fall of 1902, Mr. Holland entered the University of Michigan, at Ann Arbor, Mich., but left in the late fall of 1903 to accept an appointment as Committee Clerk in the Senate of the State Legislature of Michigan. In the spring of 1904, he accepted a position with the Reo Motor Car Company, of Lansing, Mich., and remained at this work until the opening of college in the fall of 1905. Mr. Holland was graduated from the Civil Engineering Department of the University of Michigan in June, 1908.

Following his graduation, he was appointed Assistant in the Surveying Camp of the University of Michigan under the late Joseph B. Davis, M. Am. Soc. C. E. After the close of the Camp in the fall of 1908, he accepted a position with Gardner S. Williams, M. Am. Soc. C. E., Consulting Engineer of Ann Arbor, and for the following year was Chief of Party on a survey of approximately 12 000 acres of land for power plants and flowage along the Huron River, near Ann Arbor. From November, 1909, to June, 1910, he was a Resident Engineer for the J. G. White and Company, on the construction of a hydraulic power plant at Sterling, Ill.; and from July, 1910, to September, 1917, he was again associated with Professor Williams, as Resident Engineer and Supervisor of Construction, on a number of water-power and water-works plants.

From July, 1917, until his death, Mr. Holland was a member of the firm of Holland, Ackerman, and Holland, Consulting Engineers, of Ann Arbor, specializing in the design and construction of water-power plants. His last work was in connection with two plants on the Menominee River in Michigan.

Mr. Holland had been prominent in the Masonic orders for a number of years. He was affiliated with the Blue Lodge at Cassopolis, Washtenaw Chapter, Royal Arch Masons, at Ann Arbor, and was a member of the Shrine and a Past Commander of Ann Arbor Commandery No. 13, Knights Templars. He was also a member of the First Congregational Church, of Ann Arbor, of which he was a Deacon at the time of his death.

---

\* Memoir prepared by Louis E. Ayres, M. Am. Soc. C. E.

He was married on September 24, 1914, to Alma Marie Schmid, of Manchester, Mich. He is survived by his widow and three children, Howard Kingsbury, Jr., Roberta Louise, and John Marion, and by his brother, Ray Kingsbury Holland, Assoc. M. Am. Soc. C. E., all of Ann Arbor.

Mr. Holland was popular as a student and was a member of a number of campus societies, including Michigamua, Tau Beta Pi, and Owls; among his classmates he was highly respected. As a citizen, his counsel was frequently sought, and he took an active part in public affairs. As an Engineer, his principal services were rendered in the field, and all who knew him recognized his thoroughness in construction supervision and his sound judgment in those important problems connected with foundations of dams, power houses, and similar structures. Although of a quiet and retiring disposition, he was possessed of a strong and manly character. He will be greatly missed by many to whom he was a genuine and substantial friend, and his untimely passing is a regrettable loss both to his community and to his profession.

Mr. Holland was elected a Junior of the American Society of Civil Engineers on June 1, 1909; an Associate Member on October 29, 1912; and a Member on March 9, 1920.

**RALPH HILLS HOWARD, M. Am. Soc. C. E.\***

---

DIED SEPTEMBER 20, 1928.

---

Ralph Hills Howard was born in Zanesville, Ohio, on August 15, 1870, the son of Caleb Baxter Howard and Violetta Howard.

After completing his high school education and special study in civil engineering under the late Edmond Turner, M. Am. Soc. C. E., he entered railway service in October, 1889, as Draftsman with the Cincinnati and Muskingum Valley Railway Company. Until April, 1901, Mr. Howard served successively as Draftsman, Assistant on Engineering Corps, and Chief Clerk to the Engineer, Maintenance of Way. He designed and had direct supervision of the construction of masonry for replacing wooden, with steel, bridges, and of the construction of a terminal yard, car repair and machine shops, and an engine house at Lancaster, Ohio.

In April, 1901, Mr. Howard went to Pittsburgh, Pa., as Assistant on the Engineering Corps of the Pennsylvania Lines West of Pittsburgh, where he was engaged on maintenance and construction work. In July, 1902, he was transferred to the St. Louis Division of the Vandalia Railway as Assistant Division Engineer in charge of maintenance and construction. In April, 1905, he accepted service with the Chicago and Eastern Illinois Railroad Company as Principal Assistant Engineer in charge of construction and improvements, and in October of the same year, he was promoted to the position of Engineer, Maintenance of Way, in direct charge of all maintenance and construction work.

From May, 1910, to January, 1911, Mr. Howard was engaged on special work in connection with railroad properties for Eastern capitalists, and from January to June, 1911, he was Chief Engineer of the Great Southern Lumber Company and Engineer, Maintenance of Way, of the New Orleans Great Northern Railway Company in charge of construction and maintenance. In June, 1911, he was appointed General Manager of the New Orleans Great Northern Railway Company, remaining in this position until May, 1915, when he was appointed Chief Engineer, Maintenance of Way, of the Wabash Railway Company, with headquarters in St. Louis, Mo. In October, 1923, Mr. Howard was appointed Chief Engineer of the Company, which position he held at the time of his final illness.

Mr. Howard was a man of sterling character, and of a very pleasant personality, highly regarded by every one with whom he came in contact. He had a host of friends, who loved and admired him, and who will miss him greatly. He was possessed of unusual ability as an executive, and a great capacity for organizing and advancing large projects to a successful conclusion. His sympathetic understanding of the problems of his subordinates enabled him to develop efficient and capable men in his organization. The engineers who were associated with Mr. Howard were indeed fortunate. No matter what circumstances arose, even in the midst of some perplexing

---

\* Memoir prepared by W. S. Hanley and S. M. Smith, Associate Members, Am. Soc. C. E.

construction problem or catastrophe from flood, Mr. Howard always possessed a tranquil mind which made his decisions accurate and effective. He was an indefatigable worker and carried with him into his work a zeal and enthusiasm which was contagious and which permeated his entire organization.

Although Mr. Howard had not been in the best of health for several months prior to his last illness, he had still remained active. It was during his vacation at Petosky, Mich., that he was stricken with cerebral hemorrhage, and although he rallied from the first attack, he passed away on September 20, 1928. He was laid to rest in Woodlawn Cemetery, at Zanesville, Ohio, on September 24, 1928.

Mr. Howard was married on May 18, 1897, to Sina Larzelere, the daughter of William G. Larzelere, an influential and respected citizen of Zanesville, and a veteran of the Civil War. While blessed with no children, Mr. Howard's home life was ideally happy; he was always devoted to his wife and home.

He was a member of the Protestant Episcopal Church, and, as a boy, sang in the vested choir in the church at Zanesville. He was interested in sports and was an enthusiastic golfer, this being practically his only diversion from his work. He was a member of the American Railway Engineering Association, the Glen Echo Country Club, and the Missouri Athletic Club of St. Louis.

Mr. Howard was elected a Member of the American Society of Civil Engineers on July 2, 1913.

**WILLIAM DOUGLAS HUDSON, M. Am. Soc. C. E.\***

---

DIED FEBRUARY 25, 1929.

---

William Douglas Hudson was born at Rockbridge, Ill., on April 14, 1890. When he was still a very young child, his family moved to St. Louis, Mo., where he received his early education. In 1907 he was graduated from the University of Wisconsin, Madison, Wis., with a degree of Bachelor of Science in Civil Engineering. Preliminary to receiving his degree he had served as Rodman for James Stewart and Company and as Topographic Recorder and Instrumentman for the United States War Department.

From 1907 to 1909, Mr. Hudson was a Detailer and Designer for the Southwestern Bridge Company, Assistant City Engineer at Joplin, Mo., Office Engineer for the Town of Atoka, Okla., and Estimator and Designer for the Corrugated Bar Company. Even at this early period of his career, the trend of his interest seemed to be toward bridge construction, and during the next seven years (1910-17) he served, first, as Chief Draftsman in the Bridge Department, and then as Assistant Bridge Engineer, for the Missouri Pacific Railroad Company.

At the outbreak of the World War, Mr. Hudson attended the Officers' Training Camp at Fort Sheridan, Illinois, and served overseas with the American Expeditionary Forces, as First Lieutenant in the Third Battalion of the 344th Infantry.

Following the war Mr. Hudson became Principal Assistant Engineer with C. E. Smith and Company, St. Louis, participating in numerous important railroad and bridge design projects. These projects included the American Royal Building, at Kansas City, Mo., and the stock yards structures at Kansas City, and Oklahoma City, Okla.; the plans for the conveyor system, North Market Street Dock, St. Louis; the plant of the Barnickel Company, at Webster Groves, Mo.; and numerous track plans and arrangements in East St. Louis, Ill., in connection with the St. Louis Municipal Bridge.

In 1923, he formed an association with Harland Bartholomew and Associates, later organizing and becoming the active head of the William D. Hudson Company, Civil Engineers. In these capacities Mr. Hudson made engineering investigations and plans, with special reference to railroad, bridge, and harbor work in more than thirty cities of the United States and Canada. In general, these studies were part of a comprehensive city plan, involving wide knowledge and experience, as, for instance, the general railroad plan and grade-crossing elimination study at Toledo, Ohio, which was made the basis of a ten-year program between the city and the railroads, and for which the citizens of Toledo voted \$4 000 000 as the city's share of the cost in 1925. In other instances, Mr. Hudson prepared complete designs and specifications for particular engineering projects, such as the Franklin Street Viaduct, in Grand Rapids, Mich., a preliminary estimate of damage for the acquisition of more than \$40 000 000 worth of property in Los Angeles, Calif.

---

\* Memoir prepared by Harland Bartholomew, M. Am. Soc. C. E.

as a part of the Major Street Plan; and the relocation and grade separation of the main-line tracks of the Southern Pacific Railroad, in San José, Calif.

Mr. Hudson died in St. Luke's Hospital, St. Louis, from pneumonia, on February 25, 1929, following an operation which he had undergone three weeks earlier. He is survived by his widow, two daughters, Winnifred and Frances, and a son, George D. Hudson.

Mr. Hudson was a member of the American Railway Association, the Society of American Military Engineers, the Engineers' Club of St. Louis, and the American Legion. He was also a member of Fellowship Lodge, No. 345, A. F. and A. M., in Joplin, Mo., and of the Scottish Rite and Moolah Shrine in St. Louis.

Mr. Hudson was elected a Member of the American Society of Civil Engineers on March 16, 1925.

## CHARLES RAYMOND HUMPHREYS, M. Am. Soc. C. E.\*

DIED JUNE 1, 1929.

Charles Raymond Humphreys was born at Wayside, Md., on July 14, 1881. He was the son of Charles Humphreys and Elizabeth (Hungerford) Humphreys, and a descendant of Daniel Humphreys, who came to the United States from England in 1682, and settled in Sussex County, Pennsylvania. His great-great-grandfather, Joshua Humphreys, designed and built the first fleet of American warships, including the frigate, *Constitution (Old Ironsides)*, and was Chief Naval Constructor during the administrations of Presidents Washington and Adams.

Mr. Humphreys moved, with the family, to Wilmington, N. C., in 1893. His father was a Government Engineer and was transferred to this District at that time. He resumed his primary studies here with Professor Catlett's private classes, later going to Pantops Academy at Charlottesville, Va., where he completed his preparatory schooling. He then entered Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated with the degree of Civil Engineer in June, 1904. He was elected to membership in the Chi Phi Fraternity.

His first engineering work was during the summer vacations of 1902 and 1903, as Instrumentman with the United States Government at League Island Navy Yard at Philadelphia, Pa. After his graduation in June, 1904, and until January, 1905, he was with the Government forces on surveys and soundings of the Mississippi and Ohio Rivers.

From January, 1905, to January, 1907, Mr. Humphreys was connected with the Carolina Trucking and Development Company of Wilmington, in charge of surveys and the location of farm colonies in several Eastern Carolina Counties, and, later, he was Chief of Party on surveys and reports on water-power projects on the Pee Dee River. From January, 1907, to July, 1908, he was with the Waccamaw Land and Lumber Corporation, Bolton, N. C., engaged on title surveys, and railroad location and construction. From July, 1908, to May, 1911, he was City Engineer of Wilmington, and during the time he held this office he assisted in making an appraisal of the privately owned water and sewerage system, which the City bought and to which, under his supervision, extensive additions were made. While serving in this office he also co-operated with the North Carolina Geological and Economic Survey in making investigations and reports on the feasibility of developing the vast areas of overflowed and waste lands in the Coastal Plane Section of Eastern Carolina.

From May, 1911, to May, 1917, Mr. Humphreys conducted a general engineering business, with an office at Wilmington. During this time he established a broad field of practice, requiring the assistance of a number of engineers to carry on his work. He was a good organizer and directed parties in the different branches of the field. He was for a number of years

\* Memoir prepared by W. K. Allen, Civ. Engr., and Col. R. S. McClelland, Wilmington, N. C.

an active member of the North Carolina Drainage Association, the object of which was the promotion and advancement of the reclamation of over-flowed and waste lands for agricultural purposes. He was largely instrumental in the organization of many of the most important drainage districts in the State, directing the surveying and mapping of the areas affected and designing systems of drainage canals that made it possible to return to agriculture many thousands of acres of erstwhile jungle lands, bettering health conditions, as well as enriching those sections which had heretofore been considered worthless, and a menace to good health. He also made surveys and reports on forestry conditions for a number of Eastern North Carolina Counties, and, again, in 1917, he was Chief of Party on investigations and surveys for the development of water power on the Pee Dee River, in the Piedmont Section of North Carolina, for the Carolina Light and Power Company. It was while he was engaged in this work that his career as a brilliant engineer and a useful citizen was interrupted by his entry into the service of his country in the World War with Germany.

Immediately after war was declared Mr. Humphreys offered his services, and was ordered to the Officers' Training Camps at Chattanooga, Tenn., and American University, Washington, D. C., for military training, being commissioned with the rank of Captain, Engineer Corps, on June 19, 1917. Captain Humphreys was ordered to duty with the 105th Engineers at Camp Sevier, South Carolina, where he served as Topographical Officer and in various other capacities, leaving the United States with the American Expeditionary Forces on May 27, 1918. While in France, Captain Humphreys acted as Water Supply Officer of the American 2d Corps, and had charge of the survey of the St. Quentin Canal and Tunnel from November 4 to 11, 1918. He participated in the following engagements: Ypres-Lys Offensive, August 19-September 5, 1918; and Somme Offensive, September 20-October 8, 1918, Defensive Sector. Captain Humphreys returned to the United States on May 20, 1919, and was honorably discharged at his request on June 5, 1919.

Immediately after his discharge, Captain Humphreys took an active part in securing options, examining titles, and mapping outlines of a proposed 75 000-acre Soldier-Sailor Home Colony, in Eastern North Carolina, a project then contemplated by the Government, to provide homes and employment to ex-service men. He devoted much of his time to this movement during the summer of 1919.

From September, 1919, to September, 1921, he was City Engineer of Whiteville, N. C., during which time he directed a two-year street-paving program and water and sewerage extensions. In October, 1921, he resumed practice as a private engineer, with offices at Wilmington, and continued in this field until his health failed in the spring of 1928. During this time Captain Humphreys was in charge of road work for a number of counties in which modern roads were being built; he wrote plans and specifications and supervised the construction of this work and had a broad field of practice embracing all branches of the profession. His service and opinion on title work were sought by many corporations and holders of large areas of land over

the State. He was again employed by the Waccamaw Land Corporation with which he was engaged in 1907.

Captain Humphreys had a pleasing personality and a genial disposition, which won him friends everywhere, and he was ever ready to assist a fellow man in need and give aid to any worthy cause. He was punctilious in his habits, and painstaking in the performance of his duties.

He was married at Wilmington, on November 22, 1910, to Lillian Kenly, who, with their four children, Charles Raymond, Jr., Lillian Kenly, Mary Elizabeth, and Nancy Clark, as well as his mother and two sisters, survives him.

Captain Humphreys was elected an Associate Member of the American Society of Civil Engineers on June 3, 1915, and a Member on January 16, 1928.

**GEORGE MARTIN ALOYSIUS ILG, M. Am. Soc. C. E.\***

---

DIED JUNE 28, 1929.

---

George Martin Aloysius Ilg was born in Chicago, Ill., on November 26, 1881, the son of John J. and Christine (Schnebelen) Ilg, being one of ten children. Mr. Ilg received his early education in the public schools of Chicago and was graduated from Calumet High School in 1901.

His practical experience in engineering began shortly after his graduation, when he went to work for the American Bridge Company. He served four years with this Company as Shop Inspector, Tracer, Detailer, and Checker on steel work for bridges and buildings.

In 1905 he entered the School of Civil Engineering at the University of Illinois, paying his own way with funds he had saved during the previous four years and with the help of earnings as a Draftsman for the Kenwood Bridge Company during the summer vacations. He completed the full four-year course and was graduated in June, 1909, receiving the degree of Bachelor of Science in Civil Engineering.

After his graduation from college Mr. Ilg began his engineering work with the Chicago, Milwaukee and St. Paul Railroad Company and was soon given charge of the design of concrete and steel bridges and other structures. In 1911, he entered the employ of Holabird and Roche, Architects, as a Designer in the Engineering Department. During the next seven years, he was responsible for a large part of the firm's design work in both reinforced concrete and structural steel buildings.

In 1916, in connection with his regular work, he had occasion to design some long-span steel arches for an armory. He became interested in arch design to the extent of devoting considerable additional study in his spare time to this subject, which resulted in his preparation of a thesis on arches. Based on this, together with other requirements, Mr. Ilg received the degree of Civil Engineer from the University of Illinois in June, 1916.

In May, 1917, he left the employ of Holabird and Roche and entered the First Officers' Training Camp, at Fort Sheridan, Ill. He held a commission in the Reserves as Captain of Engineers, which commission was confirmed after training service at Fort Sheridan, Ill., and at Fort Leavenworth, Kans. On the completion of his training he was put temporarily on the inactive list and, while waiting for a call, entered the employ of the Stone and Webster Corporation, at Philadelphia, Pa., on the structural design of buildings for Hog Island Shipyard. His work here apparently was deemed as important as the more active duty in France, as he was not called for active service, but remained on the Hog Island work for the duration of the World War.

At the end of the war, in the fall of 1918, Mr. Ilg returned to Chicago and became Structural Engineer for Jarvis Hunt, Architect, in charge of design and construction. After two years in this position, he resigned on account of poor health resulting, it was thought, from overwork during the war. His

---

\* Memoir prepared by F. E. Brown, M. Am. Soc. C. E.

health did not improve, and he suffered a severe nervous breakdown. Seeking outside work, he moved to Pierre, S. Dak., in 1920, where he accepted a position as Assistant Bridge Engineer for the South Dakota Highway Commission.

After two years on this work, Mr. Ilg's health was very much improved, and in 1922 he moved to St. Paul, Minn. Here, he served for some time in the City Engineering Department, where he was engaged on the design of a number of bridges, including the Ford Bridge between Minneapolis and St. Paul. Later, he entered private practice as a Civil and Structural Engineer, with headquarters in St. Paul.

In January, 1926, Mr. Ilg returned to Chicago and entered the employ of Smith and Brown, Engineers, Incorporated. He was with this firm until his death.

He will long be remembered and esteemed by his associates for his kindly and genial disposition, his friendliness to others, and his interest in the success of his fellow workers. He enjoyed his profession fully and always took a keen delight in any unusual problem, no matter how difficult or tedious. His singularly alert mind and his fine training and experience made his services especially valuable to his associates.

On June 27, 1910, Mr. Ilg was married to Gretchen Zeit, the daughter of Dr. F. Robert Zeit, of the Medical Faculty of Northwestern University. He is survived by his widow and an only daughter, Marguerite.

He was a Mason, a member of the Triangle Engineering Fraternity, Hiram Sleifer Post of the American Legion, the Forty and Eight Club, and the Western Society of Engineers. He was also a Captain, Engineers Reserve Corps, U. S. Army.

Mr. Ilg was elected a Member of the American Society of Civil Engineers on March 12, 1923.

## JOHN DOVE ISAACS, M. Am. Soc. C. E.\*

---

DIED APRIL 26, 1929.

---

John Dove Isaacs was born on October 6, 1848, at Richmond, Va. He was educated at the University of Virginia, and was graduated in the Scientific Course, which in those days was closely associated with the Department of Liberal Arts.

From 1869 to March, 1870, he served as Draftsman with Talbott and Sons, of Richmond. He obtained further practical training from March, 1870, to March, 1874, when he was Prize Apprentice and then Draftsman at the Union Iron Works, Baltimore, Md. From March, 1874, to April, 1875, he worked as Draftsman with Hilles and Jones, Wilmington, Del.

In 1875, Mr. Isaacs went to San Francisco, Calif., and entered the service of the lines which now comprise the Southern Pacific Company, first as Draftsman in the Bridge and Building Department, then as Chief Draftsman and Designer, and, later, Principal Assistant Superintendent of Bridges and Buildings. In 1890, he was Consulting Engineer for the Piedmont Cable Company, Oakland, Calif., and, in 1891, Consulting Engineer of the California Bridge Company on the Petaluma River Draw-Bridge. In the early Nineties, he made a trip to Guatemala on a reconnaissance and preliminary survey for an extension farther into the mountains of the Ferrocarril Occidental. From 1891 to 1900, he was Second Assistant Engineer of Maintenance of Way for the Southern Pacific Company, and from 1900 to 1905, Assistant Engineer of Maintenance of Way.

During his period of service from 1875 to 1905, Mr. Isaacs was engaged in many interesting engineering projects, often referred to by him later in life. The following serve as examples: The design of the car-ferry steamer, *Solano*; the wharves and slips for the train-ferry service between Port Costa and Benicia, Calif.; the double-deck, side-wheeler ferry steamer, *Piedmont*; the Oakland Mole wharves, slips, and buildings; the Hotel Del Monte; the reconstruction of the Upper Cascade Viaduct which was burned in 1889 and rebuilt in 3½ days (420 ft. long and 100 ft. high); the development and superintendence of the Southern Pacific Company's activities in wood preservation; the design and construction of a masonry dam and tunnel, at Wright, Calif., on the Santa Cruz Branch; and the engineering and construction features of the California Mid-Winter Fair at San Francisco.

On December 1, 1905, Mr. Isaacs was transferred to the Eastern Executive Offices of the Southern Pacific Company and also became Consulting Engineer of the Union Pacific and Southern Pacific Systems, which meant that his engineering influence was exerted on all the Harriman Lines and their subsidiaries. After the dissolution of the Harriman properties in 1913, he was retained as Consulting Engineer of the Southern Pacific Company, with headquarters in New York, N. Y., which position he held until the time of his retirement in 1923.

---

\* Memoir prepared by C. R. Harding, M. Am. Soc. C. E.

On a bronze tablet recently erected at Stanford University, Palo Alto, Calif., Mr. Isaacs is given credit for his part in the early development of motion pictures. In the late Seventies, Senator Stanford sought Mr. Isaacs' advice to obtain proof to win a bet of \$25 with Mr. James W. Keene, that a trotting horse at one period of its stride has all four feet off the earth at once. Mr. Isaacs decided to use a number of cameras set side by side and make an accurate photographic record of the foot movement; he devised a simple electro-magnetic release that successfully recorded a series of photographs and settled the bet in favor of Senator Stanford. The history of the motion picture shows that others who were interested in these experiments, carried them forward, and that these tests really marked the birth of the motion picture.

Mr. Isaacs was generally recognized as one of the able authorities on wood preservation in the United States, having won distinction by his active work in the practical development of the creosoting and Burnettizing processes. He invented, jointly with the late W. G. Curtis, M. Am. Soc. C. E., a portable wood-preserving plant.

The taper rail devised by Mr. Isaacs to connect two abutting rails of different sections, has been widely used. This simple device, well known to all track men, consists of a piece of rail from 8 to 16 ft. long, so forged that the ends correspond respectively to the two sections to be joined, permitting the use of ordinary joint bars without the need of compromise joints.

The rifled pipe, invented jointly by Mr. Isaacs and the late J. B. Speed, Assoc. M. Am. Soc. C. E., in 1905, afforded a temporary solution to a difficult problem. Some of the heavy California oils could not be transported through pipe lines without expensive preheating, on account of the frictional losses in head. Mr. Isaacs and his Assistant conceived the idea of rifling the pipe like a gun bore, to give the oil a whirling motion. Then, when pressure had been applied, water was introduced, which, being somewhat heavier, would be thrown by centrifugal force, due to the whirling motion of the oil, against the pipe surface and stay there as a thin film, thus acting as a lubricant and permitting much easier passage of the oil in long-distance pumping. This use of water as a lubricant appeared to make it impossible for crude oil to stick to the pipe and impede its progress. A rifled pipe line was constructed between Delano and Volcano, Calif., a distance of 31 miles, which later was extended 282 miles farther from Delano, in the Kern River oil fields, to tide-water at Port Costa.

In 1899, Julius Kruttschnitt, then General Manager of the Southern Pacific Company, appointed committees of engineering officers of the Maintenance and Mechanical Departments to prepare a uniform and consistent system of locomotive tonnage rating on all Divisions of the Company's lines. The paper on "Locomotive Tonnage Rating—Southern Pacific Company—Pacific System",\* written by the late Mr. Curtis, Engineer, Maintenance of Way, with the able assistance of Mr. Isaacs, is an outgrowth of this work. After the study of detailed line profiles and extensive mathematical analyses, there was developed a theoretical basis for the rating of tonnage to be handled over

\* *Bulletin*, Am. Ry. Eng. and M. of W. Assoc., November, 1900.

a Division by a given class of locomotives at the required speed, according to the time tables for trains. In 1909, the first paper was supplemented by another entitled, "The Economic and Efficient Speed of Freight Trains,"\* prepared jointly by Mr. Isaacs and his Assistant, E. E. Adams, Assoc. M. Am. Soc. C. E., now Assistant to the President of the Union Pacific System.

Immediately before his appointment as Consulting Engineer, Mr. Isaacs attended a meeting that was called in 1905 to establish standards for way and structures common to all the Harriman Lines. As a result of this meeting, "Common Standards" were adopted, many of which have stood the test of time and are still in force. Such a system of using standards is still in vogue on the lines that then comprised the Harriman Lines, although they are now operated as separate units.

Important structures built while Mr. Isaacs was Consulting Engineer are too numerous to mention, and only a few of the most notable are recorded here. The double-deck, double-track Sacramento Draw-Bridge is believed to be one of the heaviest ever built. Other examples of his work are the Coos Bay Draw-Bridge, 458 ft. long; the reinforcement of the Pecos River Viaduct, 1516 ft. long and 320 ft. above the river bed, with practically no interruption to traffic; the lift-bridge over the Willamette River, Portland, Ore.; the Berwick Draw-Bridge over the Atchafalaya River, in Louisiana; the Galveston Freight Terminal and Grain Elevator; the marine ways at Alameda, Calif.; the Empalme Shops, in Mexico; and the Pacific Electric Shops and Yards at Torrance, Calif. He also had charge of the centralized plan of inspection established by the Harriman Lines in 1912.

Mr. Isaacs was a Charter Member (No. 145) of the American Railway Engineering Association, and served on the Committee on Buildings (1900); the Committee on Rails (1908 to 1915 and 1918 to 1929), having been Chairman of the Committee in 1916 and 1917. He contributed the following papers: "Locomotive Tonnage Rating—Southern Pacific Company—Pacific System"; "Effect of Physical Characteristics of a Railway upon the Operation of Trains";† and "The Economic and Efficient Speed of Freight Trains".

Mr. Isaacs passed away at the home of his daughter on Russian Hill in San Francisco, where he had been living quietly since his retirement from active service with the Southern Pacific Company on June 1, 1923. During those six years, he was seen but little by his host of friends. All his strength had been exhausted in his forty-eight years of service to his beloved "Southern Pacific", and he was content to rest during the remaining years of his life.

Mr. Isaacs was elected a Member of the American Society of Civil Engineers on March 7, 1894.

## WILLIAM DEAN JANNEY, M. Am. Soc. C. E.\*

DIED OCTOBER 30, 1925.

William Dean Janney, the son of William Warder and Marion (Dean) Janney, was born in Baltimore, Md. on September 8, 1859, of English and Scotch-Irish ancestry. After his preliminary education had been completed at the Friends School in Baltimore, he attended Lehigh University at Bethlehem, Pa., for two years.

In July, 1881, Mr. Janney entered the employ of the Baltimore and Ohio Railroad Company, and was engaged on preliminary surveys and location. In November of that year, he was appointed Assistant Engineer with the Norfolk and Western Railway Company, later being placed in charge of the masonry construction on 14 miles of line, which included 2 miles of road extending east from Pocahontas, Va. This work involved masonry for 17 bridges, 100 or more culverts, trestle footings, grading trestles, two tunnels, and continuous track-laying.

In April, 1883, he became General Agent for the Lexington Manufacturing Company, but he soon resigned this position to re-enter engineering. During the winter, he attended classes in Freehand and Architectural Drawing at the Maryland Institute of Art and Design, and, in the spring, he entered the employ of the Annapolis and Baltimore Short Line Railroad Company, which he served as Instrumentman and, later, as Chief Engineer. In this capacity, he completed surveys, made up estimates of cost, designed structures, financed the enterprise, and built the major part of the line.

Three years later, however, Mr. Janney resigned this position to return to the Norfolk and Western Railroad Company. He remained in the service of this road and its affiliated interests until 1894. He was placed in charge of both preliminary and location surveys, which included several hundred miles of construction work, with division terminals, yards, and shops, and other railroad construction of a heavy type. One difficult problem of which he had charge was the foundation work for a bridge across the Ohio and Kenova Rivers in West Virginia. During this period, he was also engaged in the construction of office buildings, the planning of town sites, the erection of dwellings, the grading of streets, the design and construction of a sewerage system, etc. This series of undertakings involved the design and construction of work amounting to several millions of dollars.

In 1891, he was appointed President and General Manager of the Wells Branch Coal Company, for the purpose of conducting the initial development of a new field. This position was created for him by the President of the Norfolk and Western Railroad Company, with which road he had so long been associated. On the recommendation of the Chief Engineer he selected the site, consummated the lease, constructed the necessary works, developed the mine, and at length put it into active operation. When he considered that it had fulfilled its purpose he sold it to private individuals.

\* Memoir prepared by the late A. E. Christliff, M. Am. Soc. C. E.

From 1894 to 1897, Mr. Janney was engaged in private practice at Ceredo, W. Va., where he undertook and completed contracts for several railroads, foundations for buildings, surveys, and general plans for a bridge over the Ohio River at Ashland, Ky. He likewise examined and made reports on timber and coal lands, conducting expert investigation of territory of obscure location and defective description which he often succeeded in retrieving for the owners. When the celebrated "King Land Case" appeared in Court, he acted as leading engineering expert by appointment of counsel for the defense, and aided in the preparation of cases, testifying at the various trials. He finally prepared all the maps used in the presentation of the case before the Supreme Court of the United States in which the decisive victory was gained.

He was employed during 1896 and 1897, with the United States Engineer Department as Assistant Engineer on surveys of the Ohio River from Pittsburgh, Pa., to Marietta, Ohio, to determine locks and dams for slack-water navigation; later, he was in charge of the Drafting Department and became Acting Geologist for a field party. In the fall of 1897, he was engaged as Chief Engineer with the W. M. Ritter Lumber Company of Welch, W. Va., and Columbus, Ohio, in charge of all surveys, laying off of timber cuttings, and the location and construction of saw-mills. He developed railroads and other means of transportation for logging operations, and determined the measurement of obscure and disputed boundary lines.

From December, 1900, to April, 1904, Mr. Janney acted as Chief Engineer of the Northern Railway Company, of Costa Rica, for the United Fruit Company. At this time, he was in charge of the location and construction of railroads, shops (including the selection, purchase, and installation of all machine tools and appliances), station buildings, bridges, and large apartment and office buildings of steel-concrete.

In July, 1904, he became Chief Engineer for the Elk River Coal and Lumber Company, and for the Buffalo Creek and Gauley Railroad Company in connection with the development of about 80 000 acres of coal and timber land in Clay and Nicholas Counties, West Virginia. After he had built the railroad into the property, designed all the structures, and reported on timber holdings and coal deposits, he started the actual development of the mines. Later, he returned to Baltimore to accept a position as General Superintendent of Construction in the building of new reinforced concrete piers for the City.

In 1911, when this work was nearing completion, Mr. Janney was engaged by D. B. Banks, Consulting Engineer, of Baltimore, to take charge of work in connection with a high-pressure system of water supply in West Virginia. In this capacity he made a topographic survey of a stream valley to determine impounds and location of dams, and, later, he located 43 miles of pipe line. He conducted all negotiations for the acquisition of lands, etc.

From 1912 to 1919, he was engaged in private practice with Mr. Banks, making examinations and reporting on various hydro-electric projects, water-works, and irrigation systems. This work consisted also of reconstruction, involving intricate engineering and construction problems, hydrographic surveys, layout of channel dredging, and the preparation and testifying in many cases of litigation on damage suits.

During the first year of the World War Mr. Janney served as Assistant Engineer with the Quartermaster Corps, U. S. Army, in charge of the distribution and allotment of railroad materials, but soon after, he was forced to resign on account of ill health.

In December, 1918, he was again engaged in private practice, and subsequently until his death acted as Special Engineer with the United Railways and Electric Company of Baltimore.

Mr. Janney was a man of high character and was well liked by all his associates. He was a member of the Engineers Club of Baltimore, and for several years the Editor of the monthly *Journal* for that Society. He was intensely interested in the organization of The Boy Scouts of America, and was a member of the Court of Honor in awarding badges. He was also an Elder and Trustee of the Second Presbyterian Church of Baltimore.

He had few recreations, but took great delight in tinkering around his own home, or in fishing, spending many hours with his rod in hand waiting for the quick jerk which told of an unsuspecting nibble.

He was married in Baltimore on February 16, 1886, to Marion Rowe; they had five children, Marion, William Rowe, Gertrude, John W., and Charles Homer.

Mr. Janney was elected an Associate Member of the American Society of Civil Engineers in 1891, and a Member on April 1, 1896.

## HENRY SCUDDER JAUDON, M. Am. Soc. C. E.\*

DIED AUGUST 22, 1929.

Henry Scudder Jaudon, the son of W. A. and Mary Jaudon, was born in Savannah, Ga., on July 20, 1871. He was an alumnus of the Georgia School of Technology and Lehigh University, from which institutions he received his degree in Engineering in 1895 and 1896.

Prior to his graduation Mr. Jaudon secured employment, during vacation periods, with firms engaged in engineering projects of importance, and he profited by the contact thus formed. Following his graduation he was made Chief Draftsman and Inspector of the dry dock at Port Royal, S. C., Inspector for the Pottsville, Pa., Iron and Steel Company, and, later, was placed in charge of dredging operations for the United States Government. In 1898, he was employed by the American Water Works and Guarantee Company, of Pittsburgh, Pa., in the service of which he remained for five years, designing and supervising the construction of a number of water-works plants, including those at Birmingham, Ala., Shreveport, La., and Meridian, Miss.

In 1903, he organized the H. S. Jaudon Engineering Company, which operated extensively throughout the South. The efficiency of his organization was well known and brought him a lucrative practice. He pointed with pride to his achievements in more than a score of cities and counties where he had planned and directed municipal improvements and highway work.

As a citizen, Mr. Jaudon was public-spirited in an unusual degree. He took an active interest in matters pertaining to the betterment of his community and, as a member of the City Council and Chamber of Commerce of Elberton, Ga., contributed largely to the material advancement of the city of his adoption. He was an active member of the Methodist Episcopal Church and served on the Board of Stewards for a number of years.

His charming personality won for him scores of friends and admirers in all walks of life. His connection with professional organizations, and with social and fraternal orders, gave him a wide circle of acquaintances who mourn his passing. He was a member of the American Society of Municipal Improvements, the Florida Engineering Society, the Alpha Tau Omega Fraternity, the Rotary Club, the Masonic Order and the Benevolent and Protective Order of Elks.

Mr. Jaudon was deeply interested in his profession and those with whom he was associated. He never failed to reward the meritorious and lend a helping hand to the unfortunate. In his passing, the Society, his family, and his friends sustain an irreparable loss.

In 1900 he was married to Sarah Louise Arnold, of Elberton, in which city he resided until his death.

Mr. Jaudon was elected an Associate Member of the American Society of Civil Engineers on February 4, 1903, and a Member on February 1, 1910.

\* Memoir prepared by the following Committee of the Georgia Section: J. W. Barnett, Chairman, and W. A. Hansell, Members, Am. Soc. C. E., and F. H. Frasier, Assoc. M. Am. Soc. C. E.

## ERNEST LESTER JONES, M. Am. Soc. C. E.\*

DIED APRIL 9, 1929.

Ernest Lester Jones, the son of Charles Hopkins and Ida (Lester) Jones, was born at East Orange, N. J., on April 14, 1876. He received his educational training at the High School in Orange, N. J., and at Newark Academy. Later he matriculated at Princeton University in the Class of 1898, from which institution he received the Bachelor of Arts Degree.

Following the completion of his studies at Princeton University, Mr. Jones was engaged in research, secretarial work, and business for a number of years. Early in 1913 he entered the service of the Federal Government, President Wilson having appointed him Deputy Commissioner in the United States Bureau of Fisheries. He remained in this position until April 14, 1915, when he became Superintendent (title changed to Director in 1919) of the United States Coast and Geodetic Survey, which position he held until his death.

During his residence in Washington, D. C., Colonel Jones served in the District of Columbia Militia, from Private to Major. During a portion of 1918 and 1919 he was on furlough from the Coast and Geodetic Survey, and was commissioned a Lieutenant-Colonel, U. S. Signal Corps. Later, he became Colonel, Division of Military Aeronautics, and served with the American forces in France in the World War. For exceptional services during the war period he was decorated by the King of Italy as Officer of the Order of S. S. Maurizio and Lazzaro, and Fatigue de Guerre (Italy); he was also an Officer of the Legion of Honor (France). Immediately following the cessation of the war, when men's minds everywhere were turned toward matters of rehabilitation, Colonel Jones was among the first to consider the welfare of those who had been at the battle front in Europe, and thus it came about that he was the organizer of the first post of the American Legion (George Washington Post, Washington, D. C.), and also an organizer and incorporator of the National Legion.

As the efficient administrator of a Federal Bureau, Colonel Jones early came to see the need for better conditions and more adequate salaries for employees in the Federal Service, and his advocacy of their cause in bringing these urgent needs to the attention of the proper authorities had an important part in securing remedial legislation. The great improvement in the efficiency of the personnel of the Federal Service, as a result of this legislation, has amply justified the wisdom of his efforts.

It was a part of his philosophy of human affairs that the best work can be done only when men have the best tools and appliances for doing it, and so it was among his basic endeavors while Director of the Coast and Geodetic Survey that the Bureau's engineers be supplied with adequate ships and modern instruments and equipment. These things he achieved in a large measure, the good effects of which are reflected in a larger and better volume of work and

\* Memoir prepared by R. L. Faris, M. Am. Soc. C. E.

a finer spirit of performance by the entire personnel, so that the Bureau now meets the purposes of its being with a growing satisfaction and increased efficiency.

Throughout his administration of the Bureau, Colonel Jones exemplified high executive ability. He was outstanding in his loyalty to the work of the organization and to his associates and subordinates, and in turn he engendered in them such sentiments toward himself. He worked constantly for the improvement of the Service under his direction so that the public might thereby be better served. He was positive in responding personally to whatever seemed necessary to advance each class of work and always co-operated with those of his associates who were making progress. He spared himself no amount of effort and toil to attain the things he thought were right and needful to be done. He had a humane and sincere sympathy for all who requested his assistance. Although firm in his opinions, yet he was considerate of the views of others. He was loyal alike to those whom he served and to those who served under him, and also to his own promises and obligations in that he gave the best that was in him in all his endeavors.

In addition to his duties as Director of the Coast and Geodetic Survey, Colonel Jones was also Commissioner of the International Boundary between the United States and Canada and Alaska and Canada, from February, 1921, until his death. He was a member of the Aerial Patrol Commission of the United States, and a member of a number of Government and scientific missions, one of the last of which was as a delegate to the International Geographic Congress, at Cambridge, England, in 1928.

Colonel Jones was a member of a large number of organizations and societies, which included scientific, engineering, social, patriotic, and outdoor recreational purposes, showing thereby a wide range of active human interest and usefulness. Among the organizations of which he was an active member may be mentioned the Washington Academy of Sciences; the Philosophical Society of Washington; the American Association for the Advancement of Science; the Washington Society of Engineers; the National Geographic Society; the Meteorological Society; the American Fisheries Society; the National Association of Audubon Societies; the Society of American Military Engineers; the Military Order of the World War; and the Society of Mayflower Descendants. His membership in various clubs and civic organizations, also eloquent evidence of his wide interest in his fellow man, included the National Press Club, the Explorers Club (New York), the Aero Club of America, the Cosmos Club, and the Federal Club.

He was the author of the following Government publications: "Alaska Investigations"; "Hypsometry"; "Elements of Chart Making"; "Safeguard the Gateways of Alaska"; "Earthquake Investigations in the United States"; and "The Neglected Waters of the Pacific". In addition, he also was the author of the following (unofficial) papers: "Evolution of the National Chart"; "Science and the Earthquake Perils"; and "Aerial Surveying".

In 1919, he was granted the honorary degree of Master of Arts from Princeton University with the following citation:

"Ernest Lester Jones, Director, United States Coast and Geodetic Survey, the oldest scientific agency of our Government, writer on our coastal waterways bordering the Pacific Ocean, a resourceful administrator, increasing largely our supply of reliable maps and supervising the use of new devices for making our waters safer, notably by detecting the perilous submerged pinnacle rocks; a Colonel in the Army during the war, on active service in France and Italy, decorated by the King of Italy, awarded the Diploma of Merit by the Aerial League of America, recommended for the French Croix de Guerre; most recently instrumental in helping to form the American Legion to perpetuate American Liberty".

As a token of its personal regard for Colonel Jones, the following resolutions were adopted by the personnel of the United States Coast and Geodetic Survey and the International Boundary Commission:

*Whereas*, on April 9, 1929, the death of Colonel Ernest Lester Jones, Director of the United States Coast and Geodetic Survey and Commissioner of the International Boundary Commission, United States-Alaska and Canada, has deprived the nation of an earnest, fearless, and efficient public servant, who always placed devotion to duty above considerations of personal welfare; and,

*Whereas*, under Colonel Jones' inspiring leadership these organizations have made outstanding contributions both to the immediate public welfare and security and to the better knowledge of scientific truth on which the future of human progress in large measure depends; and,

*Whereas*, his deep human understanding and sympathy endeared him to all with whom he came in contact, so that those who knew him best loved him most;

*Therefore, Be It Resolved*, That we, for and in behalf of his friends and associates in the Coast and Geodetic Survey and the International Boundary Commission, unite in expressing our profound conviction that in the passing of Colonel Jones the Administrative Government of the United States has suffered the loss of an executive of rare ability and achievement, and that we have been deprived of a true friend and counsellor;

*And Be It Further Resolved*, That we extend to his bereaved family our deepest sympathy and express to them our profound sorrow and our heartfelt understanding of the great loss they have suffered.

On September 28, 1897, he was married to Virginia Brent Fox, of Louisville, Ky. He is survived by his widow and two daughters.

Colonel Jones was elected an Associate Member of the American Society of Civil Engineers on April 3, 1922, and a Member on October 12, 1925.

## WALSTAN EMILE KNOBLOCH, M. Am. Soc. C. E.\*

---

DIED JUNE 3, 1929.

---

Walstan Emile Knobloch was born on St. Bridgette Plantation, the family home, in Terrebonne Parish, Louisiana, on December 10, 1862, the only son of Judge Arthur F. and Amelia (Thibodaux) Knobloch. His maternal grandfather, Henry Schyler Thibodaux, was the founder of the Town of Thibodaux, La., and, at one time, served as Governor of Louisiana.

In Mr. Knobloch's early childhood, the family moved to Thibodaux where, as a boy, he attended Thibodaux College, later entering Tulane University, at New Orleans, La., from which he was graduated in 1883. At the time of his graduation he received a gold medal for his proficiency in mathematics.

In order to gain experience, Mr. Knobloch served with the Louisiana State Board of Engineers, without remuneration, from October, 1884, to February, 1886. Subsequent to this time he was engaged as follows: From February to October, 1886, as Computer in the United States Surveyor General's Office, and from October, 1886, to March, 1887, as Recorder in the United States Engineer Office at New Orleans; from March to May, 1887, as Leveler for the Texas and Pacific Railroad Company; from May to September, 1887, as Transitman with the U. S. Engineers, at New Orleans; from November, 1888, until May, 1889, as Resident Engineer on the Costa Rica Railway, having had charge from December, 1888, to May, 1889, of the construction of the Eastern Division of this road, which included the design of all iron bridges on the line; from May, 1889, to August, 1892, as Resident Engineer on the New Orleans and Northwestern Railway, Assistant Engineer on the construction of the Natchez Sewer, Supervisor of Tracks on the Louisville and Nashville Railroad, Transitman on the survey of the Sabine and Marshall Railroad, and, also, Transitman on the survey of the Georgia, Tennessee, and Illinois Railway.

In August, 1892, Mr. Knobloch again entered the employ of the Federal Government in the U. S. Engineer Office, at New Orleans, as Surveyor in the Fourth Mississippi River District, his duties consisting of staking out and supervising the construction of levees from Red River Landing to New Orleans. In May, 1900, he was promoted to the position of Junior Engineer Superintendent in responsible charge of all levee work and of hydrographic surveys in the same District. In July, 1902, Mr. Knobloch was given additional charge of the improvement of the Amite, Bayou Manchac, Natabany, Tickfou, and the Tchefunct Rivers, and of the survey and construction of that part of the Intercoastal Canal, which is in Louisiana.

Continuing his work with the U. S. Engineer Office, he was advanced to the position of Superintendent. In 1923, while thus engaged, Mr. Knobloch suffered a stroke of paralysis and, on account of continued ill health, was forced to resign in 1926. He moved to his home in Thibodaux, where he resided with a sister, Fanny Knobloch, until his death on June 3, 1929. Mr. Knobloch never married.

---

\* Memoir prepared from information on file at the Headquarters of the Society.

In connection with his work with the Mississippi River Commission, Mr. Knobloch was considered to be one of the most competent and best-informed engineers in that service. He was an expert at levee construction and one of the first advocates of building levees by machinery. It was through his efforts that the use of such construction was extended through the Mississippi Valley below Vicksburg, Miss. His ability in forecasting river stages was almost uncanny, and in critical emergencies during flood periods his judgment many times saved a situation that seemed hopeless.

As a man, Mr. Knobloch was exceedingly modest and like many others his ability and achievements were little known beyond his own circle of intimates. His loss is deeply deplored by his fellow engineers and by others who knew him as a faithful and conscientious worker and a sincere friend.

Mr. Knobloch was elected a Member of the American Society of Civil Engineers on October 2, 1907.

**JOHN WILLIAM LIEB, M. Am. Soc. C. E.\***

---

DIED NOVEMBER 1, 1929.

---

John William Lieb was born in Newark, N. J., on February 12, 1860, the son of John William and Christine Zens Lieb. He was educated in the local public schools and the Newark Academy, following which he entered the Stevens High School at Hoboken, N. J., graduating in 1876. He then entered the Stevens Institute of Technology, from which he was graduated with the Class of 1880, receiving the degree of Mechanical Engineer.

During his college course Mr. Lieb became interested in the new discoveries which at that time were being made public in the electrical field and shortly after his graduation he entered the employ of the Brush Electric Company in Cleveland, Ohio, where he worked on the arc-light systems as a Draftsman. He soon saw that these systems had very nearly reached the limit of their development and after a few months, in January, 1881, he entered the employ of Thomas A. Edison, of the new Edison Electric Light Company, as Draftsman in the Engineering Department, at 65 Fifth Avenue, New York, N. Y. Here, he assisted in making the plans for the "Jumbo" dynamos and also in the design of the switches, regulating apparatus, and other electrical equipment for the new Pearl Street Station in New York which was to be the first central station in the world for the general distribution of electrical energy for utilization as light, heat, and power from an underground system of mains. Later in the year, he was transferred to Mr. Edison's Experimental and Testing Department at the Edison Machine Works, in Goerck Street, New York, and was engaged in researches and investigations on electric meters, regulators, and electrical apparatus, under the personal direction of Mr. Edison. Early in 1882, Mr. Lieb was assigned to the construction of the Pearl Street Station, in general charge of the planning and installation of the electrical equipment. When this Station was put into regular operation on September 4, 1882, under the auspices of the Edison Electric Illuminating Company of New York, he was given the appointment of Electrician in charge of its operation.

In November of the same year he was selected by Mr. Edison to proceed to Milan, Italy, to direct the design and installation of the first Edison Station in Milan; and on the organization of the Italian Edison Company (*Societa Generale Italiana di Electricita, Sistema Edison*), he was appointed its Chief Electrician, then Chief Engineer, and, finally, Technical Manager and Director of Stations. The Milan Station, which was put into regular service in March, 1883, was for a considerable time the largest and most successful electric light and power station in Europe. Mr. Lieb participated in the tests of the Goulard and Gibbs transformers at the Turin Exposition in 1884, and the Milan Company under his direction was among the first to install, in 1886-88, an alternating-current system of distribution, utilizing, among the very first applications, the connection of transformers in parallel according to the Zipper-

---

\* Memoir prepared by Geo. A. Orrok, M. Am. Soc. C. E.

nowsky, Deri, and Blathy patents, exploited by Ganz and Company, of Budapest, Hungary. He also did pioneer work in the transmission of high-tension alternating current at 2400 volts, through concentric underground cables, to consumers located several miles from the central station. Under Mr. Lieb's direction there were also undertaken in Milan some of the first experiments in operating large direct-driven alternators in parallel.

The Thomson-Houston Series Arc System, with arc-light machines supplying 50 lamps in series, received here one of the earliest applications in Europe, and later was extended throughout the whole city from a separate arc-light station. The earlier arc-light poles had always been offensive to his æsthetic sense and Mr. Lieb inaugurated the use of artistically designed poles which were much more pleasing to the eye. In 1893, there was put into regular service in Milan under Mr. Lieb's direction, one of the earliest trolley car systems in Italy, furnishing regular service from the Piazza del Duomo to outlying districts. The Italian Edison Company, which was at first only an enterprise installing arc and incandescent lighting plants in cities and industrial establishments all over Italy, later acquired its own manufacturing works for the production of dynamos, motors, and electrical apparatus of all kinds, including the manufacture of incandescent lamps. Mr. Lieb's interest in the incandescent lamp, which had manifested itself in his college days and continued during his work with Mr. Edison, was now used to good purpose, and his executive genius and organizing ability ensured the success of these establishments.

In the meanwhile he had returned to New York to be married to Minnie F. Engler, on July 29, 1886, taking her back with him to Milan where he continued his work in popularizing and extending the use of electric light, heat, and power. It was during this visit to America that Mr. Lieb became a member of the American Society of Mechanical Engineers. He was elected a member of the American Institute of Electrical Engineers the next year. In his connection with the Italian Edison Company, he served as adviser for many financial and industrial corporations engaged in the electric business where his active and enthusiastic mind united with the judgment of manager and executive, assured sound methods in the exploiting and extension of the electric industry. Already the possessor of three languages, German, French and English from early life, he now had become master of Italian, even speaking the local dialects with considerable ease.

In 1894, Mr. Lieb returned to America as Assistant to Mr. R. R. Bowker, then Vice-President and Executive of the Edison Electric Illuminating Company of New York. The next four years were most fruitful in the development of the use of electric light and power in New York City and Mr. Lieb made three visits to Europe with other officials of the company. This was preliminary to the design and construction of the Waterside Station and the adoption of high-tension alternating-current generation, with rotary converters and low-tension direct-current sub-stations for the Edison System. These years also saw the first storage battery installed on that System.

On January 1, 1898, the control of the Company passed into the hands of Mr. A. N. Brady, with Mr. T. E. Murray as Vice-President. At this time,

Mr. Lieb became Third Vice-President and General Manager, serving in this capacity until the Company's re-organization as the New York Edison Company in 1901. In the re-organized Company he became Associate General Manager, Vice-President, and General Manager; and, finally, Senior Vice-President, which office he held at the time of his demise. During this period he had general charge of the installation and operation of the power plants and distributing systems in New York and was the executive in charge of the Company's technical operations, with supervision over all technical research and developmental work.

In addition to being Senior Vice-President and a Director of the New York Edison Company, Dr. Lieb was President and Chairman of the Board of The Electrical Testing Laboratories; Vice-President and member of the Board of Directors of the Yonkers Electric Light and Power Company; member of the Board of Directors of the United Electric Light and Power Company, and of the New York and Queens Electric Light and Power Company; Vice-President of the Edison Electric Light and Power Installation Company; Director and member of the Executive Committee of the International Power Securities Corporation; Director of the Brush Electric Illuminating Company, the Empire City Subway Company, and the Consolidated Telegraph and Electrical Subway Company.

He was a Past-President and Fellow of the American Institute of Electrical Engineers; Past-President of the Association of Edison Illuminating Companies, National Electric Light Association, the New York Electrical Society, and the Edison Pioneers; Past Vice-President of the American Society of Mechanical Engineers and Fellow of the New York Academy of Sciences; Trustee of the Stevens Institute of Technology; Trustee and Vice-President of The Museums of the Peaceful Arts; and Trustee of the Italy-American Society. He was a member of the Illuminating Engineering Society; the Franklin Institute of Philadelphia; the American Association for the Advancement of Science; and numerous other professional and civic organizations, National and local. He was an Honorary Member of the Society of Italian Engineers and Architects, and of the Society of Italian Railway Engineers; Vice-President, Union Internationale des Producteurs et Distributeurs d'Energie Electrique; a member of the Elektro-technischer Verein, Associazione Electrotecnica Italiana, the Institution of Electrical Engineers of Great Britain, the Royal Society of Arts, and the Newcomen Society of London.

Dr. Lieb was for many years past the Chairman of the Lamp Committee of the Association of Edison Illuminating Companies, and during the World War was Chairman of the National Committee on Gas and Electric Service, representing in Washington, D. C., the public utility companies (gas, electric, and street railway service) of the United States in their co-operative relations with the various departments of the Government. He was a member of the Committee on Public Utilities of the U. S. Chamber of Commerce, on which he represented the National Electric Light Association as its National Councillor; Chairman of the Association's delegation to the International Chamber of Commerce; representative of the Association on the International Association of Producers and Distributors of Electrical Energy; member of the

New York Chamber of Commerce and of its Committee on Internal Trade and Improvements; member of The Merchants Association of New York and Chairman of its Industrial Committee; member of the National Industrial Conference Board and Chairman of the Joint Fuel Committee, representing the National Public Utility Associations; member of the Committee to Study Plans for Co-operation between the War Department and the National Association of Manufacturers; and a member of the Committee on Standardization Survey, the American Society of Military Engineers, and the National Research Council.

He also served in international matters as follows: Chairman, Section "E", International Electrical Congress, St. Louis, Mo., 1904; Representative, U. S. Department of State at the International Railroad Congress, Rome, Italy, 1922; Member, U. S. Executive Committee, World Power Conference, London, England, 1924; U. S. Delegate, International Congress on Illumination, Geneva, Switzerland, 1924; Chairman, Reception Committee, International Electrotechnical Commission Meeting, New York, N. Y., 1926; Vice-President, International Association of Producers and Distributors of Electrical Energy, Paris, France, 1928; and Executive Chairman, American Organization Committee, World Engineering Congress, Tokyo, Japan, 1929.

For his pioneer work in connection with the introduction of electric light and power service throughout Italy and the installation of the electric trolley system in Milan, Dr. Lieb was decorated by the Italian Government, being made Knight Commander of the Royal Order of the Crown of Italy and, later, being promoted to Grand Officer. In 1925 he was made "Ufficiale" of the Order of S.S. Maurizio e Lazzaro, and, in 1928, "in recognition of the services he has rendered in furthering professional industrial co-operation between French and American engineers and in facilitating the interchange between them of knowledge and experience regarding the construction and operation of central-station systems for the generation and distribution of electrical energy for light, heat, and power," was honored by the French Government, receiving the decoration of Officer of the Legion of Honor.

Dr. Lieb was most sympathetic with the youthful aspirant to a position in the Engineering Profession. He valued highly the training he had received at the Stevens Institute of Technology and maintained a very active interest in engineering education and the progress of his Alma Mater. He served as President of the Alumni Association in 1896-97 and as Alumni Representative on the Board of Trustees from 1908 to 1911. In 1921, he received, from his Alma Mater, the honorary degree of Doctor of Engineering, and, in 1927, became a life member of the Board of Trustees.

He was equally interested in technical Society affairs, becoming, as stated, a member of the American Society of Mechanical Engineers in 1886, and of the American Institute of Electrical Engineers in 1887. In the American Institute of Electrical Engineers he was elected Manager for the terms 1896-1899 and 1901-1903; Vice-President from 1899-1901 and from 1903-1904; and President in 1904-1905. In 1913, he became a Fellow of the Institute. He was elected Manager of the American Society of Mechanical Engineers

for the term 1903-1906, and Vice-President for the term 1906-1908. He was greatly interested in the affairs of United Engineering Society and particularly of its Library, serving continuously on this Committee from 1909 to 1917. Outside these activities, he gave freely of his time and advice in the furtherance of the work of these technical societies.

Dr. Lieb delivered many lectures on engineering, industrial, and economic subjects in the leading universities and technical schools in the United States, and contributed many reports, papers, and discussions to the publications of professional and learned societies. On February 4, 1924, he was awarded the Edison Medal by the American Institute of Electrical Engineers for his work in connection with the development and operation of electric central stations for illumination and power.

As a manager and executive, Dr. Lieb held very definite opinions regarding the position of utilities or public service corporations as trustees for both the public and the investors. Coming into the business during its inception, he knew the experimental and speculative side and the long, arduous years before an adequate return became possible on the funds invested. As a public service corporation is practically without competition, he held that service must be maintained as perfect as possible and at as low a rate as was consistent with fair returns on the investment. He early saw the futility and fallacy of municipal ownership blended with political control, and dependent on the tax fund to finance deficiencies. He saw his company paying a sufficient dividend to ensure the securing of additional capital when required and utilizing the best methods and devices for efficient and continuous service to the public at the lowest price conformable with a sound corporate policy.

As General Manager, the selection and administration of the Edison Company's personnel became his personal responsibility, which he considered as important as his responsibility to his stockholders and to the public. His wide sympathies were well known and his office was open to everybody, even to the youngest office boy, who had a grievance. Having worked as a mechanic, he knew the workman's point of view and respected it. His dealings with organized labor were sympathetic, but a suspicion of the "ca'canny" roused him to antagonism. He who gave of himself without limit and of the best that was in him, could not lightly suffer the cheat or "clock watcher".

With the vision of the pioneer, the well considered knowledge and training of the scientist, and the wide sympathies of the humanitarian, Dr. Lieb endeared himself to every one with whom he came in contact. In a conference or argument, he had the faculty of picking out, as it were, the underlying idea, the main trend, the crux of a situation, and divesting it of all extraneous matter, going straight to the root of things. His reasoning was never oblique, but logical and cogent, sparing none, not even himself, in the strength of his analysis of a situation.

His sympathies were wide, ranging over the entire realm of human activities; his versatility and general knowledge might be termed encyclopædic. His English vocabulary was perhaps his most wonderful achievement, and his writings have always been models of clearness and good expression, in his

use of the right word in the right place to obtain just the shade of meaning he desired.

While Dr. Lieb's first interest was always the electric industry, and particularly the Edison System, he had many hobbies, among which history, economics, art and archaeology were perhaps the most important. His long residence in Italy, with its archaeological monuments, and many survivals of mediæval times and the Renaissance, had given him a wide knowledge of these great periods of the world's history. He early became acquainted with the work of Leonardo da Vinci and studied his notebooks, learning the old Italian dialect in which they were written and becoming one of the foremost authorities on the work of that universal genius. He became greatly interested in the Etruscan monuments and the earlier Hallstatt remains. His vacations were spent in research on art and history, visiting most of the sites of ancient cities and getting first-hand knowledge of the progress of civilization. He early joined the Raccolta Vinciana of Milan and maintained a most active interest in this Society. He was also greatly interested in the work of Perret, the volcanologist, and in the development at Llarderello, Italy, utilizing the interior heat of the earth for the production of power.

Dr. Lieb's reading was most extensive because he early acquired a capacity for rapid reading, which is decidedly uncommon at the present time. When this was added to a very retentive memory and a most wide-awake and far-reaching interest in both the modern and ancient world, the scope of his activities may be fully appreciated.

Mr. Edison, paying tribute to him, says:

"John W. Lieb was one of my most able assistants, and in the early days I used him in the development of the Pearl Street Central Station. He was a most energetic and active man and had such a comprehensive understanding of my electric lighting system that I selected him to go over to Italy and establish the Milan Central Station. He made a great success of the installation and of the introduction of the system into Italy. One of his notable achievements was the lighting of La Scala, the great opera house of Milan.

"His work in Italy was of a pioneering nature and led to the promotion of the great hydro-electric system which has been so extensively exploited in that country. His work there was but the beginning of a great and noteworthy career which, unfortunately, has come to an untimely end.

"He was a man of fine and sterling character, and I always had a very warm regard for him."

Dr. Lieb is survived by his widow; two daughters, Minnie E. and Julia C. Lieb; a son, Adolph W. Lieb, who was married in 1928 to Eleanor Wilcox; and a granddaughter. A brother, Oscar J. Lieb, and two sisters, Mrs. Charles Oscar Baldwin and Miss Anna Lieb, also survive him.

Dr. Lieb was elected a Member of the American Society of Civil Engineers on October 5, 1898.

## ALBERT LUCIUS, M. Am. Soc. C. E.\*

DIED FEBRUARY 2, 1929.

Albert Lucius, the son of Frederick and Amalia (Fudikar) Lucius, was born on October 9, 1844, at Erfurt, Prussia. He was graduated from the Frankfort Polytechnic, Germany, in 1863, and was employed as a Mechanical Draftsman until 1865, in which year he came to the United States and made his home in New York, N. Y.

Mr. Lucius was engaged as a Mechanical Draftsman with the Novelty Iron Works, New York, from 1865 to 1870, at which time he severed his connection with that Company to accept the position of Superintendent of the Petersburg Iron Works, at Petersburg, Va. He remained with the Petersburg Iron Works until 1875 and then returned to New York City to accept the position of Assistant Engineer with the New York Elevated Railway. He held this position until 1877, at which time he was promoted to be Principal Assistant Engineer of the same road, where he remained until 1880.

During 1880 and 1881, he was Engineer of Construction for the Brooklyn Elevated Railway. From 1881 until 1883 he served as Principal Assistant Engineer of Bridges for the New York, West Shore, and Buffalo Railway Company, under the late Walter Katté, M. Am. Soc. C. E., Chief Engineer.

Among the personal effects of Mr. Lucius a letter addressed to "Whom It May Concern", written by Mr. Katté, and endorsed by the late Cyrus W. Field, was found, from which the following is quoted:

"I take pleasure in certifying that Mr. Albert Lucius, Civil and Mechl. Engineer, is eminently qualified to satisfactorily and skillfully perform all the duties of a Chief Engineer of Railways, Bridge Structures, Elevated Railway, and their appertaining machinery. I tendered him the position of Chief Asst. in the Dept. of Iron Bridging Structures generally, in the exercise of these duties he was responsible for correct designing and execution of details of all the Iron Structures on those lines, many of which were of great magnitude, and calling for engineering ability of a high order. It gives me pleasure to state that his performance of them was in every way commendable and satisfactory, and if I were asked to nominate a Chief Engineer of an Elevated R. R. requiring the services of a thoroughly qualified Engineer he is exactly the man I should first name."

It is of interest to find two such notable engineers combining to endorse the technical ability and qualifications of a fellow member of that profession.

During the latter part of 1883, Mr. Lucius was engaged by the late James B. Eads, F. Am. Soc. C. E., President of The Eads Concession Company, to accompany him to London, England, to assist in the plans, specifications, and negotiations for the Tehuantepec Ship Railway. This railway was to be located across the Isthmus of Tehuantepec, Mexico, for the purpose of transporting vessels overland between the two oceans. The ship railway project, however, did not materialize, and Mr. Lucius returned to New York City the next year and became a member of a firm of bridge contractors. He remained with this firm until 1886, at which time he opened an office in New York

\* Memoir prepared by A. R. Raymer, M. Am. Soc. C. E.

City as Consulting Engineer and continued in active practice in that city until his death.

Although Mr. Lucius devoted himself in his private practice to all forms of structural steel designing, he may be said to have specialized in the design of steam railway bridges, inasmuch as he designed such structures for the following: The Bessemer and Lake Erie Railroad Company; the Boston and Albany Railroad Company; the Franklin and Clearfield Railroad Company; the Lake Erie and Eastern Railroad Company; the Lake Erie and Pittsburgh Railroad Company; the Lake Shore and Michigan Southern Railway Company; the Maine Central Railway Company; the New York Central Railroad Company; the New York, Ontario, and Western Railway Company; and the Pittsburgh and Lake Erie Railroad Company. Perhaps his most notable work was his design of the double-track cantilever bridge over the Ohio River at Beaver, Pa., for the Pittsburgh and Lake Erie Railroad Company.\*

Mr. Lucius was inherently an engineer, a clear and an original thinker, and, as a man, most excessively modest. It may be truly said of him that he made many real and genuine contributions to the Engineering Profession during his long and notable career.

On August 7, 1873, Mr. Lucius was married to Octavia Wallace Sturdivant, a resident of Petersburg, Va., who died in New York during 1919. He is survived by his five children, Frederick J., William W., and Edward C. Lucius, Mrs. William E. Goeringer, and Mrs. William Grimm.

Mr. Lucius was elected a Member of the American Society of Civil Engineers on March 3, 1886.

---

\* *Transactions, Am. Soc. C. E.*, Vol. LXXIII (1911), p. 136.

**WILLIAM HENRY LUSTER, Jr., M. Am. Soc. C. E.\***

---

DIED DECEMBER 12, 1928.

---

William Henry Luster, Jr., the son of William H. and Elizabeth H. (Yates) Luster, was born at Elizabeth, N. J., on October 11, 1863. He was descended on his father's side from old Colonial stock.

Mr. Luster's early school days were spent in Elizabeth, and his later education obtained at Rutgers College, New Brunswick, N. J., from which he was graduated in 1884 with the degree of Bachelor of Science. In 1890, he received the degrees of Master of Science and Civil Engineer from his Alma Mater.

Following his graduation from college, Mr. Luster was engaged from December, 1884, to December, 1887, as Topographer with the United States Geological Survey and from December, 1887, until 1890, as Assistant to the Division Engineer of the Morris and Essex Division of the Delaware, Lackawanna, and Western Railroad Company, in charge of the maintenance of way and construction of 10 miles of new road. In January, 1890, he entered private practice and was engaged on the construction of county roads in Union County, New Jersey, and in the vicinity of New York City. He had practically full charge of four miles of construction work and laid out and graded Colonial Park, N. J., for Mr. J. R. McPherson. During this period, he was also engaged on sewer construction and had charge of the building of coal pockets for Mr. L. M. Palmer, of Brooklyn, N. Y., as well as foundations of the power house for the Edison Electric Illuminating Company, at Bay Ridge, N. Y.

In June, 1896, he was appointed a Topographer with the New York State Land Survey, which position he retained until June, 1899, when he was elected City Engineer for Elizabeth, N. J. In this capacity he had complete charge of the design and construction of public works the value of which was more than \$500 000. From January, 1913, to November, 1926, he was engaged in private practice as Engineer for the Towns of Roselle Park, Roselle, and Hillside, N. J. He made the plans for the sanitary sewer for the latter town, which finally was completed successfully by him in November, 1928.

Mr. Luster was a member of the Chi Phi Fraternity, the American Road Builders' Association, and the American Society of Municipal Improvements. He was also a Director of the Citizens' Building and Loan Association of Elizabeth and a senior partner of the firm of Luster and Luster. Aside from these affiliations, Mr. Luster was interested in hunting, photography, traveling and fishing, and, as a hobby, took great delight in the making of fine fishing rods. He was a Democrat in politics, a Rotarian, and a member of the Presbyterian Church.

In December, 1889, Mr. Luster was married to Bertha Overton Looker, of Elizabeth, who, with two sons, Clifton H. and Eric W., survives him.

Mr. Luster was elected an Associate Member of the American Society of Civil Engineers on October 3, 1900, and a Member on April 2, 1902.

---

\* Memoir prepared from information on file at the Headquarters of the Society.

## ALEXANDER MacDONALD, M. Am. Soc. C. E.\*

DIED MAY 11, 1929.

Alexander MacDonald, the son of John and Anne (Fraser) MacDonald, was born in Inverness, Scotland, on March 17, 1877. He was one of seven children. He received his early education in the public schools of his native city and was graduated in 1895 from the Nairn Academy.

Mr. MacDonald came to America in 1900, and started to work in New York, N. Y., as a street-car conductor, studying engineering through a correspondence school in the evenings. In 1902, in response to an advertisement, he entered the employ of E. W. Hess, M. Am. Soc. C. E., of Clearfield, Pa., as an Assistant Engineer. He remained with Mr. Hess until September, 1904, when he entered the Rensselaer Polytechnic Institute, at Troy, N. Y., to take a special engineering course. At Rensselaer, he achieved the honor of being the first President of the Class of 1908; he was also a member of the Rensselaer Society of Engineers.

In 1905, Mr. MacDonald left Rensselaer Polytechnic Institute, going back to the employ of Mr. Hess, at Clearfield, and until 1909, he had charge of a Field Engineering Corps on railroad location and construction, the installation of water lines and water supply reservoir, and the development of coal and clay mines and of maps pertaining thereto.

Mr. MacDonald was engaged by the North Western Mining and Exchange Company, of Du Bois, Pa., in 1909, and, until 1911, had charge of the making of a complete survey of 3 500 acres of coal land, diamond drilling, and location, the making of plans of a new shaft, with the necessary buildings and equipment using electric power. He received a promotion in 1911, being made Chief Engineer of the North Western Mining and Exchange Company and of the Blossburg Coal Company, at Du Bois, subsidiaries of the Erie Railroad Company, with holdings of approximately 90 000 acres of coal, oil, and gas lands. His duties included the supervision of mine projections and development, the design and construction of a steam turbine-driven central power plant, transmission lines and sub-stations, and all other equipment incidental to an electric mining operation. He remained in this position until 1917, when he became Chief Engineer for the Pine Run Coal Company, at New Bethlehem, Pa., where for a year he had charge of the location and drilling of gas and oil lands, in addition to the development of the mines of this Company.

In 1918, Mr. MacDonald became Chief Engineer of the Keystone Coal and Coke Company, of Greensburg, Pa., which at that time owned twenty plants. In 1922, this Company purchased the coal holdings of the Jamison Coal and Coke Company in the Greensburg Field and the addition of this property, which adjoined the original holdings, presented an interesting problem in economy of power, by centralizing the power consumed at nine of the plants located within a reasonable distance of each other. Mr. MacDonald also recommended the purchase of power from the West Penn Power Company

\* Memoir prepared by Allen S. Davison, Assoc. M. Am. Soc. C. E.

and built additional transmission lines and installed sub-stations, transformers, and metering equipment to consolidate the purchased power at a single metering point.

Although Mr. MacDonald's connection with the Keystone Coal and Coke Company continued until his death, on several occasions he had been called upon to act as Consulting Engineer on problems in Canada as well as in other parts of the United States.

Mr. MacDonald was considered one of the most capable mining engineers of Western Pennsylvania. He was a member of the American Institute of Mining and Metallurgical Engineers. He was also a member of the Hannastown, Greensburg, and Oakmont Country Clubs. He attended the Presbyterian Church.

On October 1, 1927, he was married to Florence Helen McDonald, the daughter of Mr. and Mrs. Frank A. McDonald, of Carnegie, Pa., who survives him. He is also survived by his parents, four sisters, and two brothers.

Mr. MacDonald was elected a Member of the American Society of Civil Engineers on January 17, 1927.

## DAVID EDWARD McCOMB, M. Am. Soc. C. E.\*

DIED JANUARY 27, 1929.

David Edward McComb, the son of James E. and Martha (Jorden) McComb, was born on August 23, 1850, at Chelsea, Mass. On one side of the family he was of Scotch ancestry, his father having been born in Scotland; on his mother's side he was of French lineage. His father, a school teacher, died in 1852 and, in 1855, the family moved to Washington, D. C., which thereafter was Mr. McComb's home.

He attended private and public preparatory schools in Washington until he was fifteen years of age. In 1865, he entered the Navy Yard at Washington, as a Minor in Steam Engineering, an educational course provided by the Navy Department at that time for the training of candidates for commissions as Steam Engineers. After three years of this class work, however, Congress provided, in 1868, that future appointments to such commissions should be made only from graduates of the Naval Academy at Annapolis, Md.

Mr. McComb's training, thus interrupted in 1868, had consisted largely in experimental work under William Shock, Chief Engineer, U. S. Navy, on strains in Bessemer steel, and under S. M. Green, U. S. Navy, on calorific conductivity of boiler-plate materials. He also completed a two years' course in higher mathematics and modern languages at Columbia College, now George Washington University, in Washington. From 1868 to 1870, he was engaged under John A. Coli, Civil Engineer, in Washington, on general city work; in 1870, as Assistant to John A. Partridge, on the construction of the Baltimore and Potomac Railroad; in 1871, as Assistant to the late Thomas Doane, M. Am. Soc. C. E., on the construction of the Burlington and Missouri River Railroad, in Nebraska; in 1872, as Topographer on the Jersey Shore, Pine Creek, and Buffalo Railroad, and as Engineer in Charge of the Fredericksburg, Orange and Charlottesville Railroad; and in 1873-74 as Resident Engineer on the Washington City and Point Lookout Railroad.

He entered the municipal engineering service of the District of Columbia on September 1, 1874, and continued therein except for a four-year interval, until his retirement on reaching the age limit on August 20, 1928—a half century of professional service to this municipality. The first thirty-four years of this service, from 1874 to 1908, was in the Sewer Division, of which he became Superintendent in 1888. As such, he devised a formula, based on the experimental work of Burkli-Ziegler, modified to suit local conditions, which is still applied as well as the Kutter formula, to drainage design in the Department.

Following extensive inspections of the existing sewage disposal installations in the United States, England, and France, Mr. McComb recommended a disposal project for Washington in 1890, the engineering elements of which were followed, with but little material variation, by the report made later in that year by a board of sanitary engineers appointed from the country at large by the President to consider this subject. The trunk drainage and sewer

\* Memoir prepared by C. B. Hunt, M. Am. Soc. C. E.

mains, subaqueous crossing of the Anacostia River, the subaqueous outlet system and sewage pumping station constituting this disposal project were located, designed, and constructed under his supervision.

On May 15, 1908, Mr. McComb was appointed Chief Engineer of Sewer and Paving Work in Havana, Cuba, where he served as such for four years, the appointment having been made during the period of the second American intervention. During his incumbency in this position he practically completed the subaqueous sewer crossing of Havana Harbor, the sewage pumping station and the tunnel under Cabanas Ridge, as well as many of the urban sewers and also the beginning of the paving of the city street system. His selection for this duty was made by Colonel William M. Black, Corps of Engineers, U. S. A., M. Am. Soc. C. E. (now Brigadier-General, U. S. A. (Retired)), Adviser of the Department of Public Works of Cuba, based on his knowledge of Mr. McComb's high professional ability and uncompromising integrity of character.

On July 1, 1912, Mr. McComb returned to the municipal service of the District of Columbia as an expert on asphalt paving work in connection with the contemplated establishment of a municipal asphalt plant; at the conclusion of this duty, on January 1, 1913, he was appointed Engineer of Bridges, a position that he held with distinction for fifteen years until his retirement on account of age. Under his supervision during this period were the structural features of the Dumbarton Bridge, the Meigs Bridge, the Benning Road Viaduct, the South Dakota Avenue and Van Buren Street Bridges over the Baltimore and Ohio Railroad, and many wharves, trestles, and analogous works constructed by the municipality.

Mr. McComb's professional work was marked by sound knowledge of principles, conservative design, conscientious care in execution, and remarkable integrity of administration.

His outstanding personal characteristic was rugged honesty. The circle of his friends was large and he held them throughout his life. He was fond of many sports; playing baseball with notable skill; bicycling throughout Europe and many parts of the United States; and in his later years becoming an enthusiastic golfer. He was affiliated with the Washington Society of Engineers, of which he was a Charter Member, the Capital Bicycle Club, and the Columbia Golf Club.

Mr. McComb was married on August 28, 1877, to Theresa M. Maher who pre-deceased him on March 9, 1924. A daughter, Mary E. (McComb) Fries, survives. He was a devout member of the Roman Catholic Church.

Mr. McComb was elected a Member of the American Society of Civil Engineers on February 7, 1877. His period of membership, extending within a few days of fifty-two years in length, was exceptional and notable; and he left but very few living Society members in date of membership senior to him.

## CHARLES NEIL McDONALD, M. Am. Soc. C. E.\*

DIED JULY 5, 1929.

Charles Neil McDonald, the son of Alexander and Johanna McDonald, was born on August 25, 1862, near Sidney, Nova Scotia. As a boy he attended the grade schools of Sidney, and there, too, he served an apprenticeship as a carpenter.

In 1882, after living for a short time in Boston, Mass., Mr. McDonald moved to the Dakotas, where he was employed as Bridge Carpenter and Bridge Foreman by the St. Paul, Minneapolis, and Manitoba Railway Company (now a part of the Great Northern Railway Company).

In 1884, Mr. McDonald moved to the Far West and located at Celilo, Ore., where he entered the employ of the Oregon Railroad and Navigation Company as Bridge Foreman on the construction of stone, concrete, iron, and timber bridges.

In 1890, he was appointed Superintendent of Construction for Robert Wakefield and Company, Contractors, of Portland, Ore., and for eighteen years he continued in active charge of all the numerous large construction projects undertaken by that firm. During this period, Mr. McDonald's work covered a wide scope and included docks and harbor improvements at various points along the Pacific Coast, numerous bridges for the Union Pacific System, all the bridges on the Astoria and Columbia River Railway, and several large structures for the City of Portland. He was also retained from time to time to represent the Chief Engineer of the Oregon Railroad and Navigation Company in the execution of difficult bridge foundations and in the solution of various erection problems.

In 1908, his activities carried him into the Far North. He associated himself with the Copper River and Northwestern Railway Company which was being extended into the interior of Alaska, and was placed in charge of all the bridge construction on that line.

This work, which included the famous Miles Glacier Bridge and the Kusko-lina Cantilever, was crowned with notable success in the face of most adverse circumstances. Operations were carried on far from a base of supplies; the season of the year in which climatic conditions were favorable for construction was limited to only a few months; and the work had to go on during the long stormy winters of the Copper River country and in temperatures almost unbelievably low.

Large masses of ice are discharged from Miles and Child's Glaciers into the Copper River during the summer months, and for that reason the Miles Glacier Bridge which crosses that stream was originally designed for cantilever erection. To advance the opening of the railroad a full year, however, the plan was changed, and it was decided to carry on substructure work during the winters and, at the same time, to erect the spans of falsework supported on ice. The plan was a success. The ice moved out in an unusually early spring thaw

\* Memoir prepared by S. Murray, M. Am. Soc. C. E.

just twenty minutes after the bridge was self-supporting. This dramatic incident is well described in Rex Beach's novel, "The Iron Trail."

In 1912, Mr. McDonald returned to Portland and again associated himself with Robert Wakefield and Company. For several years he was the active head of that firm in charge of the execution of important river and harbor work and large bridge projects, involving the expenditure of many millions of dollars. Included in this work was the erection of the Harriman Bridge (double-deck railroad and highway lift) across the Willamette River, at Portland, and the Interstate Bridge across the Columbia River, at Vancouver, Wash.

In 1920, he became Vice-President of the Gilpin Construction Company of Portland, and, from that time until his death, he directed its more important operations, among which were bridges across the Columbia, Willamette, and other large rivers of the Pacific Northwest.

Mr. McDonald possessed to a rare degree the good judgment that is acquired only in the stern school of experience, but he combined with it a technical knowledge and designing ability worthy of a man of great formal training. His counsel was sought by many, especially by the younger men, whom he seemed to understand. His life was marked by a succession of great achievements, bold and daring in conception, taxing amazing resources of skill and energy in execution, yet uniformly successful in realization.

Deeply religious, and of a modest and retiring disposition, generous, honorable, and upright in all things, he was an inspiration to those who came in contact with him. No man was loved more by his associates. His passing has left an empty place which they feel can never quite be filled.

In 1890, he was married to Carrie Harrison, who survives him, together with two daughters, Mrs. Joan Atwater, of Eugene, Ore., and Mrs. Jessie Acklen, of Raymond, Wash.

He was a member of various Masonic bodies and other fraternal orders, and was affiliated with the Methodist Episcopal Church.

Mr. McDonald was elected a Member of the American Society of Civil Engineers on January 17, 1927.

## LOUIS RANDOLPH McLAIN, M. Am. Soc. C. E.\*

DIED JANUARY 9, 1926.

Louis Randolph McLain was born at Washington, D. C., on March 13, 1846, the son of the Rev. William McLain and Mary (Mosby) McLain. His early education was obtained in the schools of Washington, the home of his parents. Later, he entered Hamilton College, Clinton, N. Y., with the Class of 1865, but left at the expiration of his Junior year.

Mr. McLain's first engineering assignment was in December, 1869, when he entered the service of the South Trans-Continental Railroad Company as Draftsman and Office Assistant. In 1870 he was made successively Rodman, Transitman, and Leveler, being engaged on preliminary surveys and location until the consolidation of that road and the Southern Pacific Lines under the name of the Texas and Pacific Railroad Company. Thereafter, until January, 1872, he was Resident Engineer for the Jefferson Division of the latter road, resigning to engage in railroad and other construction work, which continued until 1876. In March of that year he was made Resident Engineer of the New Orleans Pacific Railroad Company, remaining in charge of construction until suspension of the work in June, 1878. He then located and superintended the construction of the Kanomie Narrow Gauge Railroad from Bayou Bouf to Kanomie Landing, on the Red River, Louisiana.

Following its construction, he operated the road until January, 1879, when he resigned to become Assistant United States Engineer of South Pass Jetties, at Port Eads, La. On the completion of this work in August, 1879, he was engaged as Assistant in the improvement of the James River, Virginia. Later, in March, 1880, he was made Resident Engineer for the Becharant and Clifton Forge Division of the Richmond and Allegheny Railroad, now a branch of the Chesapeake and Ohio Railroad.

This work being finished, Mr. McLain became Division Engineer of the Georgia Pacific Railroad Company, now that part of the Southern Railway System connecting Atlanta, Ga., and Birmingham, Ala. Thereafter, his activities were centered in Florida. In 1884, he was made Assistant Chief Engineer of the South Florida Railroad Company, now a part of the Atlantic Coast Line, running from Sanford to Tampa, Fla. When this road was completed in 1885, he was appointed Maintenance of Way Engineer, resigning two years later to enter the field of railroad construction, active at that time in the South.

During the next ten years, Mr. McLain constructed railway lines from Thomasville, Ga., to Montgomery, Ala.; from Thomasville, to Monticello, Fla.; from Savannah to Tybee, Ga.; and in addition a line from Savannah to Columbia, S. C., now a part of the Seaboard Air Line System.

In 1898, he turned his attention to hydraulic mining of pebble phosphate in Polk County, Florida, building, equipping, and operating successfully a plant, conceded by every one having knowledge of the industry, to be the most

\* Memoir prepared by R. F. Smith, Esq., Miami, Fla.

complete in Florida. Later, in July, 1903, these interests were sold to Savannah capitalists, representing the Peace River Phosphate Company.

Mr. McLain's retirement from active work followed the sale of his phosphate interests. He then opened an office as Consulting Engineer in St. Augustine, Fla., where he made his home, representing, among others, Belgian capitalists in the direction of their Florida mining enterprises until 1917.

Aside from his professional activities and mining enterprises, Mr. McLain maintained, from 1890 to 1920, a controlling interest in two banking institutions in Florida and Alabama. The success of these, through a long period of years, was largely due to his sound judgment and wise leadership.

Mr. McLain was married on April 29, 1897, to Harriott Rutledge Ravenel, the daughter of Dr. St. Julien Ravenel and Harriott Horry Ravenel, of Charleston, S. C.

He was a member of the St. Augustine Golf Club, the St. Augustine Yacht Club, and the Commonwealth Club of Richmond, Va.

His long, useful life was characterized by thoroughness in the discharge of every undertaking and a sensitive loyalty to his friends and the interests that he served.

Mr. McLain was elected a Member of the American Society of Civil Engineers on February 2, 1881.

**GEORGE COTNER MASON, M. Am. Soc. C. E.\***

---

DIED MARCH 10, 1929.

---

George Cotner Mason, the son of James R. and Mary W. (Cotner) Mason, was born in New York, N. Y., on May 4, 1871. He received his early education in the public schools of New York and was a student in Civil Engineering at New York University from which he received the degree of Bachelor of Science in 1892, Civil Engineer, in 1893, and Master of Science, in 1894.

From 1892 to 1904, Mr. Mason was engaged as Assistant Instructor and Assistant Professor in Civil Engineering at New York University. During this period he laid out its grounds, buildings, and sewer system, and was also employed as Engineer in charge of the erection of the Young Men's Christian Association Naval Branch Building, in Brooklyn, N. Y., the Army Branch Building, at Fortress Monroe, Va., and a residence, stable, and riding ring for Mr. Frank J. Gould, in New York.

In 1904, Mr. Mason moved to Portland, Ore., where he organized the Hurley-Mason Company, serving as its Vice-President and Chief Engineer. The Company was engaged in engineering and contracting work, with offices in Portland and in Seattle, Tacoma, and Spokane, Wash. It completed many important contracts in the Pacific Northwest, notable among which are the Oak Grove Hydro-Electric Plant of the Portland Electric Power Company and Camp Lewis, a 45 000-man Army Cantonment, near Tacoma. The latter was a World War activity and was completed in record time.

The Hurley-Mason Company also constructed many important buildings and structures throughout the Northwest. Among these are the Todd Shipbuilding Plant and the Northern Pacific Railway Station, in Tacoma; the U. S. Veterans' Hospital, at American Lake; the Seattle Construction and Dry Dock Plant, in Seattle; the Sherwood Building and Elks Temple, in Spokane; the Lewiston Hotel, in Lewiston, Idaho; and the Electric, Board of Trade, Gas Company, and Lipman-Wolfe Buildings and the Portland Flouring Mills, in Portland.

In 1926, Mr. Mason retired from the Company and, until his final illness, was engaged in the private practice of his profession, with offices in Portland.

He took a keen interest in civic matters and served as Civil Service Commissioner for the City of Portland from 1916 to 1925. He was also active in the affairs of the Society and was particularly interested in the development of the Student Chapters and in the establishment of closer relations between the profession and the students during their college years. He represented District No. 12 as a Director of the Society from 1923 to 1925.

Mr. Mason was an engineer of independent and courageous judgment, thorough and painstaking in all his work, and these characteristics are evident in the many structures built by his Company.

---

\* Memoir prepared by Ben S. Morrow, Assoc. M. Am. Soc. C. E.

In 1900, he was married to the daughter of a prominent pioneer family of Portland, M'Iss McCracken, who, with one son, Henry M. Mason, Jun. Am. Soc. C. E., survives him.

Mr. Mason was elected a Junior of the American Society of Civil Engineers on March 6, 1894; an Associate Member on May 3, 1899; and a Member on September 1, 1908.

**GEORGE THOMAS MAWSON, M. Am. Soc. C. E.\***

DIED OCTOBER 9, 1928.

George Thomas Mawson was born at Cockermouth, Cumberland, England, on January 14, 1881. Educated at the Carlisle Grammar School, the youth was then articled as a pupil to George Watson and Sons, Architects and Surveyors, Penrith, England, from 1897 to 1900. From this source he received his technical education in the design and construction of public and private buildings and on various municipal undertakings.

In August, 1900, Mr. Mawson went to India to join his brother Mr. E. O. Mawson, of the Public Works Department, where he spent some time on famine relief work in the Rajkot District. He later acted as Personal Assistant to the Under Secretary to the Government Public Works Department of Bombay, on the design and construction of large dams, canals, aqueducts, and irrigation in connection with Government famine relief measures.

In 1903 he joined C. F. Stevens, Architect, in Bombay, as Chief Assistant in charge of the office and superintendence of work. In this position he was engaged on the design and construction of many large banks and churches in that city.

In December, 1903, Mr. Mawson became associated with Messrs. Marsland Price and Company, as head of the Poona Branch. During this service he carried out chiefly Government and public works to the value of \$400 000; he held this position until September, 1912, when he was transferred to Bombay, as General Manager, a position he retained until he founded his own firm of Messrs. Mawson, Vernon and Company, in 1919, of which he was Governing Director, until his retirement in June, 1927.

The following is a list of a few of the buildings with which Mr. Mawson was associated in Bombay: The bank building for Messrs. King, King and Company, the Chartered Bank of India, the Mercantile Bank, the Hong Kong and Shanghai Bank, The Times of India, the Church Missionary Society's Building, St. Peter's Church, the British and Foreign Bible Society, the Royal Insurance Company, the Light-foot Refrigerating Company, Limited, and the Free Masons Hall.

In the latter part of his professional career Mr. Mawson was closely identified with reinforced concrete construction, and it may be truly said that he was one of the pioneers of this particular class of work in India. In 1922, he was selected to act on a committee appointed by the Government, which had for its terms of reference,

"To investigate the utility of Reinforced Concrete for structures in Bombay City by examining such structures as have been in existence for more than 8 years and reporting on their condition, as well as the probable reasons for the corrosion of the steel in any such structures which may be found to be defective."

Thoroughness in all he undertook was the keynote of Mr. Mawson's life. No detail was too small for his personal attention, and clients entrusting

\* Memoir prepared by W. Shedden Sinclair, Esq., Bombay, India.

work to him, regardless of its nature or size, had every confidence that they were receiving unprejudiced as well as highly technical advice; they felt assured that their interests were safe in Mr. Mawson's hands. He could have extended his business very considerably, but he regulated the number of his contracts so that he could give each one his personal attention and supervision.

Despite his many professional activities, Mr. Mawson interested himself in all questions relative to engineering. He was a Vice-President of the Bombay Branch of the Institute of Engineers (India), a member of the Bombay Engineering Congress, and was, at all times, ready and willing to give ungrudgingly and cheerfully of his best to the many who sought his aid and advice.

As a member of both English and Scottish Constitutions of Free Masons, he made a wide circle of friends among all classes. He gave much in an unostentatious way to charity and his early death in the prime of life is deeply mourned; India is indeed poorer by the passing of one, who did much toward maintaining and enhancing the highest traditions of the Engineering Profession.

Mr. Mawson is survived by his widow, who was closely identified with his professional career as a Co-Director of his firm, the Mawson Vernon Company, Limited, and with whom much sympathy is felt in her great loss.

Mr. Mawson was elected an Associate Member of the American Society of Civil Engineers on June 30, 1911, and a Member on October 10, 1927.

## FRANK MOBERLY, M. Am. Soc. C. E.\*

DIED JULY 13, 1928.

Frank Moberly was born in Barrie, Ont., Canada, on July 19, 1845. Educated in both Canada and England, he was a student of law from 1861 until 1863. In 1864 he was the recipient of the First Class Military School Certificate.

Mr. Moberly's first engagement was from 1863 until 1866 in the Engineering Department of the Northern Railway Company of Canada. His work consisted of surveying and similar details; and during the latter part of this engagement he went with the late Sanford Fleming, M. Am. Soc. C. E., as Assistant on Construction of the railway from Picton to Truro, Nova Scotia, Canada. During these years he also served as an Ensign in the Second Administration Battalion on the Niagara Frontier in answer to Canada's first call for volunteers. He was later commissioned as Justice of Peace for the Northwest Territories and the District of Thunder Bay.

In 1867, Mr. Moberly was employed by the Chicago, Rock Island, and Pacific Railway Company on surveys and construction work throughout Western Iowa, but he left this Company in the summer of 1868 to join a location party on the Union Pacific Railway through Utah and Nevada, later being placed in charge of this party. During the winter of 1868 he was transferred to construction work in Weber Canyon, Utah, and remained on this work until its completion in the fall of 1869.

He entered the service of the Milwaukee, Manitowoc, Appleton, and New London Railway Company, in the spring of 1870, in charge of location north of Milwaukee, Wis. He left this position in May of the same year to become Assistant Engineer on exploration of mountain passes for the Northern Pacific Railway Company through the States of Montana, Idaho, and Oregon. Returning to Canada in the fall of 1871, Mr. Moberly was made Assistant on the location of the Muskoka Junction Railway Company from Barrie to Atherly, Ont., Canada, and of the North Gray Railway Company from Collingwood to Meaford, Ont., Canada, leaving that position in May, 1871, to take charge of the first exploration parties for the Canadian Pacific Railway Company from Fort Garry to the Howse and Yellowhead Passes. He also conducted exploration through the territory north of Lac La Biche and through the Lake Dauphin Country which extended north of the Riding and Duck Mountains, all in Manitoba.

In 1872, he went to Ottawa, Ont., Canada, and accepted the appointment of Assistant to Mr. William Murdoch, of the Canadian Pacific Railway Company, who was outfitting a party to proceed to Fort William, Ont., Canada, to make the first survey and the first location of the Canadian Pacific Railway, from that point westward to Savanna, Ont., Canada, over which the road was subsequently built without alteration. This trip to Fort William was a decidedly adventurous one and entailed a hazardous journey over 200

\* Memoir prepared from information on file at the Headquarters of the Society.

miles of waterways from Duluth, Minn., down Lake Superior in an open boat. It was at this time that Mr. Moberly received the distinction of being awarded the Dominion Government Medal for the daring rescue of the passengers and the crew from the propeller, *Mary Ward*, which met with disaster in November, 1872, in Georgian Bay.

From this time until 1920, Mr. Moberly was active in the following pursuits: In 1875, he was engaged in making an exploration of the country from Gravenhurst to Lake Nipissing for the extension of the Muskoka Junction Railway; in 1876 and 1877, he located and built the Prince Arthur Landing and the Kaministiquia Railway to connect what are now Port Arthur and West Fort William; in 1878, he was Engineer of the Mineral Hill Silver Mine in Nevada; in 1879, Division Engineer with the Canadian Pacific Railway Company surveying and building the line from the mouth of the Nipigon River to the north end of Long Lake and then, in turn, from Long Lake to Missinaibi, Ont., Canada, which was later rebuilt by the Canadian Northern Railway Company; during the summer of 1880 he was engaged on the survey for the Newfoundland Government of a railway line from St. John, New Brunswick, to Harbor Grace, Newfoundland; in 1881 he took charge of the location and construction of the Pambina Mountain Branch of the Canadian Pacific Railway and, subsequently, became Chief Engineer of the Northern Pacific Junction Railway of Ontario; in 1882, he made an exploration, for the Canadian Pacific Railway Company, of the crossing of the South Saskatchewan River at the Elbow and of a line up the Red Deer River; in 1884, he took a contract for the grading of six miles of railroad eastward from the Pie River, which was followed by his accepting the appointment of Commissioner of Police by the Dominion Government, with jurisdiction over Ontario, and his being sent to restore order after the riots in Michipicoton, Ont.; and in 1887 he completed the railroad to Sault Ste. Marie, Ont., Canada.

In 1891, and extending over a period of five years, Mr. Moberly was engaged in various private undertakings. In addition, he made a survey of Collingwood Harbor for the Department of Railways and Canals of Canada, and was active also in the construction of the St. Lawrence and Adirondack Railway, as well as surveying and promoting an air line from Toronto, Ont., to Collingwood; in 1896, he went to Rossland, B. C., Canada, where he was engaged in prospecting east and west of Kootenay, and in part of the Yale Districts, as well as on the construction of Red Mountain Railway into Rossland, and on the location of the Crows Nest Pass Railway, along the shore of Kootenay Lake. In 1900 he was employed with the Department of Lands and Works of British Columbia, having charge of one of two parties sent out by the Government to make surveys of passes through the Hope Mountains, which, to that time, had been considered impracticable for a railroad; in 1902, he made estimates for such a passage through these mountains and their boundary country and also plans for a railway to Dease Lake in Northern British Columbia; in 1903, he had charge of the construction of the Prince Albert Branch of the Canadian Northern Railway, from Erwood to Melfort, Sask., Canada; from 1904 to 1909, he was in charge of party on preliminary and location surveys for the National Transcontinental Railway Company,

east of Cochrane, Ont., Canada, and along the north shore of Lake Abitibi extending eastward to the Harricanaw River; and from 1910 to 1912, he made explorations and reports on the capabilities of the great clay belt for the Chairman of the Temiskaming and Northern Ontario Railway Company.

In 1913, Mr. Moberly was appointed Assistant Engineer of the Department of Public Works of Canada, for which he had charge of the territory in the Midland District and also of that around Toronto. He later was made Acting District Engineer at Midland, and Barrie, Ont., which latter place he made his home after his retirement. Altogether, Mr. Moberly was in the service of the Government of Canada for about twenty-three years which period terminated in 1920, when he retired from active work. During this time he had practically explored the Dominion from coast to coast, opening it up for settlement, and making way for its widely expanding civilization.

Coupled with Mr. Moberly's professional services and experiences during the period extending from 1880 to 1915 was a definite and continuous service on his part in civil duty to the State. The following includes some of his positions in this connection: Provincial Magistrate for the Province of Manitoba; Reeve of Neebin Municipality, District of Thunder Bay; Commissioner of Police under the Police Act of Canada for Ontario; and Commissioner under Peace Preservation on Public Works Act; Justice of Peace for the Province of British Columbia; Magistrate for the Province of Quebec; Police Magistrate for the District of Nipissing; Justice of Peace for the County of Simcoe; and President of the County of Simcoe Home Guard Rifle Association.

In 1874, Mr. Moberly was married to G. A. McIntyre, the daughter of John McIntyre, a Hudson Bay Officer at Fort William, Ont. Mrs. Moberly died in 1880, and, in 1882, Mr. Moberly was married to Mary McIntyre, a sister of his first wife, by whom, with two daughters and two sons, he is survived.

Mr. Moberly's entire life is an expression of pioneering in Canada when the Dominion's future was much less assured than it is to-day. To have been an explorer all his days, in itself, lends a glory and a romance to his name. He was a pioneer in the greater sense of the word, in that he did not settle on a small clearing of land and thereby establish a permanent comfortable home, but was ever blazing new trails in virgin country—leaving the secure and certain to encounter the risk of the unknown. He surveyed railways, hunted criminals, started clearings, dug mine shafts, and endured the prairie winter in tents, ever measuring the uncalculated and keeping continuously in the forefront of civilization; this was his life. John F. Stevens, Past-President, Am. Soc. C. E., extends to Mr. Moberly and his associates the following tribute:

"The railways—indeed, civilization itself—owes a debt of gratitude to the pioneer engineers who blazed the way through trackless wildernesses to make homes for thousands who followed them."

Mr. Moberly was elected a Member of the American Society of Civil Engineers on October 7, 1903.

**ALEXANDER BAIN MONCRIEFF, M. Am. Soc. C. E.\***

DIED APRIL 11, 1928.

Alexander Bain Moncrieff was born in Dublin, Ireland, on May 22, 1845, a descendant of an old Scottish family of Perth which numbers among its members a noted lawyer, a famous divine, and many others distinguished in military and civil affairs.

Mr. Moncrieff spent several years at the Belfast Academy, after which he was articled to the late Mr. E. Miller, Chief Engineer of the Great South-western Railways in Ireland. He served his apprenticeship in the railway shops at Inchicore, Dublin, and had seven years' experience in the workshops and in the office of the same Company. This period included twelve months spent in the blacksmith's shop, where he worked from 6:00 A. M. until 5:00 P. M., in close contact with a side of life that developed in him a feeling of keen sympathy for his fellow workers, to whom he always said he owed a great deal.

At the close of this training and experience Mr. Moncrieff went to Glasgow, Scotland, as Draftsman for the Dubbs Works, at Govan, where he was engaged mainly on the design and construction of locomotives. Because of business changes, he returned to Ireland and took charge of the rebuilding of a large water-driven flour-mill and malthouse at Milford-on-Barrow. On the completion of this work, Mr. Moncrieff assumed charge of a small workshop in London, England. After a short interval, however, he answered an advertisement issued by the South Australian Government for an efficient Draftsman. His application met with immediate success and he accordingly took ship to Australia, where he arrived in February, 1875. As Engineering Draftsman he was chosen to assist in the design of fortifications and in this capacity he was obliged to travel to Melbourne, Sydney, and Brisbane, Australia.

In 1879, Mr. Moncrieff was appointed Resident Engineer of the South Australian Railways, taking charge of the line as it was gradually extended from Port Augusta to Oodnadatta. In 1888, on the retirement of the late H. C. Mais, M. Am. Soc. C. E., he was promoted to the office of Engineer-in-Chief, which position he held for twenty years. In addition to his duties in the Railways Department, he had charge of the construction and maintenance of harbors, jetties, and lighthouses, as well as the construction of water-works and the conservation of water. The construction of the Happy Valley Water Works and of the Outer Harbor, Adelaide, are two outstanding monuments to his ability, determination, and zeal—true evidences of engineering achievement of which any engineer might justly be proud. They stand as silent memorials to a career of exceptional usefulness and conscientious public service.

On the retirement of the late Mr. Alan G. Pendleton, Mr. Moncrieff succeeded to the office of Railways Commissioner. As such, he served under nineteen Commissioners of Public Works, from all of whom he received hearty support in his work. Under Mr. Moncrieff's supervision many improvements were accomplished, including the completion and putting into service of the

\* Memoir prepared from information furnished by Alex. S. Moncrieff, Esq., Adelaide, South Australia.

Mile-End Goods Yard, by which means up-to-date freight accommodation was provided for the City of Adelaide and its suburbs; new siding accommodations at Port Adelaide; the installation of appliances for the prevention of fire at railway stations; the improvement of sanitary arrangements at stations and of the facilities on the Woodville and Henley Beach Lines; the increase in and the improvement of the rolling stock of the railways; the fitting of the Westinghouse brake to a large number of freight trucks, which made possible the delivery of parcels in the suburban area by motor vehicles; the establishment of an inquiry office at the Adelaide Railway Station (an opportunity was also given the apprentices to improve themselves by attending classes at the School of Mines); the placing of railway fares on a scientific basis; the teaching of first aid to a large number of the staff and the planting of gardens at stations which was encouraged wherever possible. Mr. Moncrieff also was the "father" of the South-Eastern Drainage Project in which he took great interest and which at its inception he personally explained to conferences of landholders held at Narracoorte and Millicent, Australia, ensuring their hearty support of his proposals.

In 1916, after forty-two years of service in several capacities, Mr. Moncrieff retired as Railways Commissioner. During this entire period his only vacations were those spent in traveling on Departmental business. When asked once by a representative why he did not take a holiday he replied, "I do not feel that I need a holiday and the fact that I have never been ill proves it." Mr. Moncrieff was a living justification of the gospel of hard work.

He was the first Chairman of the Municipal Tramways Trust and held this position from its inception in 1907 until January, 1922. He was a member of the Institution of Civil Engineers of Great Britain, and in December, 1909, under the hands of the King of England, was made a Commander of the Order of St. Michael and St. George.

Until shortly before his death, Mr. Moncrieff had enjoyed the most robust health, taking a constitutional walk to and from the city several times a week. Also, before his retirement, he walked daily to his office from his home. He was a lay reader of the Church of England, and was greatly interested in church work. Gardening, reading, mechanics, and Free Masonry were also among his recreational pursuits and in these releases from his strenuous official career he found joy and relaxation.

Mr. Moncrieff was a man of decided opinions and of great personal force. The Secretary to the Railways Commissioner, Mr. C. J. Boykett, in referring to Mr. Moncrieff, has stated that officers who were intimately associated with him in practically all the positions he occupied testify to his outstanding capability, versatility, and energy displayed in carrying out his undertakings. He was held in high esteem for his gentlemanly and honorable conduct by all those with whom he was associated in the railway service, and was regarded with warm affection by those with whom he was more intimately acquainted. A true gentleman, kindly and most gracious by nature, his passing is mourned by a great company of associates and friends. He is survived by his widow, Mary Bronson Moncrieff, a son, and a daughter.

Mr. Moncrieff was elected a Member of the American Society of Civil Engineers on July 4, 1894.

**FRED FORREST MOORE, M. Am. Soc. C. E.\***

---

DIED JUNE 2, 1928.

---

Fred Forrest Moore was born in Waltham, Mass., on October 8, 1867, the son of Edwin F. Moore and Mary E. (Small) Moore. He received a part of his education in the public schools, leaving High School in order to prepare himself for the Massachusetts Institute of Technology, from which he was graduated in 1891 with the degree of Bachelor of Science in Civil Engineering. While he was attending college, his work attracted the attention of President Amasa D. Walker, who invited him to join the Teaching Staff, but Mr. Moore preferred the practice of his profession.

Previous to entering college, he had had considerable experience in surveying, and in 1890 and 1891, having been granted a leave of absence during the Institute term, he was in charge of a plane-table party on topographical surveys of lighthouse reservations along the Maine Coast. Directly upon graduating from the Institute, he joined the Engineering Force of the Boston Water-Works, for which he was engaged on the design of the Sudbury Dam and Reservoir. In 1896, this work was taken over by the Massachusetts Metropolitan Water Board, and Mr. Moore continued in charge of designs and estimates of the Headquarters Field Office. On the completion of this work, he became Principal Assistant to the Superintendent of the Sudbury Department with maintenance and operation duties.

From October, 1900, to April, 1902, as Assistant Engineer on filtration experiments for Springfield, Mass., Mr. Moore constructed plant and carried on experiments on slow sand filtration under the joint direction of the Massachusetts State Board of Health and the Consulting Engineer. From April, 1902, to February, 1903, he was engaged on designs for a concrete railway bridge and other structures connected with the Wachusett Reservoir built by the Massachusetts Metropolitan Water and Sewerage Board.

From February, 1903, to January, 1904, he served as Principal Assistant Engineer on studies, designs, and estimates for the Aqueduct Department of the Burr-Hering-Freeman Commission on Additional Water Supply for the City of New York. During the next three months, Mr. Moore held a similar position with the Northern New Jersey Flood Commission. From April, 1904, to September, 1905, he was Office Engineer, and from the latter date to April, 1906, Hydraulic Engineer, for the Committee of Twenty of the National Board of Fire Underwriters.

From April, 1906, until his retirement on March 2, 1928, Mr. Moore was a Designing Engineer for the Board of Water Supply of New York City. In this position he was in charge, under the Department Engineer, of studies and designs for cut-and-cover aqueducts, dams, and reservoirs, including landscape work, steel pipe siphons, distribution lines, and sewage disposal works.

He was a member of the Municipal Engineers of The City of New York, the New England Water Works Association, the Massachusetts Institute of

---

\* Memoir prepared by Franklin H. Robbins, M. Am. Soc. C. E.

Technology Alumni Association, the Masonic Fraternity, the Royal Arcanum, the Arkwright Club, and the Nannahagan Golf Club.

Mr. Moore was admired by his many friends for his kindly disposition, his fair dealing, and for the ability and energy which he devoted to his professional work. On October 5, 1896, he was married to Winnefred T. Wright, who survives him.

Mr. Moore was elected a Member of the American Society of Civil Engineers on April 3, 1907.

## ARCHY MAGILL NELSON, M. Am. Soc. C. E.\*

---

DIED JUNE 26, 1929.

---

Archy Magill Nelson was born at Green Mountain, Va., on November 1, 1862, the son of Archie M. and Eliza Price Nelson. He received his education at Washington and Lee University, Lexington, Va.

Mr. Nelson's early engineering experience was acquired in service with the Pennsylvania Railroad Company and on the Schuylkill Valley Railroad from 1882 to 1885, where he advanced rapidly from Axeman to Assistant Engineer in charge of construction and location. He remained with the Pennsylvania Railroad Company until 1890 in charge of heavy construction and difficult location work.

In succeeding years he was employed in the following positions. From 1890 to 1900, as Principal Assistant Engineer on the Kansas City Southern Railroad, having charge of location and construction of approximately 500 miles of that railway, including yard and terminal and division point layouts and facilities; from 1900 to 1908, with the Kansas City, Mexico and Orient Railroad Company, in charge of very heavy and difficult location in Old Mexico (the Sierra Madre Mountains), and of construction between Chihuahua, Mexico, and the Pacific; from 1909 to 1911, with the Oregon Short Line Railway Company, in charge of a resurvey of about 2 500 miles of line, and, later, as Valuation Engineer on the Oregon Short Line and Southern Pacific Lines East of Sparks, Nev. From 1916 to 1919, he served as State Highway Engineer of Tennessee.

Mr. Nelson was prohibited from active service in the World War on account of his age, despite the fact that his services were freely offered.

In 1919, following this period, he went to Memphis, Tenn., as County Engineer for Shelby County, acting as such until the fall of 1926. In addition to the opening, renewal, maintenance, etc., of many miles of county highway, with accompanying bridges, culverts, etc., Mr. Nelson designed and built numerous plants for the storage of gasoline and the storage and treatment of oils and other ingredients used in the carpet treatment of highways. A noteworthy piece of work was an 150-ft. reinforced concrete bridge over Nonconnah Creek on the Hernando Road.

In 1926, Mr. Nelson had planned to retire from active practice, but rather reluctantly consented to plan and build twin tunnels through Missionary Ridge, for Hamilton County, Tennessee. These tunnels were each more than 1000 ft. long, and of concrete construction. They were built for highway purposes and to develop suburban Chattanooga, and to connect that city more directly with Atlanta, Ga. The cost of the tunnels was approximately \$500 000. Mr. Nelson's death occurred just before the finishing touches were put on the work.

In 1909, he was married to Lucy Beesley, of Murfreesboro, Tenn., who survives him.

---

\* Memoir prepared by M. P. Paret, M. Am. Soc. C. E.

A member of the Protestant Episcopal Church he was much interested in later years in church work in Memphis. In his life and work he was intensely practical, his engineering experience and knowledge being largely acquired in the "University of Hard-knocks". He had an uncanny ability to meet emergencies successfully.

He was a devoted husband and a loyal friend, always considerate of and highly respected by his associates and employees.

Mr. Nelson was elected a Member of the American Society of Civil Engineers on October 4, 1910.

**ROBERT VAN ARSDALE NORRIS, M. Am. Soc. C. E.\***

---

DIED APRIL 20, 1928.

---

Robert Van Arsdale Norris, the only son of Thomas Braxton and Mary Latimer (Ruxton) Norris, was born in Newark, N. J., on May 2, 1864. He came of distinguished New England ancestry, being directly descended from Governor William Bradford, John Alden, and Timothy Dwight.

After a preparatory course in the Collegiate School of New York, N. Y., Mr. Norris entered the Columbia University School of Mines, and was graduated with the degree of Mining Engineer in the Class of 1885, a class that included in its membership a number of men who became distinguished in their professions. From among them, young Norris was selected as Assistant to Professor H. C. Munroe in the Summer School of Mining and Surveying, which engagement followed his graduation. In the latter part of 1886, after he had served a short time as an Inspector of dredging operations on the Maurice River, and in the Chemical Laboratory of Herman Behr, in Brooklyn, N. Y., he joined the Engineering Corps of the Susquehanna Coal Company, then owned by the Pennsylvania Railroad Company. Here he rose through sheer ability and hard work to the position of Chief Engineer in 1900, remaining until 1904, when he resigned in order to engage in private business as a Consulting Engineer. His judgment in making the venture proved sound, for he was eminently successful. Early in 1923 Mr. Norris took his son, Robert V. Norris, Jr., into partnership with him, under the firm name of R. V. Norris and Son.

That the exercise of sound judgment was such a characteristic of Mr. Norris as to pertain to the nature of a habit is attested by the fact that he was retained as Consulting Engineer by the Coal Department of the Delaware, Lackawanna and Western Railroad Company (afterward becoming an independent organization incorporated as the Glen Alden Coal Company), the Lehigh Valley Coal Company, Coxe Brothers and Company, Incorporated, the Coal Department of the Pennsylvania Railroad Company, the Wilkes-Barre and Hazleton Railroad Company, the Lehigh Coal and Navigation Company, the Sterling Salt Company, and other important interests.

Mr. Norris specialized in the examination and valuation of coal properties, his most important undertaking of this nature being probably the appraisal of the anthracite properties of the Pennsylvania Railroad Company, which eventuated in their sale, in 1915, to M. A. Hanna and Company, of Cleveland, Ohio, and the incorporation of the Susquehanna Collieries Company as the operating company for the Hanna anthracite properties. The year previous (1914), Mr. Norris had made a valuation report on six collieries of the Temple Coal Company. Other major, or valuation, reports made by Mr. Norris were on the properties of the Lehigh Coal and Navigation Company, in 1917; the bituminous coal properties of the Stonega Coal and Coke Company of Virginia and the Consolidation Coal Company of Mary-

---

\* Memoir prepared by Edward W. Parker, Esq., Philadelphia, Pa.

land, in 1920; the bituminous coal lands of the Cambria Steel Company, in 1922; the anthracite properties of Madeira, Hill and Company and of the Hazle Brook Coal Company, in 1923; the anthracite properties of the Hudson Coal Company, Delaware and Hudson Company, Delaware, Lackawanna and Western Railroad Company, and Lehigh Valley Coal Company, in 1924; Coxe Brothers and Company, Incorporated, the Scranton Coal Company, and the Elk Hill Coal and Iron Company, in 1925; and the Jeddo-Highland Coal Company, in 1926. He also served as arbitrator in many cases involving complicated technical problems.

Mr. Norris was not only an engineer; he had a special gift in cost accounting, and, in co-operation with Col. R. H. Montgomery, of Lybrand, Ross Brothers and Montgomery, prepared a system of cost accounting for anthracite operators. His facility with figures approached the uncanny. It took him but a short time to familiarize himself with the fundamentals of the Federal Income Tax laws as applied to the involved technicalities of anthracite production, and he served as an expert for a number of companies before the Tax Authorities, in Washington, D. C.

During the World War, Mr. Norris was called to Washington to serve as an adviser to the War Industries Board on fixing prices for anthracite and bituminous coal. Later, in association with Cyrus Garnsey, Jr., and James H. Allport, M. Am. Soc. C. E., he served as a member of the Engineers' Committee of the United States Fuel Administration. He became "a-dollar-a-year" man and, giving up his own practice, rented a house in Washington and moved his family there. His two daughters, then unmarried, served as ambulance drivers.

In his busy career Mr. Norris found time to give to others the benefit of his own knowledge and experience. At various times he was a non-resident lecturer on coal mining, both at his Alma Mater, Columbia, and at Harvard Universities. The *Transactions* of the American Institute of Mining and Metallurgical Engineers have been enriched by many of his contributions. He was a Councillor of the Institute from 1908 to 1910, Vice-President in 1911 and 1912, and a Director from 1920 to 1927. He served on numerous committees at various times and was ever enthusiastic and tireless in his devotions to that which he felt was for the best interests of the organization.

In 1914, Columbia University conferred upon Mr. Norris the honorary degree of Master of Science and in 1920 he was the '89 Medallist. He was always active in the Alumni affairs of the University. In addition to membership in the American Institute of Mining and Metallurgical Engineers, Mr. Norris was a member of the American Society of Mechanical Engineers, and of the Canadian Institute of Mining and Metallurgy. He was a member of a number of clubs, which included the University and Engineers' Clubs of New York, and the Cosmos and Chevy Chase Clubs of Washington.

He is survived by his widow, Esther Wadhams (Shoemaker) Norris, one son, Robert V. Norris, Jr., of Wilkes-Barre, and two daughters, Mrs. Jane N. Zerbey, of Pelham, N. Y., and Mrs. Esther S. Triest, of New York.

It falls to the lot of relatively few men to attain so eminent a position in their profession as that achieved by "Van" Norris in his chosen profession—mining engineering, specializing in anthracite mining.

At the time of his death, and for some years prior thereto, Mr. Norris was generally recognized as the dean of the profession in the anthracite region. When important problems were to be solved, were it the fighting of a bad mine fire, like the one at the Woodward Colliery of the Glen Alden Coal Company; the valuation of coal-mining properties for purposes of sale, or for other reasons, such as that of the Susquehanna Collieries Company by the Pennsylvania Railroad Company to the M. A. Hanna interests; the arbitration of a serious dispute involving engineering problems; the adjudicating of complicated income tax matters with the Federal authorities, or ordinary tax controversies with the State and local officials—whatever the difficulty—Mr. Norris was the one selected for the job. His unimpeachable integrity, scientific training, wide experience, and sound judgment commanded the confidence of those in whose interests he served as well as the respect of his opponents.

A brief sketch of Mr. Norris' life published in a technical journal,\* closes with the following words:

"An engineer of the highest rank, a man of the most upright character and of marked personality, he was held in high esteem by all who knew him, and his death at an age when he apparently had many more years of active public service before him will be deeply mourned."

This is indeed true; he is deeply mourned, and his profession lost a brilliant disciple when he passed away.

Mr. Norris was elected a Junior of the American Society of Civil Engineers on December 7, 1887, and a Member on March 5, 1902.

---

\* *Mining and Metallurgy*, May, 1928.

## EBEN ERSKINE OLCOTT, M. Am. Soc. C. E.\*

---

DIED JUNE 5, 1929.

---

Eben Erskine Olcott was born in New York, N. Y., on March 11, 1851. He was the second son of a family of four sons and four daughters, the children of John N. and Euphemia Helen (Knox) Olcott.

After a preparatory training in the College of the City of New York, where his early interest in scientific and technical subjects manifested itself, Mr. Olcott entered the Columbia School of Mines, and was graduated therefrom in 1874 with the degree of Engineer of Mines. As a student, he stood high in a class that included among its members a group of young men who subsequently made their mark in professional life.

Immediately after graduation, Mr. Olcott began his field career as Chemist to the Ore Knob Copper Company, of North Carolina, where he was soon put in charge of the then well-known Hunt and Douglas process of copper extraction. In 1875, he was appointed Assistant Superintendent of the Pennsylvania Lead Company, Mansfield Valley, Pa. In 1876, he went to South America for the Orinoco Exploring and Mining Company, of Venezuela, and in 1878-79 served as Superintendent of the gold mines of this Company, near El Callao, Venezuela. Returning to the United States in the latter part of 1879, he spent two years in examining and reporting on mines in a number of the Western States. From 1881 to 1885 he was Superintendent of the St. Helena Gold Mining Company, Sonora, Mexico. On resigning this post, after four years of strenuous work under untoward conditions in the development of the property and erection of plant, he took up consulting practice, with headquarters in New York.

In 1886, Mr. Olcott was engaged for ten months in an elaborate examination of the Cerro de Pasco Copper District, in Peru. At the same time Mr. A. D. Hodges, Jr., a prominent mining engineer of Boston, Mass., made an independent reconnaissance. Their combined studies and recommendations furnished the basis upon which were founded, years afterward, the extensive operations of the present Cerro de Pasco Copper Company. Next, at the instance of groups of New York capitalists, Mr. Olcott headed two protracted prospecting expeditions to the gold fields of Dutch and British Guiana, and another to the Provinces of Tolima and Antioquia, in the Republic of Colombia.

In 1890-91, for the Peruvian Exploration Syndicate, of London, England, he examined and reported upon the gold and copper resources of the Sandia and Carabaya Districts of Eastern Peru. This was a task involving considerable difficulty and hardship, on account of the remoteness of the very sparsely populated regions traversed, the entire lack of modern means of transport, and the great altitude (reaching at least 17 000 ft.) of some of the terrain. After leaving the railway, south of Cuzco, the entire journey, occupying a number of months, was made on mule-back or on foot. Thereafter, for about

---

\* Memoir prepared by Prof. Robert Peele, New York, N. Y.

ten years, he was actively engaged in professional work in Mexico, British Columbia, Ontario, New Brunswick, and various parts of the United States.

Mr. Olcott was a member of the American Institute of Mining and Metallurgical Engineers almost from its inception, having been elected in 1873 (while still a student), in the third year of the life of the Institute. For two years (1901-02) he served as its President, and, in 1901, attended a meeting of that body held in Mexico, delivering a Presidential Address in the City of Mexico, in the Spanish language, before a representative assembly of State officials and engineers.

Mr. Olcott's professional and business life of fifty-four years was rather sharply divided into two distinct periods. For the first twenty-one years he devoted himself solely to mining engineering and metallurgy, as outlined previously. Then, circumstances led him into a wholly new sphere of activity, very distantly related to the profession in which he had been trained by faithful study and long experience.

Following the death of his brother-in-law, Charles T. Van Santvoord, General Manager of the Hudson River Day Line, Mr. Olcott in 1895 accepted an appointment to the managership of that line of passenger steamers, running between New York and Albany, N. Y., which had been founded by his father-in-law, Commodore Alfred Van Santvoord. On the death of the latter, in 1901, Mr. Olcott was elected President and General Manager of the Company, which at that time was operating two steamers, the *Albany* and the *New York*. In the succeeding years, as traffic increased, new steamers were added, until at his death the fleet comprised the *Hendrick Hudson*, *Alexander Hamilton*, *Robert Fulton*, *DeWitt Clinton*, *Peter Stuyvesant*, *Albany* and *Chauncey M. Depew*.

In his management of the Day Line, Mr. Olcott exhibited his characteristic energy and resourcefulness. No detail that might contribute to the success of the business was too small to receive his personal attention. He made himself familiar with every feature of the boats, from the boiler and engine rooms to the Commissariat Department. His hours of work during the operating seasons were much longer than those of any employee. Unquestionably, his engineering training aided materially in achieving the success attending his control of the Company's large business.

During this second period of his career, he continued for a number of years to give part of his time, in an advisory capacity, to the affairs of the consulting engineering firm of Olcott, Fearn, and Peele, which was organized in 1896. Later (1901), the firm became Olcott, Corning, and Peele, and, finally, Olcott and Corning.

Mr. Olcott had a forceful, impressive personality. Among his outstanding characteristics were his integrity, large humanity, kindly courtesy, and never-failing helpfulness. These qualities secured the affection, loyalty, and respect of all who were brought into contact with him—employees and business associates alike.

His wide business and social interests and his sympathetic nature are indicated by the diversity of the large number of philanthropic, religious, and other organizations with which he was connected in various capacities. Of these,

only, a comparatively few can be mentioned here: Trustee of the American Seamen's Friend Society, and Treasurer and Trustee of the American Indian Institute; Vice-President of the Lincoln Safe Deposit Company and of the Evangelistic Committee of New York City; member of the Administration Committee of the Federal Council of the Church of Christ in America; member of the Advisory Committee, American Exchange-Irving Trust Company and of the Travelers' Aid Society; member of the Board of Managers, American Bible Society; member of the New York Chamber of Commerce, Merchants' Association, Metropolitan Museum of Art, New York Historical Society, Sons of the Revolution, the American and New York State Forestry Associations, National Board of Steam Navigation, and the Board of Foreign Missions of the Dutch Reformed Church of America. He was also a member of the following New York clubs: Union League, Engineers', and the Down Town Association.

Mr. Olcott was married in 1884 to Kate Van Santvoord who, with three sons and one daughter, survives him. He died on June 5, 1929, after a long illness. His eldest son, Alfred, for years associated with him in the conduct of the Hudson River Day Line, has latterly been Vice-President and General Manager of the Line. One of his brothers, Judge William M. K. Olcott, was formerly District Attorney of New York.

Mr. Olcott was elected a Member of the American Society of Civil Engineers on July 5, 1893.

**ROBERT STEVENS PARSONS, M. Am. Soc. C. E.\***

---

DIED MAY 18, 1928.

---

Robert Stevens Parsons, the son of the Rev. Solomon and Louise (Towt) Parsons, was born in Hohokus, N. J., on May 26, 1873. He was prepared in Paterson High School for Rutgers University at New Brunswick, N. J., which he entered with a State Scholarship and from which he was graduated in 1895 with a degree of Bachelor of Science. Three years later he received the degree of Civil Engineer. As an undergraduate, Mr. Parsons' life was a most strenuous one and his days were occupied with numerous campus activities. He enjoyed the honor of being Captain in the Military Corps and of the football and track teams, as well as the further distinction of being a member of the Delta Upsilon Fraternity, and President of the Self-Governing Board and of his Senior Class.

Within a week of his graduation, Mr. Parsons entered the employ of the Erie Railroad Company as Chainman. From the very bottom rung of the engineering ladder, he worked up through all departments until he attained the position of Chief of Maintenance of Way, from which he transferred to the Operating Department as Superintendent. In this capacity, he greatly distinguished himself by handling a difficult strike. Continuing his upward climb he reached the position of Chief Engineer and, at length, Vice-President in charge of maintenance and operation.

Mr. Parsons was a Trustee of Rutgers University and one of a group that encouraged and strengthened athletic activities at the time when the Rutgers football eleven was greatly lauded among college teams. He was very active in civic work in the communities in which he resided, and during his term as Vice-President, when one of his duties was the building up of friendly relations between the communities and the railroad, became a well-known public speaker.

He was a member of the New York Railroad Club, the American Railway Engineering and Maintenance of Way Associations, and the New Jersey Highway Commission, and was affiliated with the Masonic Lodge at Nutley, N. J., and the Rotary Club. He was also a Lieutenant in the New Jersey Militia and an Officer of the Military Reserve.

In 1897, Mr. Parsons was married to Eleanor Howse, of Paterson, N. J., and is survived by his widow and two daughters, Mrs. Robert Miller, of Nutley, and Mrs. Asel Adams, of Youngstown, Ohio.

"R. S.", as he was affectionately known, had a strong, dominant personality, and an army of friends ranging from the humblest trackmen to distinguished railroad executives. He was always cheerful, a marked optimist, and although frequently under the severest of strains, he was able to cheer and stimulate his subordinates. The following revealing remark comes from one of them: "How can we crab when 'R. S.' is around?"

It is remarkable that with this friendly relationship among his associates there occurred no decrease in efficiency and co-operation, these being

---

\* Memoir prepared by Floyd Y. Parsons, Esq., New York, N. Y.

two prime essentials that Mr. Parsons always demanded. He was a real man's man, loved by thousands, and his services were invaluable to his Company. In the words of the First Vice-President of the road is expressed the thought of his many friends: "I do not see how we are going to find one to replace him".

Mr. Parsons was elected a Member of the American Society of Civil Engineers on September 6, 1905.

**L. FREDERICK PATSTONE, M. Am. Soc. C. E.\***

---

DIED JULY 13, 1927.

---

L. Frederick Patstone was born on June 24, 1876, at Providence, R. I. He attended the Providence Manual Training High School, and from 1895 to 1899 was a student in the office of the City Engineer of Providence. During this period he also studied at the Rhode Island School of Design and took a special course in Civil Engineering under John E. Hill, M. Am. Soc. C. E., at Brown University. He later received the degree of Civil Engineer from Ohio Northern University.

From June, 1899, to February, 1903, Mr. Patstone served as Assistant Engineer in the City Engineer's Office of Providence. Having taken and successfully passed a Civil Service examination, he received a Government appointment as Civil Engineer in the Philippine Islands, which service he began on March 3, 1903. Thereafter, for the remainder of his life with the exception of a brief absence during the World War, he was identified with engineering activities in the Islands and in China.

The early part of this work was in the Department of Engineering and Public Works at Manila. Successively, except for the two years, 1914 to 1916, when he was in private practice as Civil Engineering Contractor, and July, 1918, to July, 1919, when he was an officer in the World War, he was Superintendent of Streets and Bridges, First Assistant to the City Engineer, Acting City Engineer, and City Engineer of Manila. He also served as Superintendent of Water Supply and Sewers, and Acting Mayor of Manila.

To recount all the accomplishments under Mr. Patstone's direction is unnecessary; a mere general review of the different kinds of work included will give an idea of the extent and detail involved. He had charge of laying thousands of square yards of cement sidewalk and pavement. Various bridges were constructed under his supervision, including reinforced concrete arches, several highway bridges of more than 200 ft. span, and a steel lift bridge. A large stone-crushing plant, barges for handling the crushed stone, reinforced concrete school buildings, municipal markets, asphalt and macadam roads, a 3 000-ft. sea-wall—these brief items indicate the wide variety of his work.

Early in his stay in Manila he evolved a city plan covering an area of 68 sq. miles. It was his pleasure to see this plan in part developed under his supervision. Many miles of road were thus built. Much water-front land was reclaimed for developing the harbor. The extensive drainage, construction, and sanitary improvements were incidental to this development. Finally, during the latter years of his régime, he was privileged to perfect many of the plans previously evolved, for the future development of this important city.

During the World War, Mr. Patstone, already a Major in the Officers' Reserve Corps of the Army of the United States, was detailed as Colonel and Chief of Engineers of the Philippine National Guard, but he resigned from this position as soon as permission could be obtained, to enter the Engineer

---

\* Memoir prepared by A. Gideon, M. Am. Soc. C. E.

Officers' Training Camp at Camp A. A. Humphreys, Va., after which he served as Major of the 217th Engineers, U. S. Army.

In February, 1919, he returned to Manila to resume the office of City Engineer. This position, however, he resigned the following year in order to engage in a commercial interprise in Shanghai, China. He was Vice-President of the Asia Development Company, with headquarters in Shanghai, and personally directed a notable engineering work carried on by the Company in Shantung Province in 1922 and 1923 when a vast area of land was reclaimed and saved from the flood waters of the Yellow River by extensive diking. He afterward became a member of the firm of Wooten and Patstone, Architects, in Shanghai, and was thus engaged when he was taken with his last sickness. He died at the Shanghai General Hospital on July 13, 1927, after an illness of three months.

Mr. Patstone was a member of the following technical societies and clubs: The Boston Society of Civil Engineers; the Elks, and the Army and Navy Clubs, of Manila; the French, American, Union, and Columbia Country Clubs, and the Chinese-American Association of Engineers, all of Shanghai.

In addition, he was also a member of the American Chamber of Commerce of Shanghai, for which he served as Chairman on the Committees of Architects and Engineers. He was a Member of the Benevolent and Protective Order of Elks and a Thirty-second Degree Mason, Member of Affli Temple, A. O. N. M. S., Member of Bamboo Oasis of Manila, and President of the Nomad Oasis in Shanghai. He served as a Member of the Traffic Commission of Shanghai, and, after that body was dissolved, he became a Land Commissioner, having been a nominee of the Shanghai Municipal Council for that position. He also served with the Shanghai Volunteer Corps, as a member of the American Mounted Troop.

As Mr. Patstone devoted the best years of his professional life to the Manila service, it is there that he was best known and best appreciated for his true worth. His success was due not only to his technical and administrative ability, but in no small measure to his sympathetic appreciation of the real mission of the American Government employee in the Philippines: "To train the man under you to fill your position". Certainly he did that; he trained a Filipino as his own successor as City Engineer of Manila. Not until, himself at the top, he saw the City Service practically Filipinized, did he feel free to seek the greater financial gain which private practice had to offer.

In addition to his technical ability, Mr. Patstone was an accomplished musician and was endowed with a remarkable singing voice. He was always ready to use this talent for charity concerts and the pleasure of his friends.

He was married on March 21, 1908, at Calapan, Mindoro, Philippine Islands, to Daisy Suter Clark, the daughter of Captain J. J. Clark, U. S. Army, who survives him.

Mr. Patstone was elected a Member of the American Society of Civil Engineers on April 2, 1913.

**YSIDORO YGNACIO POLLEDO y SANDS, M. Am. Soc. C. E.\***

---

DIED MAY 7, 1928.

---

Ysidoro Ygnacio Polledo y Sands was born in Matanzas, Cuba, on July 31, 1865. A student in his native city, as well as in Germany and France, he also attended the School of Mines at Columbia University, in New York City, and was graduated with the degree of Mining Engineer in 1885.

Following his graduation, Mr. Polledo served as Assistant Engineer on the survey for a water-works for the City of Santiago de Cuba, Cuba. In 1886, he was appointed Assistant Engineer, and, later, Principal Assistant Engineer, in charge of track and structures for the Cárdenas and Júcará Railroad Company, Cárdenas, Cuba. From 1889 until 1890 he acted as Manager of the Santa Bárbara Plantation and Sugar Factory, at Baró, Cuba, later becoming General Manager for the Cárdenas Sugar Refining Company, at Cárdenas.

In 1895, Mr. Polledo again varied his field of occupation, when he was appointed Assistant Engineer on the Harbor Works of Havana, Cuba, which position he held until the following year, when he engaged in private practice as a Consulting Engineer. In this capacity, he re-designed sugar houses, and the evaporating, condensing, and water-cooling plants for sugar factories in Santa Bárbara, Elizalde Santa Catalina, Alava, La Luisa, Carmen de Crespo, and Narcisa, Cuba.

In 1899 he again became Assistant Engineer on the Harbor Works at Havana, under the United States Military Government, Division of Cuba, Department of Havana. During subsequent years, until 1920, Mr. Polledo was employed in the following positions: Technical Director of the Santa Lucia Sugar Factory, Gibara, Cuba; General Manager of the Matanzas Railroad Company; Manager of the "Banco Español de la Isla de Cuba"; Consulting Engineer in private practice and Vice-President of the Ferro-carril del Norte de Cuba. From 1920 until his death, he served as Vice-President of the Regla Coal and Oil Company.

Mr. Polledo was a man of strict integrity which was applied in his profession as well as in his public life. He is survived by two daughters.

He was a member of the Cuban Society of Engineers, the American Institute of Mining and Metallurgical Engineers, and the American Society of Mechanical Engineers.

Mr. Polledo was elected a Junior of the American Society of Civil Engineers on January 2, 1889, and a Member on November 4, 1903.

---

\* Memoir prepared by Dra. Ciria Polledo, Matanzas, Cuba.

**CHARLES LEWIS POTTER, M. Am. Soc. C. E.\***

DIED AUGUST 6, 1928.

Charles Lewis Potter, the son of Benjamin R. and Susan E. (Smullen) Potter, was born at Lisbon Falls, Me., on January 24, 1864. His boyhood was passed on a farm in his native State and his early schooling was obtained in the public schools in the vicinity.

Mr. Potter entered the United States Military Academy at West Point, N. Y., in 1882, and was graduated therefrom in 1886, standing fifth in his Class. He was commissioned a Second Lieutenant and assigned to the Fifth Cavalry, on July 1, 1886. He served on frontier duty at Fort Supply, Indian Territory, in September and October, 1886, and then in garrison at Fort Leavenworth, Kansas, until March 29, 1887. He was transferred to the Corps of Engineers, on February 2, 1887, and was sent to the Engineer School of Application at Willets Point, N. Y., from which he was graduated in 1889.

Lieut. Potter's first Engineer assignment came in October, 1889, when he was appointed Assistant to the Engineer Officer in charge, at Montgomery, Ala., on the improvement of rivers in Alabama, Georgia, and Florida. His subsequent assignments were distributed over a great part of the United States as follows: Fortifications in San Francisco Harbor, and rivers in Southern California, 1891-1897; rivers in Oregon, 1897-1898; the Mississippi River at Memphis, Tenn., 1900-1903; the Great Lakes, Duluth, Minn., 1903-1906; Porto Rico, as Chief Engineer, Lighthouse Service, 1907-1910; the Mississippi River, at St. Louis, Mo., 1910-1912, and at St. Paul, Minn., 1912-1915; rivers and harbors at Portland, Ore., 1915-1916; at Boston, Mass., 1916-1917; at San Francisco, Calif., including fortifications, 1918-1920; and, finally, as President of the Mississippi River Commission, at St. Louis, from March 19, 1920, to June 12, 1928.

He was promoted to the rank of Captain on July 5, 1898; Major, September 14, 1904; Lieutenant-Colonel on February 27, 1911; and Colonel on November 27, 1916.

During the Spanish-American War and the Philippine Insurrection, Colonel Potter was Chief Engineer, in the Philippines, of the 8th Army Corps, on the Staffs of Generals Merritt and Otis (1898-1899), and during the World War he was Director of Gas Service (now the Chemical Warfare Service) at Washington, D. C. (1917-1918).

Colonel Potter's outstanding work was as President of the Mississippi River Commission. He was a man of very attractive personality, cordial and frank. He readily secured the confidence and respect of the leading men with whom the Commission had to deal, which had a far-reaching effect on harmonizing its many interests. During this service he was also Division Engineer of the Western Engineer Division, comprising river improvement works in the Engineer Districts in the Mississippi Valley from the head-waters to the Red River, including the rivers tributary to the territory of the Commission, except the Ohio and Illinois Rivers, and the Mississippi below Red River.

\* Memoir prepared by William S. Mitchell and James W. Skelly, Members, Am. Soc. C. E.

His greatest work came in 1927, following the phenomenal and disastrous flood of that spring in the Lower Mississippi Valley. During the months following this flood, to the end of 1927, he labored unceasingly in the preparation of comprehensive plans for the control of this great river, to be submitted for the consideration of Congress, frequently appearing before its Committees in advocacy of the Commission plan for the solution of the great problem. There is no doubt that the strain under which he labored so long and so assiduously weakened and undermined his health.

On reaching the military age for retirement, on January 24, 1928, he was retired, but was immediately recalled to active service, continuing as President of the Mississippi River Commission. The Flood Control Act of Congress, pending at the time, carried the provision that the President of the Mississippi River Commission should have the rank of Brigadier-General. Recognizing the importance of the Commission and of Colonel Potter's great service thereon, he was promoted to that rank on May 15, 1928.

Deeply interested in the vast work to be carried on by the Commission, he looked forward with eager anticipation to its prosecution. His wish was not fulfilled. To his great surprise and disappointment he was relieved from active duty on June 12, 1928, and shortly after was forced to undergo what was expected to be a comparatively safe surgical operation. His impaired physical condition, however, left him unable to rally from the shock of the operation, and he passed away quietly, on August 6, 1928.

General Potter made readily, and retained loyally, friends in every walk of life. He loved Nature and the outdoors. He was a keen student of archaeological and historical matters and of fraternal subjects concerning which he possessed a fine library. He contributed numerous articles to engineering journals concerning the river problems before him. These were widely read and appreciated for sound engineering wisdom, great common sense, and clarity of statement.

He was a member of many Masonic bodies, having joined the organization in Memphis, where he was advanced to the Thirty-third and last Degree of the Ancient and Accepted Scottish Rite in a most unusually short time. In spite of frequent changes of station incident to Army life, General Potter was one of the few officers ever to attain this distinction. His funeral services were held in the Scottish Rite Cathedral at St. Louis, and his ashes were deposited in Valhalla Mausoleum near-by.

General Potter is survived by his widow, Mrs. Sophie H. Potter, and his step-daughter, Caralisa Nichols.

General Potter was elected a Member of the American Society of Civil Engineers on April 1, 1903.

## HENRY GOSLEE PROUT, M. Am. Soc. C. E.\*

DIED JANUARY 26, 1927.

Henry Goslee Prout was born in Falls Village, Va., on August 10, 1845, the son of William and Amanda (Goslee) Prout, and a direct descendant of Timothy Prout who came from Biddeford, Devonshire, England, and landed in Boston, Mass., in 1644.

As the family had moved from their Southern home to New York and, later, to Massachusetts, Mr. Prout's boyhood was spent entirely in Northern surroundings. His education, prior to the Civil War, was not a very systematic one, but was gleaned intermittently at Stockbridge (Mass.) Academy and under the private tutelage of the Rev. Franklin Le Barron. In 1863, at the age of 18, he enlisted in Company D of the 57th Regiment of Massachusetts Volunteers, and served with the Army of the Potomac in the Wilderness Campaign, the siege of Petersburg, and the resulting pursuit of General Lee. In 1865, he was mustered out of service and after a two-year period of adventure and study, entered the University of Michigan, at Ann Arbor, Mich. He was graduated in 1871 with the degree of Civil Engineer, later receiving the honorary degrees of Master of Arts from Yale University in 1902 and Doctor of Laws from the University of Michigan in 1911.

During his second year in college Mr. Prout commanded an expedition of reconnaissance in Southwestern Colorado and so distinguished himself by his astronomical achievements that he was brought to the notice of Gen. William T. Sherman, then at the head of the U. S. Army and previously in command of the Military Division of the Missouri. In consequence, Mr. Prout was one of six young men who, at the request of the Khedive of Egypt, was recommended for military service by General Sherman. He was commissioned as Major of Engineers and remained in Egypt four and one-half years, during which time his experiences were both humorous and tragic, and his strength and endurance were given the most severe of physical and mental tests. In these years of service he rose to the position of Colonel in the General Staff and became Governor General of the Provinces of the Equator, relieving Gen. Charles George Gordon when he went to Khartoum as Governor General of the Sudan. An interesting problem which Colonel Prout undertook while he was in the Equator Provinces was the transportation of an 80-ft., screw-propelled steamer which was to be erected at Duffi, across 60 miles of broken country on the backs of negro bearers. It was in this steamer that Emin Pasha was sent to meet Stanley at the time of the famous "rescue".

On his return to America, Colonel Prout was employed as Signal Engineer by the Toucey and Buchanan Interlocking Switch Company, of Harrisburg, Pa., which later developed into the Union Switch and Signal Company. He remained in this position, however, for only a little more than a year, and in 1880 entered the printing business with the firm of Atkin and Prout, publishers of *The Railroad Gazette*. In March, 1887, he assumed the Editorship of this journal, which position he held with distinction for sixteen years.

\* Memoir prepared from information on file at the Headquarters of the Society.

At the expiration of this time, his interests were again directed to the Union Switch and Signal Company with which he had been associated and, in consequence, in 1903 he resigned his position as both Editor and Director of *The Railroad Gazette* to accept the office of First Vice-President and General Manager of the Union Switch and Signal Company, at Swissville, Pa. He resigned this position in July, 1914, shortly after the death of the late George Westinghouse, M. Am. Soc. C. E., in whose general business interests he had been an adviser, and in November of that same year became President of the Hall Switch and Signal Company, of Garwood, N. J.

In 1915, Colonel Prout retired, giving up at this time all active business pursuits. It was during this period of his life, while he was living at his home in Summit, N. J., that he wrote the well-known biography of George Westinghouse, published in 1924, which, in addition to being an accurate portrayal of its subject, also sheds great light on the character and personality of its author.

In his diversified career, Colonel Prout was an outstanding figure in military, editorial, and professional achievement. His early associations with the great world figure, General Gordon, his startling editorial read on the floor of the United States Senate to which was due the choice of Panama instead of Nicaragua as the route for the Isthmian Canal, and his skill in mercantile leadership and its allied associations with the switch and signal companies—all lend unending tribute to his name. A distinguished scholar and a gentleman, he is well described in the following sketch of appreciation by his lifelong friend and associate, Mr. William H. Boardman:

"The sum of it is that he is inspiring. He has such a fund of general and specific information, such a love of truth and thoroughness, such a scorn for lying and carelessness, such a ready quality of human sympathy that, with a faculty for memory cultivated and quickened by editorial habit, he can subordinate himself and skillfully direct conversation so as to draw out others."

Colonel Prout was a member of the American Geographical Society, the Sigma Phi Fraternity, the Century Club, the Railroad Club, and the University Club, of New York, N. Y.

He was married at Fort Leavenworth, Kans., in 1877, to Gabriella Perin. He is survived by his widow, two sons, Henry B. and Curtis, and three daughters, Elizabeth, Mrs. Pierpont V. Davis, and Mrs. Paul G. Tomlinson.

Colonel Prout was elected an Associate of the American Society of Civil Engineers on November 6, 1872, and a Member on September 3, 1879. He served as a Director of the Society from 1893 to 1895.

**JOHN RICHARD RABLIN, M. Am. Soc. C. E.\***

---

DIED SEPTEMBER 17, 1928.

---

John Richard Rablin was born in Plymouth, England, on October 25, 1868, the son of William H. and Mary Edwards Rablin. He came to the United States with his parents when he was about three years of age.

He was graduated from the Boston Latin School, Boston, Mass., and entered Harvard College, but the death of his mother, which caused the removal of the family to Maine, ended his college education.

Mr. Rablin began his technical career in 1888 as an Engineering Assistant on the Old Colony Railroad, under the late B. T. Wheeler, M. Am. Soc. C. E. His professional education was obtained under Mr. Wheeler's tutelage, and by studying nights by himself, while he was working during the day. When Mr. Wheeler went to the City of Boston as Superintendent of Streets in 1895, Mr. Rablin went with him, remaining there until some time in 1896, when he became associated with the contracting firm of Horton and Hemenway, as Contractor's Engineer. This firm had contracts in connection with the construction of the South Terminal and Back Bay Stations. The principal work on which Mr. Rablin was engaged was the construction of the Back Bay Station.

His service with the Metropolitan Park Commission commenced in 1899, when he was made Assistant Engineer in charge of construction of the Charles River Speedway. In 1904, he was appointed Chief Engineer of the Commission, a position which he retained until his death.

There was a tremendous expansion in the amount and kind of work done in the Metropolitan Park System after Mr. Rablin assumed the position of Chief Engineer. The work was not only construction and maintenance of parks, but also the construction of many important boulevards and their later improvement to enable them to carry heavy automobile traffic, as well as the construction of a number of bridges in the district. The great diversity of his work would be better understood, perhaps, if it were mentioned that he also had charge of shore protection and the construction and maintenance of sea-walls at various points along the shore in the general vicinity of Boston.

Among the works which Mr. Rablin constructed were the Revere Beach Parkway; a dam at Newton Lower Falls, Mass.; the Lynn Shore sea-wall; the Nantasket Beach sea-wall; shore protection at Revere and Winthrop, Mass.; dam, tide-gates, and boat lock at Medford, Mass.; the Northern Artery; and approximately twenty-eight bridges, the majority of which were spans of considerable size. Among these are the new bridge on the Old Colony Parkway, the Larz Anderson Bridge, over the Charles River, and the Cottage Farm Bridge.

He was continually reading and seeking knowledge regarding up-to-date methods and the latest developments in engineering along all the various

---

\* Memoir prepared by Lewis E. Moore, M. Am. Soc. C. E.

lines into which the wide diversity of his work led him. He showed a great deal of ingenuity in varying types of construction to avoid duplication.

The following appreciation by Chairman Keniston, of the Metropolitan District Commission, was printed in *The Boston Transcript* shortly after Mr. Rablin's death:

"An able and devoted servant of the Commonwealth, John R. Rablin, passed away this week. Mr. Rablin became Assistant Engineer to the Metropolitan District Commission in 1899, was appointed Chief Engineer in 1904, and continued in that capacity until his death. During that time the construction of many public improvements in metropolitan parkways, bridges, and reservations came under his direct care. The wise planning and satisfactory completion of these public works was largely due to his engineering skill and attention.

"Mr Rablin's life work was the development and maintenance of the Metropolitan Parks. He was ever ready to give freely of his time and strength, and his early death may be attributed in part to his attempt to resume too soon his duties after a serious illness. He still maintained an interest and oversight of his work as long as his strength permitted. The name of the engineer may not be known or remembered by those who enjoy the benefits of the public improvements for which he was responsible, but the works themselves will remain as a tribute to his earnest and successful efforts. May the public occasionally think gratefully of such men as Mr. Rablin."

Mr. Rablin was a man of very decided character, strong in his likes and dislikes, and much beloved by his friends. He was a member of the Society of American Military Engineers; the Boston Society of Civil Engineers; the American Road Builders' Association; the Massachusetts Highway Association; the International Road Congress; the Boston City Club; and the Wollaston Golf Club. He attained the ultimate in golf by "making a hole in one."

On November 15, 1893, Mr. Rablin was married to M. Frances Loring. He leaves, in addition to his widow, a son, Richard Loring Rablin.

Mr. Rablin was elected a Member of the American Society of Civil Engineers on August 31, 1909.

## JOHN CHESTER RALSTON, M. Am. Soc. C. E.\*

DIED JULY 15, 1928.

John Chester Ralston was born in Kincardine, Ont., Canada, on May 12, 1864, his parents being James Glendenning Ralston, of Paisley, Scotland, and Mary Amanda (Johnston) Ralston, of Otterville, Ont., Canada.

His father was descended from an old Scottish family, the McDuffs, Thanes of Fife of Renfrewshire, the earliest records thereof being dated 1190. The last son of that ancient family, Ralph, on receiving a grant of land, named a part of it for himself, Ralph's Town, afterward abbreviated into Ralston—hence, the family surname.

Both Mr. Ralston's father and grandfather were graduates of the University of Edinburgh. His mother was a descendant of the Johnston and Harris families of Massachusetts and Rhode Island, noted in the history of the Minute Men of the Revolution. One of her earlier forebears is credited with being the author of the first book ever written in America, a quaint volume entitled "God's Dealings with Zion's People".

Mr. Ralston received his early education in one of the public schools of Ontario, under a Head Master who afterward became Minister of Education for the Dominion of Canada. There, the foundation was laid for a liberal academic course to be developed in either a Canadian or an American university; but these plans were suddenly terminated by the death of his father, who left him, at the age of thirteen, the eldest of nine children. Thereupon the inspiration of the classroom had to be replaced by the harsher curriculum of self-support. Having seen the metes and bounds of his father's property re-surveyed, young Ralston developed a nebulous hope of becoming a surveyor and ultimately an engineer.

In 1880, he went into the West and found early employment in the United States Engineer Corps, under the direct supervision of Mr. Charles S. Pease, on the reclamation of the Missouri River, at the beginning of the Federal improvements on the Missouri, Mississippi, Ohio, and their tributaries. It was under the encouragement and personal help of Mr. Pease and his Staff that Mr. Ralston's engineering self-education was directed and inspired. The members of the Staff were largely graduates of the Rensselaer Polytechnic Institute, who thus exemplified in their lives a generous spirit of service.

Under this tutelage the curriculum of the Rensselaer Polytechnic Institute was followed by difficult, arduous, and, at times, most discouraging effort. The nature of the pioneering and improvement plans of the Missouri River, however, was ever fascinating and inspiring, and the discouragement of lamplight study was always transmuted during the day into Aladdin's mysteries. The wizardry of the laws of hydraulics, the nebulous latitudes of river regions and channel erosions, the numberless problems, and the never-ending devices for control or remedy, were a challenge to engineering study. Under such special environment the college classroom as an educating medium was surpassed.

---

\* Memoir prepared by J. A. L. Waddell, M. Am. Soc. C. E.

In later life Mr. Ralston undertook a broadening, non-technical course of study, following the curricula of Columbia University and the University of Chicago.

In 1882 he was transferred from the Missouri River at Omaha, Nebr., to the Potomac River, on the reclamation of the Potomac Flats at Washington, D. C., and Georgetown, Md., Harbors, and on the building of what afterward became Potomac Park, Washington, D. C. He was given responsible charge of the construction of the mattress foundation of the sea-wall behind which the channel dredgings were deposited to form the terra firma of this interesting park. This sea-wall was more than five miles long, and required several seasons to complete. The wall defined the final north shore line of the main channel of the Potomac River from Georgetown Harbor, past the historic Long Bridge, to a confluence with the south shore of the Washington Channel entrance to the city docks, enclosing a peninsular area that separates the two main navigable channels. This area reclaimed a large and offensive part of the mud flats of the Potomac River, while the dredgings from the widened outside channels supplied the necessary material to raise the flats well above high tide and to create a fertile acreage for landscape gardeners. More than 400 acres were thus reclaimed.

When, in 1885, the major part of the reclamation had been fairly completed, Mr. Ralston was tendered a position as Assistant Engineer on the Construction Staff of the Union Pacific Railroad. For the first two years of his railroad experience he was employed directly by the late Jacob Blickensderfer, M. Am. Soc. C. E., Chief Engineer, principally in collaborating the history of the Pacific Railroads, on the building of which Mr. Blickensderfer, together with the late Grenville M. Dodge, Hon. M. Am. Soc. C. E., and the late Adna Anderson, M. Am. Soc. C. E., had served so conspicuously.

Minor executive duties also were required of young Ralston in the line of reports, and in furnishing supplies for the many field parties of location and construction in the several Western and Northwestern States crossed by this road. Most valuable experiences were gained and studies pursued under the kindly and inspiring direction of this new Chief, who always took the liveliest personal interest in the welfare and education of his assistants. Three nights a week were devoted to study and instruction in the astronomical observatory of Mr. Blickensderfer, whose work in this field was well and favorably recognized by the United States Astronomical Observatory at Washington. Here the principles of railroad engineering and the early basis of railroad economics, in both engineering and operation, were studied with a dogged determination and with a lively appreciation, in the realization that a master of this temper and vision was not to be found every day.

In 1887, a new Chief Engineer was appointed in the person of the late Virgil G. Bogue, M. Am. Soc. C. E., who early granted Mr. Ralston his long cherished wish to be put into the field. An extended experience in preliminary and final location in many of the rugged Western States, including Colorado, Wyoming, Nevada, Western Montana, Eastern Washington, and Idaho, and on construction work in Kansas, Nebraska, Colorado, Wyoming, and Montana,

gave a diversity and comprehension of the widest application of railroad engineering, such as seldom come to young men. Mr. Ralston was given charge of the remodeling of the Butte City, Mont., yards to meet the growth of the expanding mining industries of that region. In that work he was called on to examine and report on the first water-power sites contiguous to the smelter region that later was to be so remarkably developed.

Other notable work arising out of that time and region was the preliminary and final location of the high-line development of what, in later years, became the famous Butte, Anaconda, and Pacific Railway, the first electrically-operated, heavy-freight carrying railroad in the world. To these works and allied activities Mr. Ralston, as Assistant Engineer, contributed with distinction.

In 1889 and 1890, he took charge of the preliminary surveys and much of the final location of the west end of the Pacific Short Line through Wyoming and Utah, employing and directing a half dozen field parties. He succeeded in shortening the main-line distance 90 miles between the Missouri River and Ogden, Utah, and in finding a most economical crossing of the Continental Divide, nearly 1200 ft. lower than that of the near-by competitor. Across the uplands of the Big Sandy drainage he was able to locate a long tangent on a 0.5% grade, at exceptionally low cost, the east end of which was within eight miles of the Continental Divide. In 1890 the first period of his career ended, when a suspension of active railroad development in the West was declared.

Mr. Ralston immediately took up steel skeleton building construction, foundation work, and elevated railway erection in Chicago, Ill., and pursued this class of occupation continuously until 1897. During this period he erected a number of early steel skeleton buildings and special structures, especially for the Illinois Steel Company in South Chicago, and for the Lake Street Elevated Road, including the down-town loop along Lake Street to and down Wabash Avenue to Harrison Street, etc. This erection constituted the first down-town loop, and was quickly followed by the joint loop structures, located in what has since developed into the most congested metropolitan district of the world.

Several notable steel skeleton structures were erected in Buffalo, N. Y., Pittsburgh, and Philadelphia, Pa., including the Ellicot Square Building, in Buffalo, and the Presbyterian Building, in Philadelphia, each notable in its day for size and construction.

In the midst of these activities, in the spring of 1897, Mr. Ralston was called to Spokane, Wash., by some of his earlier friends of Butte, Mont., to assist in certain mineral developments and in the construction of reduction works. He assisted in the design and construction of the largest plant of its kind in the State of Washington; and in this, the third period of his career, he established himself as a Consulting Engineer, his practice quickly growing into substantial proportions. It covered examinations, reports, and valuations in the fields of hydraulic development, hydraulic power, and later, hydro-electric power in British Columbia, Washington, Oregon, Idaho, California, Montana, and Nevada, including a fascinating diversity of technology.

Intense activities in those fields, especially in California, led to an examination of the water supply and power possibilities of the Tuolumne and its Hetch Hetchy Valley, the Stanislaus, and the Mokelumne, out of part of which, and certain parts of the Merced, was finally carved the so-called Hetch Hetchy water supply for San Francisco, Calif. Another interesting work was his study of the hydraulics involved in the disposal of the underground waters of the famous Comstock Lode, their siphonic behavior, vadose waters, accumulations, and colonization. A year was spent on this work and on the plans for the complete unwatering of certain of the leaner parts of the Lode, involving a blending of the technology of the Civil Engineer and the rudiments of Economic Geology.

In April, 1906, the San Francisco earthquake destroyed much of that beautiful city and caused Mr. Ralston to be sent to the hospital, where a major operation became imperative, and rendered him a permanent invalid. This put an end to field activities for all time, and left to him as a residue only a limited consulting practice. Notwithstanding these almost insuperable physical handicaps, he was able to take up the duty of re-organizing the Engineering Staff of the City of Spokane, Wash., which was tendered him at that time. He succeeded in bringing into that sadly depleted organization an *esprit de corps* and a technological staff of singular merit, one comparable to the best metropolitan standards. Under the atrophying influences of indurated city politics, a brief but decisive encounter followed, resulting in the establishment of a permanent and high-minded Engineering Corps. Under this régime Mr. Ralston was able to replace eight old and dilapidated wooden Howe truss bridges by designing and building an equal number of reinforced concrete structures, literally making Spokane the "City of Bridges". Among these structures is the famous Monroe Street Bridge, said by many to be the most monumental concrete arch bridge in the United States. The main deck is a segmental arch of 290 ft. span, with a rise of 140 ft. Several of the other bridges are notable in design, and are representative of the true arch bridge.

Large paving areas were inaugurated for the first time for the city; and a new underground water supply of exceptional quantity and purity was designed and built under Mr. Ralston's direction; thus the struggling Western outpost was transformed into a modern metropolitan city. This city-building activity demanded a liberal and wide technology, with a generous spirit of service on the part of the entire staff.

Mr. Ralston was ever an earnest advocate of the principle that the engineer always should take the leadership in professional, civic, and political life. He maintained that the engineer by native mental qualities and education is more fitted for leadership in the activities of men and society than the lawyer, the divine, or the physician. He especially insisted that the engineer should have a command of forceful, fluent, and happy diction commensurate with the leadership to which he should aspire. He lived to see the day when the best thought in the profession is becoming vocalized and insistent on this subject, in direct contrast to two or three decades ago when the engineer was seldom an advocate on any subject except engineering.

In respect to the use of the English language, Mr. Ralston practiced what he preached; for both his speech and his writings were conspicuous for an extensive vocabulary and a fluent diction. Occasionally, some of his brother engineers smiled over his use of long or unusual words, but those words were always well chosen, apropos, and forceful.

During his invalid years from 1906 until his death, aside from his work as City Engineer, he found enough physical ability to report on a number of hydro-electric projects and on straight hydraulic developments aggregating 750 000 h.p., in units varying from 3 000 to 50 000. Prior to the entrance of the United States into and during the World War, Mr. Ralston served as a member of the Naval Consulting Board for the State of Washington—a period extending from 1915 to 1918. During this time he was also one of about 2 000 entrants who were asked to submit plans and specifications for the dissemination of American propaganda among the German people. His plans were accepted; and he was one of the first four to receive Presidential recognition and a monetary reward.

He also served as a member of the Committee on Development of the Society, sharing actively in its deliberations during 1918-1920. From 1920 to 1924, Mr. Ralston served as a member of Engineering Council. In this Council he represented, as the Executive Member, the States of California, Nevada, Oregon, Idaho, Washington, and Montana.

From 1900 until 1918, he acted as Consulting Engineer, and, for a part of that time, as Vice-President, of the Pacific Coast Pipe Company with a factory at Seattle. This Company manufactured all sizes of wood-stave pipe, notably the continuous-stave type, up to diameters of 120 in. Its use was mostly for penstocks and pressure pipe for hydro-electric plants and for inverted siphons in irrigation. He was one of several engineers of the Pacific Coast who developed and made popular this pipe for more extended use, and this work properly may be said to have been a great contribution to the current engineering development of the time.

He was an early worker in the Boy Scout movement, a pioneer in social hygiene work, a deep lover of the arts, and ever willing to aid in the betterment and beautifying of his city, having planned outlines for the economic and beauteous development of the falls and river of Spokane. He was President of the Art Association, and a brilliant, original, and much sought speaker. He never feared to tell the truth, possessing a decided vision of life and of engineering, which also found expression in his great enjoyment in writing. He was interested in and always ready to assist young men.

While Mr. Ralston was certainly a self-made man, he differed essentially from most of the American engineers of this class. Not only was he a great reader and student, but his studies were laid out systematically and were followed religiously, so that eventually he was in no whit inferior to the leading alumni of the best technical schools.

For two decades the writer had held Mr. Ralston in the highest esteem, having greatly admired him as a man, a citizen, and an engineer—as, truth to tell, did every one else with whom he was thrown into intimate contact.

In corroboration of this statement, quotations from a few of the letters of sympathy received by Mrs. Ralston will serve.

That from an associate reads:

"He was a fine citizen, a capable and resourceful engineer; and as a friend I have not known his superior."

That from a subordinate is:

"The great pleasure of working for and with 'Ralston' was the being in contact with a man of vision; for to him engineering was not the mere application of formula and instrument, but combined with these the foresight to conceive projects which should lead men's feet over the hills to an era."

Of the Humboldt County, California, Project, it was stated:

"We undertook a very daring project; and, thanks to his skill, accomplished it with brilliant success. The North Mountain Power Project was one of the first of its kind in the West, and its record for time has never been beaten."

M. E. Cooley, M. Am. Soc. C. E., wrote:

"My acquaintance with Mr. Ralston dates from his service on the Board of Federated Engineering Societies. I learned then of his sterling qualities, his high ideals, and the inspiration of his presence."

That from L. W. Wallace, President, Federated Engineering Societies, read:

"He lived a life of rich accomplishment and endearment, a rich heritage to his friends. He will be mourned and missed in the Engineering Profession, to which he contributed a great deal."

A College President stated:

"His understanding of his associates was an indication of his very generous and universal kindness."

A Bishop of the Protestant Episcopal Church wrote:

"He was a rare man. He was a true and loyal man in all the relations of life. His ability, courtesy, and consideration for others always impressed me greatly."

Mr. Ralston's day is past; his work is done; but it will be many, many years before he is forgotten. The history of such a life should be an inspiration to young men who desire to become engineers, but who are unable to secure money for a regular course of technical instruction.

Mr. Ralston was married in New York, N. Y., in April, 1897, to Mary Kean Buckner, of Kentucky, whose family came from England to Jamestown, Va., in Colonial days. He is survived by his widow, a son, John W. B., a daughter, Mary Elizabeth, two brothers, and five sisters.

Mr. Ralston was a member of the Spokane Engineering Society, the Seattle Engineering Society, the American Institute of Mining and Metallurgical Engineers, the Cosmos Club of Washington, D. C., the Spokane City Club, and the Sons of the American Revolution. He was also a Thirty-second Degree Mason, a member of the Protestant Episcopal Church, and a staunch Republican.

Mr. Ralston was elected a Member of the American Society of Civil Engineers on October 3, 1906.

## BEVERLEY STROTHER RANDOLPH, M. Am. Soc. C. E.\*

---

DIED FEBRUARY 5, 1929.

---

Beverley Strother Randolph was born on July 17, 1851, at Berkeley Springs, Va. (now West Virginia). He was the eldest son of the late James Lingan Randolph, M. Am. Soc. C. E., Chief Engineer, and, later, Consulting Engineer, for the Baltimore and Ohio Railroad Company, and the late Emily (Strother) Randolph, a sister of Gen. David Hunter Strother.

Mr. Randolph attended Cornell University for two years and then went into active civil engineering work. He was engaged for some time on location for the Baltimore and Ohio Southwestern Railroad Company (now a part of the Baltimore and Ohio System). He then went to Nicaragua on the construction of the first railroad to cross that country. On his return to the United States, he was appointed Superintendent of the mines of the Consolidation Coal Company, with headquarters at Frostburg, Md., which position he held for twenty years. During this time it is interesting to note that not a single strike occurred among his men.

In 1904, Mr. Randolph retired from active engineering work to his farm at Berkeley Springs, W. Va., where he bred horses for the New York market. He later moved to "Tonoloway" near Hancock, Md., where he continued raising horses and also operated a glass sand deposit on his farm. In 1927, at the age of 76, he sold "Tonoloway" and bought a farm, "Hawkhurst", in Berkeley County, West Virginia, near which he was killed in a grade crossing accident on February 5, 1929.

Mr. Randolph was a man of remarkable physique and at the age of 72 was still schooling horses to jump. At the time of his death, he was making plans to go into the breeding and training of trotting horses on a more extensive scale than he ever had attempted before.

He was a Member of the Order of the Cincinnati, and a Life Member of the American Institute of Mining and Metallurgical Engineers.

On September 20, 1882, he was married to Mary Jewette, of Baltimore, Md., who died on December 26, 1918. He is survived by his three nephews, James Robbins Randolph, O. Robbins Randolph, and Lingan Strother Randolph, Jr., and one niece, Mrs. Emily Randolph Deitrick. His brother, the late Lingan Strother Randolph, M. Am. Soc. C. E., died in 1922.

Mr. Randolph was elected a Member of the American Society of Civil Engineers on May 2, 1888.

---

\* Memoir prepared by O. Robbins Randolph, Esq., Rutherford, N. J.

## HARRY FAY ROACH, M. Am. Soc. C. E.\*

DIED JULY 28, 1929.

Harry Fay Roach was born in St. Louis, Mo., on May 7, 1871, the son of Harry E. and Sarah (Haley) Roach. His mother was a native of Kalamazoo, Mich. His father was an Architect and Builder and the son grew up in an atmosphere of construction, spending his spare time in his father's office and on work in the field. He thus acquired considerable valuable training in his early youth.

Mr. Roach was graduated from the St. Louis Manual Training School in 1889, and in the fall of that year entered the Massachusetts Institute of Technology. He remained there until the summer of 1891, taking the course in Architecture, after which he entered into partnership with his father for the practice of his profession in St. Louis. In 1894, he traveled through England, France, Belgium, Germany, Switzerland, Italy, and Greece, studying the architecture of those countries. His partnership with his father was terminated in 1903, and thereafter, until the time of his death, he was engaged in architectural and engineering work. He designed many important buildings in St. Louis, among which are the Hamilton-Brown Building, the Times Building, the Buckingham Club, and the Syndicate Trust Building.

Mr. Roach was a mathematician of note and had an ingenious mind and mechanical ability of high order. He developed the means of generating electricity for the lighting of railway trains as early as 1899. He patented railway joints and angle-bars, designed rail sections, and invented a method of photographing the deflections in railway track and structures under moving loads by the use of motion picture camera and reflectors. All the work of invention and research that Mr. Roach did, was actuated by the love of scientific investigation and not with the hope of any pecuniary reward. His discussion of engineering subjects was always instructive, and his friendship was prized by a large circle of professional men in St. Louis.

Mr. Roach was affiliated with the following organizations: The Third Baptist Church, of St. Louis; the Masonic Order; the American Institute of Architects; the Society of American Military Engineers; and the St. Louis Railway Club. After a severe illness of three months, he passed away on July 28, 1929.

In 1893, he was married to Mary E. Gallop, who survives him. He leaves also two daughters, Mrs. Donald B. Pheley, of Pasadena, Calif., and Dorothy E. Roach, of St. Louis; and four sons, Harry F. Roach, Jr., and Alan Douglas Roach, of St. Louis, Alden G. Roach, Assoc. M. Am. Soc. C. E., of Pasadena, Calif., and Noyes H. Roach, of Joliet, Ill.

Mr. Roach was elected a Member of the American Society of Civil Engineers on January 19, 1925.

\*Memoir prepared by a Committee of the St. Louis Section consisting of F. G. Jonah, C. D. Purdon, and Baxter L. Brown, Members, Am. Soc. C. E.

## THEODORE CHARLES ROBERTS, M. Am. Soc. C. E.\*

DIED SEPTEMBER 28, 1928.

Theodore Charles Roberts was born in New Orleans, La., on December 3, 1875. He spent his boyhood there and, simultaneously with his early school days, worked in a system of shops owned by his father, thus acquiring a knowledge of mechanics and manufacturing, together with his elementary education. Following his public school preparation, his education was continued at Tulane University, at New Orleans, and at Colorado College, Colorado Springs, Colo. He was a tireless student both through his school and college days and throughout his life. Were it a problem in mathematics or mechanics, a question of industrial or political economy, the design of an industrial plant, the location of a railroad, the management of a high enterprise, the purchase of equipment, or a game of bridge, his ever active mind was alert and eager.

His dissipation, like that of many other engineers and authors, was in his work. His rise in the industrial world was rapid. Always eager for mental advancement, he spent approximately six years teaching mathematics while serving as Field Engineer and Construction Superintendent for the Canon City Light, Heat, and Power Company, as Manager for several combined exchanges for the Colorado Bell Telephone Company, and as Construction Superintendent and Engineer for the Telluride Power Company, Telluride, Colo. At this time, while he was associated with Mr. Ralph D. Mereshon, a number of high-tension electrical principles were established.

Subsequent to these engagements, Mr. Roberts became Manager of several mining and milling companies in Colorado. With the experience accumulated up to this time he entered the field of Consulting Engineering and Contracting, at Leadville, Colo. His keen insight, strong personality, and executive ability created a demand for his services with the United States Reduction and Refining Company as Engineer in charge of all design, construction, and operation for its various plants.

From 1904 Mr. Roberts served two years as Chief Electrical Engineer for the American Smelting and Refining Company, in charge of all electrical equipment. His efficiency here caused his transfer to the position of Chief Engineer and Master Mechanic in charge of engineering and mechanical operations for the Pueblo, Colo., Plant.

In 1908 the electrical industry had exceeded all expectations and left the works inadequate for the demand. This exigency grafted Mr. Roberts into the position of Chief Engineer and General Superintendent for the Arkansas Valley Railway, Light, and Power Company, at Pueblo, Colo., a property of H. M. Byllesby Company, of Chicago, in charge of the rebuilding, expanding, and bringing up to date its steam and hydro-electric power plants, street rail-

\* Memoir prepared by W. R. Palmer, M. Am. Soc. C. E., and John G. L. Cunningham, Esq., New York, N. Y.

ways, high and low-tension transmission lines, and the electrification of various industries to be served by them.

By 1912 the expanding copper industry in Arizona had outgrown entirely its reduction plants which caused a complete re-organization of operations. The United Verde Copper Company, one of the properties of the late Senator Clark, as did the others, decided on this expansion and engaged Mr. Roberts for the work. It consisted of a new reduction plant, for 9 000 000 lb. of copper per month; a housing development for 10 000 people, with the attendant roads, streets, public utilities, steam and electric railroads, and land reclamation; as well as the management of the operations for the existing plant. In this position his wide experience and ability brought him into all the large engineering developments of the State.

With the beginning of hostilities in 1917, and prompted by his patriotic spirit, Mr. Roberts offered his services to the United States Government. He was commissioned a Major in the United States Army and became engaged in the manufacture of dyestuffs and chemicals.

Soon after the Armistice was signed he became associated with the phonograph industry, as Assistant to the President in Charge of Engineering and Manufacturing for the Columbia Graphophone Manufacturing Company, where, under his direction, the production of the plant was increased from \$15 000 000 to \$100 000 000 per year, gross sales. Unfortunately, the heavy responsibility and concentrated application for many years had so broken his health that thereafter he had to limit his services as a consultant to a few selected clients. His liberal disposition and interest in others caused him to devote himself through his spare moments to scientific and other writings in order to perpetuate as far as possible his broad experience.

Mr. Roberts died as simply as he had lived. He attended his club in the afternoon, passed the evening with his family, and joined the staff of his Creator very quietly before dawn on September 28, 1928.

In the world of recreation Mr. Roberts' intensive work was broken now and then by a skillful game of golf, a friendly bout with the gloves, a wild-game hunting trip, a cruise in his yacht, or a clever game of bridge. He was a member of the American Society of Mechanical Engineers, the American Institute of Mining and Metallurgical Engineers, the American Institute of Electrical Engineers, the National Electric Light Association, the American Institute of Architects, the Engineers and Columbia Yacht Clubs of New York, the Country Club of Norwalk, Conn., and the Country Club of Prescott, Ariz. He affiliated himself with the Masonic Fraternity early in life, working through the various degrees to that of Knight Templar and Master of the Royal Secret of the 32d Degree, and became a Noble of the Mystic Shrine.

Mr. Roberts is survived by his widow, Marion Wall Roberts, M. D., and a daughter, Margaret Mary. A son, Theodore Merton, died in 1916.

The sudden demise of Mr. Roberts, in the prime of life, took from the engineering world a thinker and a leader, and from his family, his friends, and his associates a boon companion, a genial host, and a gallant gentleman. Once more the Builder has called. In the ranks of the valorous another engineer of great distinction stands, in silent, smiling dignity—enobled by his service and sacrifice for humanity and enshrined with his peers in the perpetual glory of great accomplishment.

Mr. Roberts was elected a Member of the American Society of Civil Engineers on September 11, 1917.

**ALBERT FOWLER ROBINSON, M. Am. Soc. C. E.\***

---

**DIED JANUARY 20, 1929.**

---

Albert Fowler Robinson, the son of William Dirgin and Ruth (Fowler) Robinson, was born on October 12, 1853, of Puritan stock, at Henry, Ill.

He was graduated from the University of Illinois in 1880 with the degree of Bachelor of Science in Civil and Mining Engineering, and, in 1881, took a Post-Graduate Course in Bridge Engineering. In 1891, the University recognized his high scholastic attainments and fine record in his profession by conferring upon him the degree of Civil Engineer.

Immediately after his graduation and prior to taking his Post-Graduate Course, Mr. Robinson entered the service of the Denver and Rio Grande Railway Company as Chainman. In 1882, he became Assistant Bridge Engineer on the Chicago and Alton Railway, and, in 1883, accepted a position with the Union Bridge Company, Athens, Pa., as Calculator. His first service with the Atchison, Topeka, and Santa Fé Railway Company began in July, 1884, at which time he was appointed Bridge Engineer. In September, 1885, he accepted a similar position with the Chicago, Burlington, and Northern Railroad Company.

In 1889, Mr. Robinson became associated with the late E. L. Corthell, Past-President, Am. Soc. C. E., in Chicago, Ill., as Chief Designer; and, in 1891, he accepted a position as Chief Draftsman with Purdy and Henderson, Architects, in Chicago. In June, 1892, he became Assistant Engineer with the Chicago, Rock Island, and Pacific Railway Company, with which he remained until August, 1894, when he entered private practice. In 1896, he again entered the service of the Atchison, Topeka, and Santa Fé Railway Company as Bridge Engineer, with headquarters at Topeka, Kans. He was appointed Bridge Engineer of the entire System in 1901, with headquarters in Chicago subsequent to 1904, which position he retained until his death.

Mr. Robinson was recognized as an outstanding leader in his profession, and took an active interest in the work of the various engineering societies of which he was a member. He was a pioneer in many respects, notably in ballasted floor construction for railroad bridges and in timber preservation, as applied to railroad cross-ties and piling in particular. He looked upon his engineering work as more than a means of livelihood. In fact, he felt that it was his service to mankind to do his work well; and in truth he might, for upon the design of bridges depends the lives of many railroad passengers. These structures are enduring monuments to his work and stand in great numbers from Chicago westward to the Pacific and southward to the Gulf Coast. Two of the outstanding structures are the Missouri River Bridge, at Sibley, Mo., and the Mississippi River Bridge, at Fort Madison, Iowa.

In his various activities, Mr. Robinson made a host of friends, and to those who knew him intimately, his engineering achievements are over-

\* Memoir prepared by a Committee of the Illinois Section consisting of Messrs. Albert F. Reichmann, *Chairman*, and G. W. Harris, *Members*, Am. Soc. C. E., and J. de N. Macomb, *Assoc. M. Am. Soc. C. E.*

shadowed by his fine character. His keenness of mind, his exceptional ability, and his personal qualities endeared him to all, particularly to the younger men who frequently sought him for advice and guidance, and to whom he gave freely of his time and thought.

It was in 1885 that Mr. Robinson was married to Loretta Kate Elder, at Topeka, by whom, with three sons, Raymond Elder, Albert William, and Donald Bruce, he is survived. A fourth son, Phillip Edward, died in 1891. Mr. Robinson's family life was ideal.

He was a member of the American Railway Engineering Association, the Western Society of Engineers, the American Society for Testing Materials, the Chicago Engineers' Club, and Tau Beta Pi Fraternity. He was also a member of the Masonic Fraternity, the Glen Oak Golf Club, and the First Congregational Church of Oak Park, Ill.

Mr. Robinson was elected a Member of the American Society of Civil Engineers on November 2, 1887.

## ARTHUR WELLS ROBINSON, M. Am. Soc. C. E.\*

DIED MAY 23, 1929.

Arthur Wells Robinson was born at Collingwood, Ont., Canada, on March 28, 1861. He was the son of Joseph Orr Robinson, a Solicitor of the Middle Temple, London, England, who at that time was engaged in legal work in connection with the town site of Collingwood, and of Georgiana Buchanan, the daughter of James Buchanan, H. M. Consul at New York, N. Y.

Mr. Robinson was educated at Leamington, England, and at St. Catharines, Ont., Canada, and the Brantford (Ont.), Collegiate. As a mere boy he showed great ability in mechanical invention and design and at the age of seventeen went to Montreal, Que., Canada, to work under the late John Kennedy, M. Am. Soc. C. E. (afterward Sir John Kennedy), Chief Engineer of the Montreal Harbor and St. Lawrence River Ship Channel. He remained with Mr. Kennedy for eight years during which time he was engaged on the design and maintenance of a fleet of forty dredges and vessels used in connection with the Ship Channel, and thus he obtained an intimate knowledge of this great waterway.

In 1885, Mr. Robinson opened an office in Philadelphia, Pa., as Consulting Engineer, but very soon became associated with the Bucyrus Company, of South Milwaukee, Wis., as Designer and, later, as Managing Engineer. In this capacity he laid the foundation of much of the standard practice in dredge and steam-shovel design and took out many patents. He also developed the American steam shovel, including the large types used in the iron ore mines of the Lake Superior Region. In 1900, he returned to Canada and practiced as a Consulting Engineer in Montreal and, later, was engaged by the Department of Public Works of Canada. In addition, he acted as Consulting Engineer to the Egyptian Government and the Government of the Sudan, as well as to the Crown Agents, for various Colonies.

At the request of the Egyptian Government in 1907, Mr. Robinson visited the Upper White Nile and made a report on the great swamp area, known as the Sudd Region. In this area much of the water of the White Nile was lost through evaporation, and the problem was to prevent the spreading of the flow from the main channel, thereby checking evaporation and saving the water for use in Egypt, 2 500 miles further down the river. In the Sudd Region the great swamp grasses and papyrus reeds grow 15 ft. high and cover the country for miles. Aided by his sound judgment and knowledge of the rank growth of this region, Mr. Robinson designed three dredges specially adapted to such work and by their use the river was confined to its proper channel and the flow very greatly increased, thus enabling many more acres to be irrigated in Egypt. He also designed a shallow draft self-propelling dredge to cut through the constantly shifting sands of the River Niger. This dredge was used in Mesopotamia during the World War—had it been sent there earlier, it would have aided greatly the Relief Expedition of the River Tigris.

During this period in Mr. Robinson's career he designed dredges for land reclamation work in many places, notably Lincoln Park, Chicago, Ill., which

\* Memoir prepared by F. E. M. Robinson, Esq., Upper Melbourne, Que., Canada.

is land largely reclaimed from Lake Michigan. The same kind of work was done in Bombay, India, where large areas were reclaimed and added to the city by one of his machines. Many dredges, large and small, were also built from special and individual designs for harbor and river works in India, China, Japan, Siam, Burmah, and many other places. The Panama Canal was largely excavated by machines of his earlier type, and the Cape Cod Canal by two dredges specially designed for the purpose. In all, more than 400 separate and distinct dredges were constructed from his designs and this without counting several thousand steam shovels of which many, of course, are built of a single pattern. Scarcely a river or harbor in the world but shows his influence, directly or indirectly, and it is not too much to say that no man has made so great a mark on the physical surface of the world as Mr. Robinson. His active professional life lasted just fifty years.

He had a unique gift amounting to genius for mechanical design and this with habits of great industry enabled him to produce a constant stream of new and original designs and inventions until the very week of his death. Many patents were taken out in England and the United States and a still greater number of inventions, equally as original, were left unprotected. He utilized but little mathematics and used graphical methods to check his almost unerring instinct for appropriate size and strength of material. Many can bear witness to his almost uncanny facility in design, and to the speed with which he could produce a finished drawing of the new thoughts and inventions as they came to him. His was the creative power of a great artist working in steel.

For the last twenty years most of his dredges for use outside Canada and the United States were built by Messrs. Lobnitz and Company, Renfrew, Scotland, and with this firm he had the most pleasant relations. At the time of his death the Company was building several dredges from his design for use in the Sudan. Mr. Robinson returned early in April, 1929, from a five months' trip to Manchuria, Korea, and Japan where he inspected twenty-six harbors, and until just before his death was engaged in designing machines for work in these countries.

He was very devoted to the simple life and loved the quiet of the country; he was exceedingly fond of music and flowers and had a wonderful gift for landscape gardening; but greater than his achievements was the man himself: A devout Christian, Mr. Robinson lived in the realization of his Master—"seeing Him who is invisible." His faith was unshakable, his honor stainless, and, of him, his sorrowing friends may well say: "Whatever record leap to light, he never shall be shamed."

He was a member of the American Society of Mechanical Engineers, the Institution of Civil Engineers, London, England, and the Engineering Institute of Canada.

In 1892, he was married to Margaret Beatrice, daughter of the late T. M. Taylor, of Montreal, Que., Canada, who survives him, together with a son, F. E. M. Robinson, of Upper Melbourne, Que.

Mr. Robinson was elected a Member of the American Society of Civil Engineers on February 3, 1892.

## EDWARD STANLEY SAFFORD, M. Am. Soc. C. E.\*

DIED DECEMBER 31, 1929.

Edward Stanley Safford was born at Boston, Mass., on September 6, 1847. Following his graduation from the English High School in Boston in 1865, he entered, in the same year, the Massachusetts Institute of Technology which school had just been organized. He was enrolled as a member of the first graduating class, that of 1868, and took the course in Mining and Civil Engineering.

Mr. Safford was employed as Rodman on the first survey for the Atchison, Topeka, and Santa Fé Railroad, on July 7, 1868, from Topeka to Burlingame, Kans., a distance of 29 miles. Later, he was engaged on the long preliminary surveys, and, as Division Engineer, had charge of the construction of 45 miles of the road from Emporia to Florence, Kans.

In the fall of 1871, Mr. Safford laid out what is now the flourishing city of Hutchinson, Kans., on the Arkansas River, at the mouth of Cow Creek. He returned to Boston in the spring of 1872, and was engaged as Contractor on public works in and about Boston until 1878. He was Chief Engineer of the New London Northern Railroad Company from 1878 to 1880, after which he served as Division Engineer on the West Shore Railroad (then the New York, West Shore, and Buffalo Railroad) first at Newburgh, N. Y., in charge of construction in Orange County, New York, and, later, at the Buffalo Terminal. In 1884 and 1885, he was employed on the Philadelphia Branch of the Baltimore and Ohio Railroad, with headquarters at Upper Falls, Md. Subsequently, he established a home in Arlington, Mass. In 1885, he became Principal Assistant Engineer on the Mobile and Birmingham Railroad, remaining in Alabama from 1886 to 1888; later, he acted as Chief Engineer for the Shelby Iron Company, at Shelby, Ala.

In the winter of 1890-1891, Mr. Safford made a survey on snowshoes in Nova Scotia. From 1892 to 1895, he was Engineer in charge of construction of the Palisades Tunnel and the building of the two large coal-shipping trestles on the Hudson River, in addition to a terminal for the New York, Susquehanna, and Western Railroad Company, all of which work passed into the hands of the Erie Railroad Company soon after its completion.

In 1897, he went to Mexico and made surveys for the Chihuahua and Pacific Railroad Company from Chihuahua, Mexico, extending west for 200 km. He subsequently was chosen as Chief Engineer of this line, made location surveys, and finished the construction by May, 1900. Mr. Safford remained in Mexico until June, 1904, when he returned to the United States. He lived at Somerville, N. J., and at Sharon, Mass., for about three years, and then became Engineer for the contractors who were eliminating grade crossings on the New York, New Haven and Hartford Railroad, at New Bedford, Worcester, and Dorchester, Mass. In 1911, he went to Haiti on railroad construction. He returned to the United States the following year, thus terminating his business activity.

\* Memoir prepared by Louis P. Gaston, M. Am. Soc. C. E.

Mr. Safford was notable among engineers of an older generation as one who had special ability as a Locating Engineer at a time when railroad location and construction were at their height in this country. He will also be remembered by his many friends for his genial disposition and for his cheerfulness under a great affliction—deafness.

Mr. Safford was elected a Member of the American Society of Civil Engineers on December 6, 1882.

## ARTHUR CHARLES SANDSTROM, M. Am. Soc. C. E.\*

---

DIED AUGUST 4, 1929.

---

Arthur Charles Sandstrom was born on April 26, 1888, at Roswell, N. Mex., the son of Joachim Charles Sandstrom and Jacobina Elsa (Funnemark) Sandstrom. Although a fourth generation American, he was of absolutely pure Norwegian strain, his great-grandparents having left Norway to settle in the United States in the early part of the Nineteenth Century.

The story of this remarkable man is one of stern courage and strenuous effort. On the death of his mother, his sole surviving parent, he, at the age of 13, found himself alone face to face with the problems of life. He had to earn his own living, support and educate himself, his three younger brothers, and a sister, as best he could.

In 1906, when 18 years of age, Mr. Sandstrom began his engineering career as Surveyor's Assistant in the employ of the Southern Pacific Railway Company in Central Oregon, which position he retained until the end of 1907. Subsequently, he was engaged as Surveyor and Draftsman on road construction and land surveys in the same State, studying assiduously the while at night and in his leisure through the International Correspondence Schools.

From May, 1908, to September, 1909, he was engaged as Levelman, Transitman, and Chief of Party on land sub-division, extensive topographical surveys, and railway location and construction for the United Railways Company, Portland, Ore.

From September, 1909, until May, 1910, he studied engineering at the Oregon Agricultural College, and, during the Christmas vacation, was Chief of Party on railway location for the United Railways Company. Later, until September, 1910, he worked as Chief of Survey, Draftsman, and Estimator for the same Company.

From October, 1910, until May, 1914, Mr. Sandstrom was both student and Assistant Instructor of Civil Engineering at Leland Stanford Junior University, California. During the summer vacations he was engaged on railway and hydro-electric studies in the Cascade Mountains, in Oregon, in the various capacities of Draftsman, Instrumentman, Chief of Party, Estimator, and Hydrographer. From June, 1914, he worked with the Standard Oil Company on the construction of oil tanks, laying pipe lines, and testing machinery.

He was appointed Resident Engineer in October, 1914, on the location and construction of twenty-five miles of highway which he finished in two years (July, 1916). He also did special work for the Spring Valley Water Company, of San Francisco, Calif., in the calibration of current meters, besides designing and constructing an irrigation system. Subsequently, he held the post of Inspector of Sewerage and Water Supply and other miscellaneous work for the City of Palo Alto, Calif. In this year, 1916, he was graduated as Civil Engineer from Stanford University.

---

\* Memoir prepared by Robert W. Hornsby, M. Am. Soc. C. E.

South America now offered a wider field for his energies, and in July, 1916, Mr. Sandstrom entered the service of the Braden Copper Company in Chile, as Locating and Preliminary Design Engineer and Estimator for three large hydro-electric projects. He was Engineer-in-Charge over all work at the Pangal Plant (15 000 kw.) for one year, carrying out the construction of roads, housing, excavation of aqueduct, which included fifteen tunnels, and all the accessories of a great establishment. Then, successively, he was for one year, Assistant to the Construction Engineer in special hydraulic studies; in charge of the Materials Department, including requisitioning, tracing shipments, etc., to the extent of \$10 000 000 (gold) worth of plant. As is usual in all mining work, his duties were of a most varied nature. He looked after the equipment and supplies; for four months he was Superintendent of Construction (and Manufacture) of 12 km. of 80-in. wood-stave piping (mastic lining), and an 8-mile timber tailings flume; completion of dwellings; operation of the aqueduct for the hydro-electric plant; transport of 15 000 tons of material over difficult mountain roads; and repair of hydraulic works destroyed in storms.

In November, 1919, Mr. Sandstrom transferred his services to the Andes Copper Company at Potrerillos, Chile, as Hydraulic Engineer in direct charge of surveys, designs, and estimates of a 65-km. wood-stave pipe line in the High Andes (La Ola Pipe Line), including the partial excavation of several long hand-driven tunnels. He also made studies of possible hydro-electric plants in the same locality, surveys for a 90-km. railway and aerial tramway at an elevation of 17 000 ft. He was likewise Assistant Superintendent of Construction on preliminary work for large copper reduction plants.

In February, 1920, the Compania Chilena de Electricidad secured his services and Mr. Sandstrom was put in direct charge of the construction of a hydro-electric plant, "Maitenes", and the revision of an already existing plant, "La Florida", totaling 43 375 kw., together with all their accessory works (8-km. aqueduct) which he finished; he also made studies and surveys for future hydro-electric plants on near-by streams. He remained with this Company until June, 1920, having meanwhile solved the difficult problem of eliminating the unusual quantity of sand and gravel carried by the supplying streams.

Mr. Sandstrom's professional services as hydro-electric expert were then requisitioned by the Whitehall Securities Corporation, of London, England, whither he was called to work on designs and estimates for several proposed hydro-electric plants for Chile (22 000 h.p.) from July, 1924, to January, 1926.

Returning to Chile, he assumed the position of Chief Engineer with the Compania Hidro-Elctrica del Volcan (a subsidiary company of the Whitehall Securities Corporation), for which he studied several hydro-electrical projects, making final surveys, plans, and estimates for a 40 000 h.p. plant on the Rio Maipo, near Santiago, Chile. He spent five months in England and the United States, completing the plans, ordering construction plant, and making the final arrangements to execute the work (the "Queltehues" Plant).

From April, 1926, until the day of his death Mr. Sandstrom superintended the construction of the Queltehues Plant (Rio Maipo) as Chief Engineer in

direct charge of the entire technical construction, and of the commercial phases of the work in Chile. This, his last work, was completed at the time of his death in all but a few minor details. It was particularly difficult, the plant being situated in the upper reaches of the Maipo near its confluence with the Rio Volcan 80 km. southeast of Santiago, and 14 000 ft. above sea level, in the roughest country. The work was extremely heavy, and occupied 2 400 men during approximately 2 years. The aqueduct was 12 km., 3 m., long, 5 166 m. of which was covered, and 2 162 m., open canal. It also included five tunnels with a total length of 3 km., 495 m. The service roadway was 23.5 km. long, with township power houses and proportionate accessories. It is, to date, the largest plant on the Pacific Coast of South America.

On Sunday, August 4, 1929, Mr. Sandstrom was killed by a fall of 65 m., while inspecting a portion of the work. He had been ill in Santiago, but, ever attentive to duty, he rose and accompanied a commission of the management to look over the plant. He was standing on the edge of a chasm leading to the intake, in order to observe better the accumulation of sand, a problem that was always troubling him; the earth gave way, and he was precipitated to the bottom of the chasm and killed instantly.

The news of his death struck Santiago society, both native and foreign, with consternation and grief. His funeral was one of the largest ever seen in the Capital, as if his death had been a National loss (for so, indeed, it was considered), more than 1 000 persons having attended. Such was the end of this great American Norseman.

Mr. Sandstrom was a man of most noble character. There is a trite saying that "there is no greater enemy than one of one's own profession"; but such could never be said of him. He was a born leader (not driver) of men, a just and kindly chief, and a true comrade; hence, he compelled respect and admiration from all with whom he came in contact.

He had a most striking personality, and, as Walt Whitman aptly puts it, "he convinced with his presence." Cast in an heroic mould, of gigantic stature and physique, he worthily represented that mighty race which changed the history of the world, ten centuries ago, and whose descendants to-day form the best elements of English-speaking nations all over the earth.

He was adored by his workmen (for many of whom he had risked his own life on repeated occasions), and by his assistants who looked upon him as upon a father. He handled everything down to the minutest detail in his work, details which others usually leave to their assistants. He was always ready and eager to listen to any suggestion, even from his lowest workman, and to adopt it, did he find it feasible.

In social life Mr. Sandstrom was retiring, and preferred his family and his home which was his Paradise. Although a quiet, proud man, yet he was the essence of kindness and consideration for others. He took an interest in Freemasonry, and was a member of the American Lodge ("Huelen Lodge") at Santiago.

Mr. Sandstrom possessed all the qualities of a great engineer, and was looked upon as the future organizer of projects of vast proportions embracing the whole of the Andes Range. His death at the early age of 41 years is a serious blow to the Engineering Profession.

In 1920, he was married at São Paulo, Brazil, to Lena Richardson, a native of Manchester, England, who, with four children, survives him.

Mr. Sandstrom was elected an Associate Member of the American Society of Civil Engineers on May 31, 1916, and a Member on July 16, 1928.

## LLOYD SCHWARTZ, M. Am. Soc. C. E.\*

---

DIED NOVEMBER 7, 1929.

---

Lloyd Schwartz, the son of John G. and Martha Jane (O'Neil) Schwartz, was born on September 1, 1889, in Golden, Ill. His early education was obtained in the public schools of that town. He was graduated in June, 1911, from the University of Illinois with the degree of Bachelor of Science in Civil Engineering. While at college he was a member of the University baseball team, playing an outfield position regularly. Later, during the second semester of 1913, Mr. Schwartz took post-graduate work in Structural Engineering at the University, and at the same time was an Instructor in Surveying.

Immediately after his graduation in 1911, Mr. Schwartz accepted employment with the Division of Highways of the State of Illinois, and except for the time spent in post-graduate work at the University of Illinois and in the United States Army during the World War, he remained with that organization until his death. His advancement was continuous and in July, 1919, he became District Engineer of the Ninth District, which includes the southernmost fourteen counties of the State with headquarters in Carbondale, Ill. In this position, he directed all State highway activities in the District, including design, construction, and maintenance, and also acted as Consultant in county and township work.

From June, 1918, to June, 1919, Mr. Schwartz was in the service of the United States as a Master Gunner in the 72d Regiment of the Coast Artillery Corps. His overseas service extended from August, 1918, to May, 1919.

He was a member of the Dyhrkopp Engineering Company, a partnership of three, which was formed in October, 1925. He served this Company as Consultant Engineer until its dissolution in 1927. A few months after the Company was formed, he applied for, and after an examination, received his license as a Structural Engineer.

Mr. Schwartz was active in many civic, fraternal, and social enterprises. He held membership in the Carbondale Rotary Club, the American Legion, the Benevolent and Protective Order of Elks, the Masonic Blue Lodge, the Chapter, the Commandery, and Shrine, the Jackson Country Club, the Midland Hills Country Club, and the Dog Tooth Bend Hunting Club.

Lloyd Schwartz was a clean and ardent sportsman with marked ability in many forms of athletics. However, his recreational activities indicated a preference for golf in the summer and hunting in the fall and winter; and it was while hunting ducks at the Dog Tooth Bend Hunting Club on the Mississippi River that he met his death. Late in the afternoon of November 7, 1929, he had shot a duck which fell into the river a short distance from the blind. In attempting to retrieve it, he waded off a shelf in the river bed into deep water, and the weight of his hunting togs gave him no chance for his life.

---

\* Memoir prepared by E. R. Knight, Assoc. M. Am. Soc. C. E.

Funeral services were held at his home in Carbondale, Ill., under the direction of the Knights Templars of Beauseant Commandery, after which interment ceremonies were completed in Golden, with the Masonic Blue Lodge of that town in charge.

He was married on February 14, 1920, to Lucinda A. Wesson, at Aurora, Ill., who survives him, together with three sisters, Mrs. Glen Cutforth, of Eldorado, Kans., Mrs. Laura E. Duff, of Cedarville, Wis., and Mrs. May Reitman, of Chicago, Ill., and two brothers, Earl Schwartz, of San Francisco, Calif., and Clyde Schwartz, of Quincy, Ill.

Mr. Schwartz was elected an Associate Member of the American Society of Civil Engineers on March 12, 1918, and a Member on March 15, 1926.

## CHARLES ALFRED SHEPPARD, M. Am. Soc. C. E.\*

DIED OCTOBER 18, 1928.

Charles Alfred Sheppard was born at Southampton, England, on February 12, 1866, the son of George and Ellen (Major) Sheppard. In 1870, the family came to the United States and settled at Beatrice, Nebr.

Mr. Sheppard began his engineering career by employment in minor capacities, on railroad location surveys and construction work during the great development of the West in the Eighties. At that time he was engaged in work for various railroads which have since become part of the Chicago, Burlington and Quincy Railroad System. In 1888, he devoted a year to special study at Fairfield College, Fairfield, Nebr., and, in 1889, became Assistant Engineer in charge of second-track construction for the Louisville and Nashville Railroad Company.

An extensive industrial development was started at Granite City, Ill., in 1892, and Mr. Sheppard was placed in charge of the field work, supervising the construction of the sewer system, water-works, streets, paving, etc. To a large extent, this undertaking proved to be the turning point in his career, as from that time on practically all his work was in connection with the growth of the St. Louis Industrial District on the east side of the Mississippi River in the construction of railroads, levees, sewers, drainage systems, and highways. This work grew to such an extent that, in 1900, he formed a partnership with Mr. W. H. Morgan, with offices at Edwardsville, Ill. This partnership continued until his death.

When the construction of the Chain of Rocks-Kingshighway Bridge across the Mississippi River was begun in the fall of 1927, Messrs. Sheppard and Morgan were retained to supervise the work on the east side of the river, and Mr. Sheppard devoted most of his time to this work until October, 1928, when he took a short vacation to visit a sister in Omaha, Nebr., who was ill. As he was preparing to return from this trip on October 18, his automobile was struck by a heavy truck and he was instantly killed.

Like many other engineers, Mr. Sheppard was very modest as to his ability. He was held in high esteem by all who knew him. One of his principal pleasures was derived from his membership in the choir of St. John's Methodist Episcopal Church of Edwardsville. His true character as a man cannot be better expressed than in quoting from a resolution prepared by the Official Board of that Church:

"He had profound and clear Christian convictions, and translated them into the practices of his daily life. All his conduct was a practical application of his religious principles. Recognizing that beliefs are individual, he did not attempt to impose his beliefs or rules of conduct on others, and could hold and express differences of opinion without giving or taking offense. Capacity for integrity, sound judgment, and industry, a talent for friendship, never failing good humor, are qualities he shared with many; few are as faithful in daily life to lofty spiritual ideals.

\* Memoir prepared by Baxter L. Brown, M. Am. Soc. C. E., and W. H. Morgan, Esq., Edwardsville, Ill.

"The close of his life, like the setting sun, leaves to the world the glow of perfect day.

"Walk with him and keep unbroken  
The bond which Nature gives,  
Thinking that our remembrance, though unspoken,  
May reach him where he lives."

In 1895, Mr. Sheppard was married to Olive Morgan, of Bostwick, Nebr., who died on June 25, 1927. Three children survive them: Leila, Robert, and Charles H. The latter succeeded his father in the re-organized firm of Sheppard, Morgan, and Schwab, with offices at Edwardsville and Alton, Ill.

Mr. Sheppard was elected a Member of the American Society of Civil Engineers on November 30, 1909.

## MERRITT HAVILAND SMITH, M. Am. Soc. C. E.\*

---

DIED DECEMBER 9, 1926.

---

Merritt Haviland Smith, the son of Merritt Haviland and Mary Adelia (Howard) Smith, was born in New York, N. Y., on May 21, 1862. During his attendance at the Pennsylvania Military College, from which he was graduated in 1880 with the degree of Civil Engineer, he received both engineering and military instruction.

After his graduation, Mr. Smith studied law for a year, and then entered the Engineering Corps of the Pittsburgh and Western Railroad Company, with which he remained until 1884. On leaving the railroad service he was employed by the City of New York in the Department of Public Works on the Croton Aqueduct until 1890. For approximately two years thereafter, he was engaged on general engineering and land development work in Florida.

In 1892, Mr. Smith re-entered the service of the City of New York in the Department of Finance, continuing in that Department until 1906. He was then appointed Department Engineer in the Board of Water Supply in charge of the Southern Aqueduct Department, and, in 1910, promoted to the position of Deputy Chief Engineer. On August 1, 1914, he was appointed Chief Engineer of Water Supply in the Department of Water Supply, Gas, and Electricity, and continued in this position until he was retired on December 3, 1926.

In Mr. Smith's engineering association with the City of New York, which covered a period of about forty years, the major portion of his service was in connection with its water supply system; but while he was in the Finance Department, he also was called upon to do important work in connection with virtually all the engineering activities of the City. As Department Engineer in charge of the Southern Aqueduct Department, he was responsible for the construction of the Catskill Water Supply System from the Hunter's Brook Siphon to the city line, including the Kensico and Hillview Reservoirs. From 1910 to 1914, his work on the Catskill System was mainly of an administrative character. As Chief Engineer of Water Supply he had the responsibility of maintaining and operating the entire water supply system of the City of New York, including extensive construction work connected therewith.

In addition to his engineering activities, the military career of Mr. Smith stands out for the extended service which he rendered to his State and Country. This military service started when he joined Company F of the 7th Infantry, New York National Guard, on October 19, 1880; he was appointed Corporal on March 2, 1886; and was honorably discharged on September 19, 1889. He again enlisted as a private in Troop 1, Squadron A, N.Y.N.G., on January 2, 1896; was promoted to Corporal, April 18, 1896; Sergeant, April 27, 1899; and honorably discharged on January 1, 1902. On January

\* Memoir prepared by William W. Brush and Jules Breuchaud, Members, Am. Soc. C. E., and Robert Ridgway, Past-President, Am. Soc. C. E.

6, 1902, he was commissioned a Lieutenant of Squadron A; promoted to the rank of Captain on February 3, 1906; and resigned on April 24, 1907. He was commissioned as Captain of the First Cavalry, N.Y.N.G., on February 7, 1912; promoted to the rank of Lieutenant-Colonel on May 23, 1912; appointed Lieutenant-Colonel of the First Field Artillery, N.Y.N.G., October 19, 1914; advanced to the rank of Colonel on March 23, 1917; and was honorably discharged from the military service of the State, while in the United States Army, in 1919.

Colonel Smith's service with the United States Army shows that he was commissioned by the President on June 7, 1898, as Captain, for service in the Spanish-American War, and was assigned to Company D, First United States Volunteer Engineers. His regiment was part of the force sent to Porto Rico, and he was commissioned Major of the regiment on January 24, 1899, and honorably discharged, January 25, 1899, on the mustering out of the regiment on that date. He was commissioned a Lieutenant-Colonel, Field and Staff, First Field Artillery, N.Y.N.G., October 20, 1914; and was called into the Federal Service on June 28, 1916, when his regiment formed part of the force sent to the Mexican Border that year. He was mustered out of the Federal Service on November 15, 1916, and again mustered into the Federal Service on June 22, 1917, for the World War. He left the United States for overseas' service, June 30, 1918, and was actively engaged in the field with his regiment, the 104th Field Artillery, returning to the United States on January 1, 1919. He was honorably discharged on February 12, 1919.

The character of Colonel Smith's military work in the World War is shown by the citation that he received in Special Order No. 86, 27th Division, 1919, for exceptional devotion to duty during the operations of the 52d Field Artillery Brigade in the vicinity of La Claire Farm, and Bois de Forges, France, on September 9 to October 18, 1918, before and during the Meuse-Argonne Offensive. The War Department record further states: "This officer rendered conspicuous services, and although seriously ill, continued in the performance of his duties until completely prostrated."

Although Colonel Smith was physically unable to continue actively in the military service after his return from France, he maintained a live interest in its work to the time of his death.

In addition to his engineering and military service, Colonel Smith took part in the official work of the City of Yonkers, N. Y., of which he was a resident, acting as Park Commissioner from 1900 to 1902, and as Police Commissioner during 1905 and 1906.

No description of Colonel Smith's life would be complete without special reference to his exceptional ability as a leader in any gathering. In height he was several inches above his fellows, with a fine military bearing. His voice in song or story would hold the attention of all, and added greatly to the enjoyment of those present at the many social and other functions that he attended. As a result of his varied activities, his friends were numbered literally in the thousands.

On December 30, 1890, he was married to Maude M. Underhill, by whom he is survived. His two children were Merritt H., Jr., born in 1891, who died during the World War while at the Plattsburg, N. Y., Training Camp, and Roderick Ray, who died in childhood.

He was a member of the American Water Works Association, the Municipal Engineers of the City of New York, the American Society of Mechanical Engineers, and the Chamber of Commerce of the State of New York.

Colonel Smith was elected a Junior of the American Society of Civil Engineers on June 5, 1889, and a Member on April 3, 1907.

**GEORGE FETTER STICKNEY, M. Am. Soc. C. E.\***

---

DIED JANUARY 27, 1929.

---

George Fetter Stickney was born on January 24, 1869, in St. Paul, Minn., the son of Amos Stickney and Virginia (Fetter) Stickney. His boyhood days were spent in various cities where his father, who was a Major and later a Brigadier General in the Corps of Engineers, United States Army, was stationed in charge of river and harbor improvements. He received the degree of Bachelor of Philosophy from the Sheffield Scientific School of Yale University in 1891, where he was a member of Chi Phi Fraternity.

Mr. Stickney's first employment was with the Mexican International Railroad Company. From 1891 to 1893, he served as Rodman, Leveler, and Resident Engineer retracing location surveys on the Durango Extension, supervising the construction of 30 km. of line, including yards and freight and passenger depots in the City of Durango, Durango, Mexico, making reconnaissance and preliminary surveys to Rio Tunal and supervising the grading of 25 km. of the Sierra Mojada Extension.

He entered the Government Service in 1893 as United States Assistant Engineer in charge of repairs on locks and dams on the Kentucky River in Kentucky, and made surveys for the location of Lock No. 7 at High Bridge, Ky., building the lock-gates and designing boats, barges, dwellings, etc. From 1895 to 1898, he was in local charge of the operation and care of five locks and dams, a dredge and a snag-boat on Green and Barren Rivers and a lock on Rough River, Kentucky. In addition, he rebuilt part of Dam No. 2 and finished the construction of Lock No. 2 at Rumsey, Ky.

Mr. Stickney served for nearly two years in the United States and Cuba during the Spanish-American War as Captain in command of Company C, Third Regiment, United States Volunteer Engineers. In 1899 and 1900 he made a survey for the location of a terminal railroad at Sabine Pass, Tex.; graded streets on the outskirts of Paducah, Ky.; and made plans for the improvement of Jefferson Barracks, Missouri, with layouts for sewers, retaining walls, roads, and the grading of the parade grounds.

In 1901 he made the surveys and designed the masonry for a bridge for the Mississippi River and Bonne Terre Railroad Company in Southeastern Missouri. In 1901 and 1902 he had charge as Assistant Engineer, for the Lake Superior Power Company, of constructing the "compensating works", a movable dam of five large Stoney gates, at the head of the rapids in St. Mary's River, at Sault Ste. Marie, Ont., Canada. He also superintended the construction of piers and abutments of the Louisville and Nashville Railroad Bridge across the Alabama River at Selma, Ala., for Paterson, Collier and Company, Contractors.

In 1903, Mr. Stickney superintended the construction for the J. S. Paterson Construction Company of a concrete arch viaduct forming the east approach to the Southern Illinois and Missouri Bridge, at Thebes, Ill. In 1904 and 1905, as U. S. Assistant Engineer, he was employed on harbor work in

---

\* Memoir prepared by Joseph Ripley, M. Am. Soc. C. E.

Northern New Jersey and along Long Island Sound. For nine years, from 1905 to 1914, Mr. Stickney was employed in the Department of the State Engineer and Surveyor of New York, as Supervising Engineer, in connection with the Barge Canal; and in addition he had general charge of the design of large sections of the New York State canals, namely, the Erie, Champlain, Oswego, and the Cayuga-Seneca Canals, together with the supervision of construction on more than 250 miles of waterway, including approximately one-third of all the canal structures, the construction cost of which exceeded \$35 000 000.

Another important engagement was that of Consulting Engineer to the Lake Erie and Ohio River Canal Board of Pennsylvania from 1915 to 1917. As such Mr. Stickney had charge of preliminary investigations, surveys, preparation of plans, estimates, etc., for the proposed waterway which was estimated to cost \$100 000 000. This latter work included the canalization of the Beaver and Mahoning Rivers, in Pennsylvania and Ohio, and the construction of a canal from Niles, Ohio, to a point on Lake Erie just west of Ashtabula, Ohio, with locks, dams, and reservoirs, as well as port developments at Lake Erie and at various cities along the route of the canal.

As a Consulting Engineer Mr. Stickney maintained an office in Albany, N. Y., from 1917 to 1928, and made many hydraulic investigations for water-power developments and river improvements. He also was an expert witness in several claim cases involving water rights. He was the inventor of the siphon spillway for discharging water through dams, and of an automatic movable crest for dams. He contributed a paper entitled "Siphon Spillways"\* to the *Transactions* of the Society, as well as articles on engineering subjects to various technical publications.

Mr. Stickney was a man of keen intellect and had the faculty of quickly sifting out the essential elements of a problem and the ability to work out in detail an accurate solution. His skill in sketching rapidly and accurately with a few lines materially aided in making plain his conception of the subject or of an object. He was very methodical and kept his records in precise and complete form. He was self-reliant and on occasion was tenacious in holding to his views. Always he was a thorough gentleman, with an ever-present quiet dignity. He had been in declining health for three or four years before his death, the cause of which he had attributed to heart trouble, not knowing he had cancer of the stomach. He was buried at West Point, N. Y.

In 1894 he was married to Katherine Halloran, of Frankfort, Ky., and is survived by his widow, two children, Josephine Stickney and George Fetter Stickney, Jr., and by his mother and two sisters, all residing in New York, N. Y.

Mr. Stickney was elected a Junior of the American Society of Civil Engineers on May 1, 1894; an Associate Member on April 5, 1899; and a Member on September 4, 1906.

\* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1098.

## EDWARD AHLERT STUHRMAN, M. Am. Soc. C. E.\*

DIED MAY 31, 1929.

Edward Ahlert Stuhrman was born in New York, N. Y., on December 18, 1884, where his early life was spent and where he prepared himself for college.

He was graduated from Columbia University in the Class of 1907, with the degree of Bachelor of Science in Civil Engineering. Later, he was granted a license by the State of Illinois to engage in the practice of Architecture and was a Registered Engineer in the State of Florida.

After his graduation, Mr. Stuhrman was employed for a short time as Timekeeper and Foreman, by the Carlin Construction Company, of Brooklyn, N. Y. He then entered the service of the Turner Construction Company of New York, as Draftsman and Assistant Engineer, resigning to become connected with the Industrial Engineering Company of New York.

Upon leaving New York, he went to Chicago, Ill., where he was employed by the Chicago, Milwaukee and St. Paul Railway Company, serving with that Company for several years. From Chicago, Mr. Stuhrman went to Baltimore, Md., with the Arthur Tufts Company, and was in charge of the design and construction of warehouses and concrete water tanks for the Coco Cola Company at Baltimore, Los Angeles, Calif., New Orleans, La., Kansas City, Mo., Winnipeg, Man., Canada, and Atlanta, Ga. While in Atlanta, he was engaged as Engineer on the Candler Warehouse, Emory University Buildings, and Wesley Memorial Hospital.

Mr. Stuhrman moved to Miami, Fla., in 1924 and during the few years of his residence there, he was connected with some of the largest construction projects in Southern Florida. Some of the more important buildings on which he served as Engineer are the Congress Building, Seybold Building, First Trust and Savings Bank Building, City National Bank Building, Miami Senior High School, Gulf Stream Apartments, at Miami Beach, Whitehall Hotel, Palm Beach, Rolyat Hotel, at St. Petersburg, and the passenger station and hangars for the Pan-American Railways at Miami.

Mr. Stuhrman was a member of St. George's Protestant Episcopal Church, of New York. He was a Thirty-Second Degree Mason and a member of Yaraab Temple, A. A. O. N. M. S., of Atlanta, Ga. At the time of his death, he was President of the Miami Engineers' Club. He was also a member of the American Concrete Institute, and the Kiwanis Club.

In Mr. Stuhrman's untimely death, Florida has lost one of her most brilliant adopted sons.

He was married in Brooklyn, N. Y., on August 26, 1908, and is survived by his widow, Violet L. Stuhrman, and two sons, Everard and Ahlert.

Mr. Stuhrman was elected a Member of the American Society of Civil Engineers on September 10, 1918.

\* Memoir prepared by Meldrim Thomson, Esq., Miami, Fla.

## CHARLES FREDERICK TAYLOR, M. Am. Soc. C. E.\*

DIED APRIL 14, 1927.

Charles Frederick Taylor was born on March 27, 1860, at Lewiston, Ill. He was but a little lad when his family moved to Mooers, N. Y., a small town in the northern part of the State near the Canadian Border. Here he received his primary education and later, was prepared to enter Syracuse University, at Syracuse, N. Y.

Many amusing incidents are told of Mr. Taylor's early boyhood in the society of his several brothers and sisters. At the age of four, he had occasion to set forth on his first journey by train, going by way of the "Grand Trunk." He presented a very sad figure when through disobedience he lost his hat out of the car window and for penance was made to wear his sister's bonnet "home to grandpa's".

In 1880, Mr. Taylor and his brother, Henry L. Taylor, entered Syracuse University, where Mr. Taylor was enrolled for three and one-half years as a student in engineering. He was graduated in the Class of 1884 with the degree of Bachelor of Civil Engineering, and also with some months of special work at Rensselaer Polytechnic Institute, Troy, N. Y., to his credit. He received an honorary Civil Engineering Degree from his Alma Mater in 1905. He was affiliated with both the Phi Delta Theta and Sigma Psi Fraternities.

Mr. Taylor's active professional career included a wide variety of positions and great expanse of territory. The majority of these engagements are given in the following brief survey: From July to November, 1883, as Chainman and, afterward, Rodman and Leveler, on the construction of an extension of the Portland and Ogdensburg Railroad; from July to November, 1884, as Transitman on the construction of the Canada Atlantic Railroad; from May, 1885, to May, 1889, with Moffett, Hodgkins, and Clarke, on work including preliminary surveys of Grenell Island Park near the Thousand Islands and surveys at Oneida Lake for the Central City Water-Works Company of Syracuse; from September, 1885, to February, 1886, as Assistant Superintendent of Construction for the Newark, Ohio, Water-Works; from May, 1886, to January, 1887, as Construction Engineer on the Kankakee, Ill., Water-Works; from January to December, 1887, as Inspector of pipe laying and similar detail at the Canada Pipe Foundry for the Belleville, Ont., Canada, Water-Works; from April to December, 1888, as Construction Engineer for the Berlin, Ont., Water-Works and, later, with the Coburg, Ont., Water-Works. From May, 1889, to January, 1890, he served as Division Engineer on the construction of the Kinderhook and Hudson Railway from Niverville to Stuyvesant Falls, N. Y.; and after January, 1890, as Construction Engineer for the entire line as far as Hudson, N. Y.

In October, 1890, Mr. Taylor entered a field of service which gave him, personally, wide and rich experience in his chosen profession. He was engaged

\* Memoir prepared from information supplied by Dr. Henry L. Taylor, University of the State of New York, Albany, N. Y., and Paul P. Wiant, M. Am. Soc. C. E.

for six years with the Syracuse Water Board in charge of surveys at Skaneateles Lake and along the Skaneateles Outlet, and also on surveys connected with the condemnation proceedings to acquire the plant of the Water Company, water-power rights, etc. Early in his association with the Board he became Engineer in Charge of City Distribution of the Water-Works of the City of Syracuse. His faithful service in this employ put him in touch with financial backing that was in itself rare experience. During the last year of his service (1896), he personally supervised the laying of 80 miles of water mains.

From 1897 to 1903, Mr. Taylor acted in the capacity of Contractor for New York State on canal construction. During the latter part of this period, he also served as Treasurer of the Boston Tunnel Construction Company and probably the most noteworthy of his engineering feats was Section B on the East Boston Tunnel—more than a mile in length under the harbor. The tunnel was constructed "101 ft. below mean-tide level, the side walls and arch of concrete in the largest span ever constructed at that date in soft materials." It is remarkable that there occurred "the loss of but two human beings at a time when work was abandoned on the New York North River and the dead had not been removed from the flooded works." Also, at this time, the anthracite coal strike threatened alarming and continued financial disaster.

His Boston subway experience so fitted Mr. Taylor for under-water work, that he became Engineer or Treasurer of a dredging company operating in the Hudson Valley. The assembled plant made possible the successful bids for about one-third of the work of enlarging the New York State Canals under an appropriation of \$9 000 000. In 1905, Mr. Taylor served as Treasurer and Chief Engineer of the Seely-Taylor Company, Engineers and Contractors, on a contract for the 30-in. submerged, cast-iron pipe sewer at New Rochelle, N. Y. At the conclusion of this work, he became President of the Maritime Dredging Company of New York, and was engaged on marine dredging work in New York Harbor until the close of the World War. His headquarters in New York demanded the presence of his family in the vicinity, and, after a few years in the city, he moved to New Rochelle where he resided until the death of his wife in the winter of 1918.

After a brief rest at Clifton Springs, N. Y., Mr. Taylor again took up his work, specializing in coal investigations, and, in this connection, he made extensive trips through the mining centers of the United States. In February, 1919, he began the settlement of his affairs and at a time of life when most men do not plan to undertake new and untried tasks, he offered himself to the Board of Foreign Missions of the Methodist Episcopal Church for service in any foreign field where he might be needed for building or other technical work. He was accepted early in 1922 for a short term of service in Foochow, China. The primary purpose of this engagement was to cover furloughs of the then existing staff of the Fukien Construction Bureau, an organization for doing professional work in the Fukien Province of China.

Within a month after his arrival in Foochow, he was given full charge of an extensive building program, which he was able to manage very successfully, due to his extremely broad experience in the handling of materials and men.

He constructed several notable buildings in this far distant country, which will stand for generations as a monument to his energy.

Mr. Taylor's term was to have been for three years, but this was extended to five, and would have been longer had it not been for local conditions which make all forms of building work dwindle to insignificant proportions during various intervals. He spent his month's vacation annually in travel. The first journey in 1923 in Northern China covered 3 000 miles; the second in 1924 through China, Korea, and Japan, 6 000 miles; the third in 1925 to Hong-kong and The Philippines, 2 500 miles; and the fourth in 1926 to Chung King, West China, 4 000 miles.

When his work was completed in Foochow in December, 1926, he set out on his fifth and last journey, which was to be a leisurely trip around the world, with the intention of stopping at whatever place he might find something useful and worth while to do. He had traveled through the Straits Settlements, India, many of the East India Islands, Australia, and parts of South and Central Africa, when he was overtaken by illness at Old Umtali, in South Rhodesia. The end came very suddenly and peacefully, on August 14, 1927, while he was sitting in a chair reading a paper, apparently without the least premonition that death was near. His illness, which he thought to be only slight, proved to be myocarditis, and was fatal. A few days before he died, he had received a cable asking him to proceed to Monrovia, Liberia, to construct a school building for the Methodist Mission Board, which he was preparing to accept.

Mr. Taylor was a good business man and very honorable and upright in all his dealings. He was most painstaking and thorough, and never considered his work finished until it was done right. He had many of those qualities of geniality and brotherliness which made his friends think highly of him. By his outstanding character he made a very strong impression on the Chinese community in which he had lived for five years.

A letter from Mr. R. C. Gates, of Old Umtali, to Dr. Taylor, of Durban, South Africa, his nephew, bears the following message which tells of the affectionate memory in which Mr. Taylor is held:

"Our hearts were very heavy over the sudden death of our brother missionary who had so recently come among us, and who had so won our affection and esteem. Among other traits, I especially admired his high code of honor. But we all felt glad that since he died on his journeys that he at least could die among friends and be buried on mission land where his grave can be looked after and his name kept in memory."

Mr. Taylor was married on March 27, 1888, to Emma R. Gibbs, of Hamilton, Ont., Canada, whose death preceded that of her husband. He is survived by two brothers, the Rev. B. S. Taylor, of Los Angeles, Calif., and Dr. Henry L. Taylor, of Albany, N. Y., and two sisters.

Mr. Taylor was elected an Associate Member of the American Society of Civil Engineers on September 4, 1895, and a Member on April 4, 1905.

## ALEXANDER MILLER TODD, M. Am. Soc. C. E.\*

DIED SEPTEMBER 11, 1929.

Alexander Miller Todd, the son of George T. and Marion (Miller) Todd, was born September 28, 1874, in Rankin County, Mississippi. His early education was obtained in the public schools of Rankin County. He matriculated at Texas Agricultural and Mechanical College in September, 1890, and was graduated in June, 1894, with the degree of Bachelor of Civil Engineering.

On the completion of his college course, Mr. Todd entered the service of the Mississippi River Commission, Third District. He started as a Rodman at the bottom of the Engineering Department, and by hard work advanced rapidly through the grades of Levelman, Transitman, and Inspector, to become a Superintendent of Construction in 1900.

His early survey work brought him into intimate field contact with the Mississippi River and gave him a practical background that proved invaluable later when he reached a position to study the problems of river control. From the first, he manifested a lively interest in the behavior of the Mississippi, and his keenly analytical mind early began to consider the difficult problems of controlling the mighty "Father of Waters".

Mr. Todd devoted his whole professional life to the Federal Service. From a Superintendent of Construction in 1900, he rose steadily through the various grades in the Engineer Department, until at the time of his death he held the position of Senior Engineer. His entire service was in what is now called the Vicksburg Engineer District.

During the war-time emergency, from 1917 to 1919, he served as District Engineer of the Third Mississippi River Commission District and directed, during this trying time, the prosecution of many important works. His services were so highly regarded by the Federal Government that he was made a Special Disbursing Agent, United States Engineer Department, U. S. Army.

Mr. Todd was a practical student of many of the important flood-control problems on the Mississippi River. His studies of gauge relations were most exhaustive and were used extensively in determining levee grade lines and in predicting flood crests. He gave much time to the study of bank protection works, and his influence was felt, not only in the theoretical analysis of this problem, but in the practical design of machinery for placing revetment. In levee building, also, he became an authority. In the District Office his opinion, as to the relative merits of revetment or levee construction in the solution of a particular local problem, was the deciding factor in making the recommendations for construction.

In 1913, when it became apparent that a much extended program for Mississippi flood control would be necessary, Mr. Todd foresaw that the available supply of material for the older types of bank protection works or revetment would be insufficient to meet the demands. The use of concrete was coming

\* Memoir prepared by Elliott J. Tucker and George R. Clemens, Associate Members, Am. Soc. C. E.

into prominence, and it was soon realized that this offered a possible solution of the problem. When the articulated concrete mat was developed, Mr. Todd designed an all-steel floating plant for the manufacture and placing of this mat, which proved most successful. This plant was unique, in that it was equipped with the first known concrete mixer utilizing a horizontal distributing boom.

The demands of the 1914 Mississippi River Commission program for increased height and section of levees were such that it was apparent to the levee student that improved methods of construction would be necessary. Accordingly, Mr. Todd devoted much of his time and energy to the study of more economical methods for placing earthwork. Early experiments, with a taut-line cableway machine, were not as satisfactory as desired. Further experiments with a slack-line drag-bucket cableway were more successful and, in 1916, in collaboration with engineers of the Bucyrus Company, he designed the tower levee machine embodying this principle. This machine proved very successful and has been used with but very little change in the original design to the present time (1929). The capacity of these machines is approximately 150 000 cu. yd. of earthwork per month—something impossible with the older type of equipment.

In addition to his work on the main Mississippi River, Mr. Todd directed certain surveys on the tributaries. In 1910, he made the field survey and report for the power development on the Upper Ouachita River, near Hot Springs, Ark., out of which has developed the project (Federal Power Commission No. 271) for three power dams—Rommel (built), Carpenter (under construction), and Blakely Mountain (proposed).

Personally, Mr. Todd was held in the highest esteem. At more than one heated conference his was the quiet head that calmed the discussion and brought order and progress out of argument. His ability to serve in difficult capacities was attested by the fact that he was appointed in May, 1925, by the President of the Mississippi River Commission to serve as a member of the Investigating Board of the *Norman* steamship disaster at Memphis, Tenn.

He was keenly conscious of his civic duties and served in many capacities in a number of organizations. He was a leader in community betterment and devoted much of his time to these interests.

Death came to Mr. Todd very suddenly, while on an inspection of the Carpenter Dam construction near Hot Springs, Ark. His life was cut short by apoplexy at the crest of his active career. Funeral services were held at the First Baptist Church, Vicksburg, with interment at the City Cemetery. He is survived by his widow, Sue C. (Carleton) Todd, to whom he was married May 17, 1898, in Chicot County, Arkansas, and by three children—Carleton R. (Lieutenant, U. S. Navy), Marion E. (Todd) Rogers, and Elizabeth A. (Todd) Burnett.

Fitting testimonial to Mr. Todd's many sterling qualities was given in the following public announcement of his death, made by the District Engineer, Major John C. H. Lee, Corps of Engineers, U. S. A., M. Am. Soc. C. E.:

"With deepest regret the District Engineer announces the death of Sr. Engineer Alexander Miller Todd, resulting from a stroke of apoplexy while

inspecting the construction work at Carpenter Dam, Ouachita River, Arkansas, about 11 A. M., September 11, 1929.

"Mr. Todd died on duty, ending a career of outstanding merit and remarkable service to the United States as well as to the people of the valley. In this career of devoted and unsurpassed service, Mr. Todd identified himself with all phases of Mississippi flood control. He has not only been an invaluable student of great flood control problems, but he has exemplified a practical ability to execute work and hold the devoted loyalty of his fellow employees.

"Mr. Todd was one of the senior members of the American Society of Civil Engineers in Mississippi; an active member of the Vicksburg Chamber of Commerce and the Vicksburg Rotary Club. He was a Deacon of the local Baptist Church, a Director of the Y. M. C. A., and has held the honored respect of the entire community. To all who have known him, 'Sr. Engineer Todd's life has been an inspiration. Revered, admired, beloved by his fellow men, this able public servant and loyal citizen of a bereaved community will live always in the memory of his friends."

Mr. Todd was elected a Junior of the American Society of Civil Engineers on October 1, 1895; an Associate Member on October 2, 1901; and a Member on June 6, 1905.

**JOB TUTHILL, M. Am. Soc. C. E.\***

DIED DECEMBER 28, 1928.

Job Tuthill was born, of Puritan stock, in Blooming Grove, N. Y., on October 26, 1855, the son of Benjamin S. and Mary Elizabeth (Cooley) Tuthill.

He was graduated from the University of Michigan, at Ann Arbor, Mich., in 1883, with the degree of Bachelor of Science in Civil Engineering. He at once entered railway service as a Civil Engineer and continued actively in this work for the remainder of his life. His ability as a designer and builder of railway structures came to be widely recognized, chiefly through his work on the Pere Marquette Railway. He served this Company and its predecessor lines as Assistant Engineer, Bridge Engineer, Assistant Chief Engineer, and Chief Engineer, during a total of thirty-five years.

Mr. Tuthill was a constant and thorough student of engineering subjects. He took an active interest in the work of the various engineering societies of which he was a member, and gave liberally of his time to the work of their committees. He possessed, in full measure, the engineer's habit of mind, viewing his work as the fulfillment of a responsibility to his employers and his countrymen, to build safely and well, and to make proper use of, and conserve, Nature's materials. His conscience is reflected in the hundreds of well-designed and carefully executed structures standing as monuments to his faithful labor.

His distinguishing quality was his fine character. He will be remembered for his gentlemanly, courteous manner toward his associates, his loyalty to his profession and his friends, his modesty, reticence, quiet speech, unbounded sympathy, and his charitable attitude toward human weakness or misfortune. He was ever ready to aid those in need of moral support or material assistance.

During his professional life many young men passed under his tutelage. These were uniformly influenced to their lasting benefit—in their attitude toward their work, by Mr. Tuthill's careful instruction, and, in their characters, by his fine example. In 1914, his College conferred upon him the Honorary Degree of Master of Engineering. Dr. Hutchins, in bestowing the degree, eulogized Mr. Tuthill as follows:

"A graduate of the University of Michigan, Department of Engineering, in the Class of 1883. Prominent as a builder of railway bridges and terminals, he has won praise for his work and respect for his modest manhood."

In 1884, Mr. Tuthill was married to Florence B. Craig, of Kalamazoo, Mich., by whom, with a daughter, Louise Kingsbury, he is survived. A son, Benjamin Sayre, died in 1910.

Mr. Tuthill was elected a Junior of the American Society of Civil Engineers on June 6, 1888, and a Member on October 4, 1893.

\* Memoir prepared by the following Committee of the Detroit Section: Charles S. Sheldon, Chairman, J. F. Deimling, H. E. Riggs, Members, Am. Soc. C. E., Paul Chipman, Assoc. M. Am. Soc. C. E., and A. L. Grandy, Esq., Detroit, Mich.

## CHARLES CLIFTON UPHAM, M. Am. Soc. C. E.\*

DIED JANUARY 7, 1928.

Charles Clifton Upham was born on May 5, 1852, of good old New England stock. He was of the seventh generation, in direct line of descent, from John Upham who came from England in 1635 with a colony of twenty-one families under the leadership of one, Joseph Hull. They settled in what was then called Wessaguscus, afterward named Weymouth, in Massachusetts. John Upham was evidently a man of consequence in his community having been a Delegate to the General Court as well as Selectman of the Town. He was one of six who treated with the Indians for the lands of Weymouth, the settlers previously having occupied this site as squatters. Later, in Malden, Mass., to which he soon moved, John Upham served as Selectman as well as Moderator of the Town Meeting. His son, Lieut. Phineas Upham, who gained his title in the Colonial Wars, was also a man of prominence. It was said of him that "Worcester [Massachusetts] owes its foundation in no small degree, as it appears, to his activity and energy."

Other Uphams in the direct line of descent appear to have been men of prominence and enterprise. Several of Mr. Upham's ancestors, not of that name, however, came to Massachusetts in the early half of the Seventeenth Century. His father's mother was a *Mayflower* descendant. His father, born in Castine, Me., had moved to Boston, Mass., and was one of a party of ten to sail from there for California, around Cape Horn, in 1849. After eighteen months, he returned and lived in Woburn, Mass., where Charles Clifton Upham was born. In 1853, the family moved to Dixon, Ill., where young Upham was brought up. The father was recognized in Dixon as a man of education and of excellent literary taste. Charles Clifton Upham had a fine family heritage.

Beginning at eighteen years of age, from 1870 to 1872, Mr. Upham was Assistant Engineer on the Illinois River Improvement, Slackwater Navigation. The next three years found him gaining his first experience in railroading as Assistant Engineer of the Grand Junction Railroad and the Belleville and North Hastings Railroad, in Ontario, Canada. Then, for three years he was in Del Norte, Colo. During at least part of this time, he was expecting to install lixiviation works for reducing ores, but this project never materialized.

Meanwhile, he qualified as a United States Deputy Mineral Surveyor. He enjoyed relating that, while he was in Del Norte awaiting developments, he and a friend, who later became Cashier of the local bank, worked with pick and shovel on highway construction, and that he loaned the contractor money when he needed it to complete his contract.

For several years Mr. Upham was with the Atchison, Topeka, and Santa Fé Railroad Company on location and construction, having served at one time as Transitman on part of the difficult location of the line through the Grand Canyon of the Arkansas. When the Mexican Central Railroad was started from Paso del Norte (now Juarez) south toward Chihuahua, he became

---

\* Memoir prepared by C. Frank Allen, M. Am. Soc. C. E.

Locating Engineer, there being then no Chief Engineer. After several hundred miles had been located, he was offered the berth of Chief Engineer at the same salary, \$250 per month. This he refused as he deemed the salary inadequate. He was much needed on the work and did not hesitate to remain as Locating Engineer, the salary being then, as he thought, adequate for that position. This was an example of the refusal of desirable advancement because of an honorable respect for the dignity of his profession—and this on the part of a man not above working with pick and shovel, at a time when he had ample funds in his pocket. Mr. Upham needed no formal code of ethics; instinctively, he steered straight.

By that time he had acquired a comfortably ready use of the Spanish language and was very popular with the various Mexican officials at Paso del Norte. He was conspicuously an asset to the railroad. It was at this time that his locating party was wiped out by a band of Yaqui Indians on the war-path, and it was first thought that he was with the party; but as it developed later he happened to be en route elsewhere. His obituary had been published, however. When the news reached Paso del Norte, his Mexican friends were most seriously disturbed and it was surprising how quickly the cavalry regiment was put in motion, the Colonel at its head. With Mr. Upham in danger, it was a matter of personal friendship rather than a routine sortie.

Following this, Mr. Upham very soon was offered and accepted the post of Resident and Chief Engineer of the Tampico Branch of the Mexican Central Railway, extending from Tampico to San Luis Potosi. This railroad he located and constructed. It was in very heavy work and very difficult location for which, no doubt, his experience in the Grand Canyon of the Arkansas especially qualified him. He was able to improve very materially on the location previously made by another engineer.

When this work was completed, he became, in 1884, Chief Engineer of the Colorado Railway Company, with headquarters at Denver, Colo. Shortly afterward he was appointed Chief Engineer of the Chicago, Burlington, and Northern Railroad Company, then under construction, with headquarters at St. Paul, Minn. Following this, he was appointed General Superintendent of all the lines in Illinois, of the Chicago, Burlington, and Quincy System. Temporary ill health resulting from exposure in the great strike on that System caused him to relinquish this post.

His health recovered, Mr. Upham was, in 1895, a Consulting Engineer, as well as Chief Engineer and General Manager of the Salt Lake Rapid Transit Company, operating a 30-mile electric line. Later, he was General Manager of a 60-mile electric street railway at Lincoln, Nebr., in which he also had some financial interest.

Somewhat later, Mr. Upham moved to New York, N. Y., where he became Consulting Engineer for the New York Steam Heating Company, and subsequently served as its Vice-President and General Manager; he remained in that position until ill health caused him to retire several years before his death which occurred in New York on January 7, 1928. While he was engaged with this Company he made an extensive study of methods of pulverizing coal and transporting it by water carriage through pipes from the mines to large

cities. Nothing tangible resulted, however, whether because he was ahead of the times, or because of inherent difficulties in the process, it is impossible to say.

Mr. Upham was a member of the Sons of the American Revolution; the Society of Colonial Wars; and the Society of Mayflower Descendants.

He was a man of fine presence, tall, blonde, well built, physically and socially attractive, and of fine character; a gentleman in appearance, manner, and substance; he made many friends. As reflecting in some degree the influences which formed his character, his brother who compiled the Upham Genealogy which has supplied some of the foregoing data, in closing wrote:

"If its effect is \* \* \* as I have hoped it may be \* \* \* to cause each one bearing the name of Upham to feel that he has responsibility for bearing it creditably, then indeed will a grand object have been attained, and we may adopt the sentiment of the New Brunswick Uphams:

"If it is not in all mortals to command success, we will do more, deserve it."

Charles Clifton Upham qualified; he deserved success; he also secured it. The writer of this memoir, who was associated with him in Mexico and in New Mexico, holds him in fond remembrance.

He is survived by his widow, Anna St. John Eells, to whom he was married in December, 1883, and who also traced her ancestry to the early colonists of New England.

Mr. Upham was elected a Member of the American Society of Civil Engineers on April 7, 1897.

**GEORGE SCHERZER WALSH, Sr., M. Am. Soc. C. E.\***

---

DIED MAY 28, 1929.

---

George Scherzer Walsh, Sr., was born at Lockport, N. Y., on December 22, 1871, the son of George M. and Ellen (Scherzer) Walsh. At the age of 8, his mother having died, he accompanied his father to Lincoln, Nebr., where the Walsh home was established.

Mr. Walsh was graduated from the Shattuck School, at Faribault, Minn., in 1890, and from the Rensselaer Polytechnic Institute, at Troy, N. Y., with the degree of Civil Engineer, in 1894. While at Rensselaer, he was affiliated with Delta Kappa Epsilon.

On the completion of his college course, Mr. Walsh went to San Salvador, Salvador, Central America, where he was associated until 1904 with his uncle, the late Albert J. Scherzer, M. Am. Soc. C. E., in the construction of the Santa Ana Railroad from the Port of Acajutla to Santa Ana, Salvador.

From 1904 to 1906, he was one of the Corps of Engineers on the Panama Canal construction, after which he went to Colombia, South America, and was in charge of the building of the Colombia Pacific Railroad, extending from Buena Ventura to Cali, Colombia. He was occupied in this work until September 28, 1909, when he returned to the United States.

In 1910, shortly after his marriage, he returned with Mrs. Walsh to Lincoln, where they lived until September, 1911, at which time Mr. Walsh was called back to Colombia as General Manager of the San Benigno Mines, a high placer operation on the Upper Porce River. He again returned to the United States in May, 1912, but went back to Colombia in November to continue the operation of the mine until May, 1913.

In January, 1914, Mr. Walsh sailed for London, England, to make certain reports to English capitalists on South American enterprises, and while abroad his son, George Scherzer Walsh, Jr., died in Lincoln. In February, 1915, he went to Panama, where he was Construction Engineer and General Manager for R. W. Hibbard and Company, on the David, Concepcion and Boqueti Railroad. This line opened up the mountainous region of Northern Panama. On the completion of this railroad, he returned to the United States just prior to its entrance into the World War.

Early in 1918, Mr. Walsh became interested in the Buffalo Brick Company, at Buffalo, Kans., the largest manufacturers of paving brick in the Middle West, and he went to Buffalo as General Manager of this Corporation. In June, 1918, he went into the Government service as District Engineer in charge of District No. 6 for the Emergency Fleet Corporation, with headquarters at Houston, Tex. After the Armistice he returned to Buffalo, where he again took charge of the Buffalo Brick Company on its re-opening in May, 1919. He operated the plant of this Company until his death, at Rochester, Minn., on May 28, 1929, where he had gone for treatment for heart trouble, which he contracted from influenza five years previous.

---

\* Memoir compiled from information on file at the Headquarters of the Society.

Mr. Walsh established an enviable record as a railroad and mining engineer in the United States and in Central America and South America. He was a devoted and true friend, wise in counsel, charitable, kind, and loyal. His ability, efficiency, integrity, and high standing among his associates commanded the respect and devotion of those who knew him both in professional and private life. He was a member of the Protestant Episcopal Church and of the Masonic Order.

He was married at Louisville, Ky., on June 1, 1910, to Mary-Estes Leavell, of Lexington, Ky., who, with a daughter, Anna, and a son, Homan, survives him.

Mr. Walsh was elected a Junior of the American Society of Civil Engineers on February 2, 1897; an Associate Member on May 1, 1901; and a Member on March 31, 1908.

## WILLIAM HENRY WARREN, M. Am. Soc. C. E.\*

---

DIED JANUARY 9, 1926.

---

William Henry Warren, whose life was so intimately associated with the development of engineering education in Australia, was born in Bristol, England, on February 2, 1852, in the year that also saw the birth of the American Society of Civil Engineers, an institution for whose work and publications he always expressed the most profound admiration. It was, indeed, one of Professor Warren's striking characteristics that, although in private life a somewhat vehemently patriotic Britisher, yet, in matters affecting the Engineering Profession, he was a whole-souled Internationalist. To his classes he always spoke enthusiastically of the achievements of American engineers and especially of the great bridge builders, some of whom were his warm friends. He maintained a correspondence not only with several of the leading engineers of his own land, but also with many in the different countries of Europe, especially with men engaged in his favorite study—the investigation of the properties of materials of construction. Thus, to his mind, such a happening as the dissolution of the International Association for Testing Materials following as an indirect consequence of the World War could seem nothing less than a tragedy.

William Henry Warren was one of the numerous company of young Englishmen of his generation, who felt that in the Colonies of their Motherland would be found a wider field and ampler scope for their energies and ambitions. His early training as a Civil Engineer was the fairly customary one of the Sixties in England. In those days there were, of course, practically no engineering colleges as understood to-day. A lad obtained the elements of his professional knowledge under articles of indenture to some engineering office or works. Young Warren left school soon after he was 14 years of age and entered on a six years' pupilage in the London and North Western Railway Works, at Crewe, England. During this period he passed through the various departments of this famous Railway Company under the direction, first, of Mr. J. Ramsbottom and afterward of Mr. F. W. Webb, both of whom were among the best-known of the British railway men of those days.

He next spent three years in attending ordinary collegiate courses of study in pure and applied science in London and in Manchester, England, and achieved a worthy list of distinctions in the various examinations. Among other honors he was awarded a Royal Exhibition, a Whitworth Scholarship, and the Society of Arts First Prize and Scholarship. Then, possessing a good foundation both of scientific knowledge and workshop practice, Mr. Warren devoted six years to accumulating experience in the design and construction of various works in the north of England, the most important of them being the large Municipal Gas Works at Manchester. This enterprise was, for its date, a very notable undertaking, and Mr. Warren, who acted in the capacity of Designing and Supervising Engineer for the contracting firm, always looked

---

\* Memoir prepared by Sir Henry Barraclough, Dean of the Eng. Faculty, Univ. of Sydney, Sydney, N. S. W., Australia.

on it as his most valuable piece of training and as concluding the "journeyman" period of his life, after which he was ready to devote the remainder to whatever might happen to be the ultimate task to which he was called. He little thought, at the time, that this task was to be chiefly the education of students for the Engineering Profession.

It was in 1881 that Mr. Warren finally left England and took up what was to be his permanent residence in Sydney, New South Wales, Australia. Here, he immediately obtained a position in the Public Works Department of the State and, at the same time, undertook in the evenings the direction of the Department of Mechanical Engineering at the Sydney Technical College. Toward the end of 1883 the appointment of Lecturer-in-Charge of the newly established Department of Engineering at the University of Sydney was offered him, and he thus began the long period of University service which closed only a few days before his death.

In view of Professor Warren's retirement from the Russell School of Engineering on New Year's Day, 1926, the Governing Council of the University of Sydney formally adopted the following resolution, which conveniently summarizes his life's work and reputation:

"The Senate, having accepted with great regret, the resignation offered by Professor W. H. Warren, LL.D., of the Chair of Engineering, as from December 31st, 1925, hereby appoints him Emeritus Professor of Engineering from January 1st, 1926.

"At the date of his retirement Professor Warren will have completed 43 years in the service of the University, 42 of them as Professor of Engineering, this being the longest occupancy of any Professorial Chair in the history of the University since its foundation. Included in this period were terms of office as Chairman of the Professorial Board, as Dean of the Faculty of Science, and as the First Dean of the recently established Faculty of Engineering. Professor Warren has been associated with the Department of Engineering from its earliest beginnings to its present recognised position as one of the leading Schools of Engineering in the British Empire. His devotion to the task of building up sound systems of Engineering teaching and research in Australia, and his enthusiasm in helping adequately to develop the Engineering Profession, have made his name a household word amongst the Engineers of the Commonwealth.

"Particularly in connection with the testing and investigation of the materials of construction, Professor Warren has greatly enhanced the reputation of the University. By his unrelenting labours in this direction for nearly forty years the University now possesses a magnificent laboratory for the testing of materials, and by his industry and energy in carrying out researches into our natural supplies of building materials, Professor Warren has added greatly to the industrial resources of the country.

"The Senate trusts that Professor Warren may live long to enjoy his leisure and to aid by his sympathy and advice the labours of those who follow after him."

This wish on the part of the Senate was not to be realized. Although arrangements had been made for Professor Warren to retain his old room at the University where he might do his technical writing—a plan that caused him much satisfaction—it was decreed that he should not return there again. The long vacation (of the Southern Hemisphere) had scarcely begun when the University was startled by his unexpected death. His end came suddenly

and without pain or distress on January 9, 1926, while he was talking to a friend in his own home at Elizabeth Bay, Sydney.

To those who knew him intimately there was something fitting, something almost characteristic, in his end. Having finished his work he turned promptly to the next thing, as was his customary way. Promptness was to Professor Warren a cardinal virtue. Procrastination and unpunctuality were no failings of his. As his colleagues often had occasion to notice, when a letter on his desk was opened and read, his hand instinctively reached toward a sheet of paper and a pen to begin the reply—he wrote almost all documents by hand at the University, rarely dictating anything. The only hopeful way of tempting him on occasion to delay dealing instantly with a paper was to offer to draft the reply for him; he cheerfully and gratefully admitted the seductiveness of this method when the subject-matter permitted it. This plan of allowing one or more of his colleagues to draft a document for his consideration, especially where it affected the Engineering Faculty at large, became one of the recognized methods which, in his later years, was adopted by general consent.

Within these few lines no detailed account is possible of Professor Warren's professional achievements, of his services to the community on Royal Commissions of inquiry, and on the Councils of scientific and technical Societies, nor of his work in the Engineering Department of the University of Sydney. From his colleagues and brother engineers his labors received ample recognition. For several years he represented Australia on the Council of the Institution of Civil Engineers (England); he was elected as the first President of the Institution of Engineers, Australia, and twice was President of the Royal Society of New South Wales; the distinction that gratified him more than any other was the honorary degree of Doctor of Laws conferred on him by the University of Glasgow.

He was the author of many technical papers and reports, but was probably best known by his two-volume textbook "Engineering Construction, Part 1, In Steel and Timber; Part 2, In Masonry and Concrete," which has obtained a wide circulation. His investigation work was confined almost entirely to the study of construction materials. The equipment of the University Laboratory for the testing of materials was one of his chief pre-occupations. Even if at times he was thought by some to be spending too large a proportion of available funds on equipment for this Laboratory, his efforts resulted in getting together a magnificent collection of testing machines and measuring apparatus culled from the standard types of the different nations.

During his forty-three years of service Professor Warren had seen his Department grow from two rooms, as its quarters, and himself as the entire Teaching Staff, to a large Faculty of Professors and Lecturers, and a range of laboratories that have few equals in the Engineering Schools of the British Empire. These things gave him immense and undisguised pleasure. Every advance made by the School (against what, especially in the earlier and middle years, he regarded as neglect and opposition) caused him to exult greatly. The Engineering School of the University was his chief hobby—as well as his task.

Perhaps, indeed, it is not inaccurate to state that Professor Warren's attitude, generally, to life was the amiable one of the "hobby-ist". He had definite limitations, or, perhaps, more accurately, he deliberately limited his activities to those things in which he was naturally and keenly interested, and he was somewhat impatient of the others. One can rarely remember seeing him at work on anything for which he did not seem to have a zest. It was the same in his spare hours; as all his friends well know, he then devoted himself with equal enthusiasm to his three hobbies—golf, prize bulldogs, and music, especially singing. His knowledge of operatic music was a surprise to many professional singers. His remarkably trained voice and the obvious enjoyment with which he would let himself be persuaded to sing a series of songs, will long be a pleasant tradition.

His most striking quality was a very human one—people felt there was something about him "you could not help liking." It was this personal quality, perhaps, that gave him many friends, even among men with whom he had strong differences of opinion and active controversy, and that made him so popular with the graduates and undergraduates of the Engineering School. The student who first called him "Bill," and the occasion for the remark, are not recorded, but they belong to the very early days of the School. The name gathered an atmosphere of affection and respect with each succeeding generation of students, and to be so addressed as he always was on festive occasions, gave the "Professor of Engineering" genuine satisfaction.

It is proverbially difficult to merit one's epitaph, but Professor Warren was not entirely unworthy of the motto of his family crest inscribed on a memorial tablet erected to his memory in an English church where he was once a choir boy—*Cadenti porrigo dextram*. Especially among his old students are there men who realize that his cordial right hand did them many a kind turn.

For the earlier graduates in Engineering, for many men scattered in engineering positions over the surface of the globe, as well as for those who, like the writer, have long been his colleagues, it is difficult to think of the Engineering School in Sydney apart from Professor Warren. We are conscious of an element of astonishment at the idea of the School without him. We find it hard to imagine laboratories and lecture rooms in which his familiar figure does not come and go. It was, with us, in the Engineering School as if

\* \* \* having lived thus long, there seemed  
No need the King should ever die."

The Russell School of Engineering with which Professor Warren was so intimately associated was setting off afresh the year he left it. New buildings were coming, additional laboratories were in project, and a larger staff called for. The School's long future will, doubtless, be greater in achievement than its past, but no other period can equal in romantic interest its first forty years, and no single individual will ever be so uniquely identified with its development as its first and (as it turned out) its only "Professor of Engineering."

Professor Warren was elected a Member of the American Society of Civil Engineers on February 5, 1890.

## ROY IRVIN WEBBER, M. Am. Soc. C. E.\*

---

DIED MAY 14, 1929.

---

Roy Irvin Webber, the son of Irvin B. Webber, M.D., and Jane Mary (Wilson) Webber, was born in Warsaw, Ind., on August 27, 1876. He was enrolled in the course in Civil Engineering at Purdue University and was graduated in 1899. He obtained the degree of Civil Engineer from the University of Illinois in 1906, where he was an Instructor from 1902 to 1906.

Following his graduation from Purdue University, Mr. Webber worked for a year as Rodman for the Pennsylvania Railroad Company, and then spent six months as an Engineer for the Pressed Steel Car Company. From 1900 to 1902, he was Borough Engineer in Sewickley, Pa., from which position he went to the University of Illinois as Instructor in Civil Engineering.

In 1906, Mr. Webber was engaged as an Instructor in Civil Engineering at The Pennsylvania State College and was advanced to the rank of Associate Professor. In 1912, he was placed in charge of the Department of Architectural Engineering, a position which he held until 1918, when he was made Superintendent of Grounds and Buildings. In this last position, which he held at the time of his death, he had charge of the maintenance and operation of the college buildings and service plants, and either designed, or supervised the design of all new work and alterations.

At the time of Professor Webber's death, extensive building construction work was in progress for the College, and expansions had been planned for the immediate future with the \$2 250 000 building fund appropriated by the State. All this work was under his direction and at the time of his death he was completing specifications for the architect on the remodeling of Old Main and the erection of a new power plant. He was in almost daily consultation with college officers concerning these buildings and had been working strenuously at his construction tasks for weeks, apparently in his usual excellent health. His death occurred very suddenly from a heart attack induced by acute indigestion. "It is indeed a great loss," said President Hetzel, of Penn State, "Mr. Webber was a most valuable man and one with whom it was a pleasure to be associated. We shall miss him."

Professor Webber was likewise actively interested in local affairs. He served as a member and President of the Borough Council and, in that capacity, he took part in the formulation of a comprehensive program of municipal improvements. He had also designed and constructed several business buildings and residences at State College. He was a Director of the First National Bank and a leading member of several social and fraternal clubs. He was an organizer and the first President of the State College Kiwanis Club, and ever since its organization he had been a leading member and officer in the State College Chamber of Commerce. He was also prominent in the Masonic fraternity, and a member of the Acacia fraternity.

---

\* Memoir prepared by P. B. Breneman, M. Am. Soc. C. E.

A resolution passed by the Board of Directors of the First National Bank of State College on the death of Professor Webber includes the following:

"Resolved, that we express our heartfelt and most solemn regret at the loss of one so worthy of the confidence and esteem of the community and who has contributed so much to the success of the several institutions with which he was identified. By his wise counsel and generous service, performed oftentimes at no little sacrifice of personal interest, he came to occupy an enviable place in the esteem of his co-workers and endeared himself to his official associates."

He was married to Olive Holtzberger, of Lafayette, Ind., who, with a son, Dean, and a daughter, Mrs. E. A. Dambly, survives him.

Professor Webber was elected an Associate Member of the American Society of Civil Engineers on April 1, 1908, and a Member on April 21, 1920.

## TIMOTHY SIDNEY WHITE, M. Am. Soc. C. E.\*

DIED APRIL 15, 1928.

Timothy Sidney White was born in New Brighton, Pa., on April 3, 1852. His parents, Timothy Balderston and Olive (Howland) White, were Quakers. He spent his early life in New Brighton, where he attended a local public school. From there he went to Cornell University, at Ithaca, N. Y., from which he obtained the degree of Bachelor of Science in Civil Engineering in the Class of 1873.

In 1835, or thereabouts, Mr. White's father had established a contracting business in New Brighton, specializing largely in the design and construction of masonry, timber, and steel bridges. This, it is thought, was the oldest company of its kind in Western Pennsylvania. It eventually grew into the Penn Bridge Company of Beaver Falls, Pa., which was incorporated in the early Eighties. Mr. White became Chief Engineer and eventually Vice-President and Chief Engineer, remaining in this dual capacity for about thirty-nine years. He retired from active business in 1924.

During this period the Bridge Company, under his engineering direction, grew rapidly. A large number of highway and railroad bridges throughout the eastern part of the United States were designed and built, all of which construction was done under Mr. White's direction as Chief Engineer. This work was highly diversified and included, not only bridges and buildings, but a great deal of specialized construction for the United States Government and various State, county, and city governments, and for many corporations as well. Among the important steel bridges built by the Penn Bridge Company are the four suspension bridges over the Ohio, at Rochester, East Liverpool, and Steubenville, Ohio.

Mr. White's professional life was identified with the development of the all-metal bridge from the small ones of wrought iron to the large modern bridges of high-tension steel. He was a student of engineering and deeply interested in the development of the steel bridge in general and especially in its details as they were related to facilities of manufacture. Under his direction as Chief Engineer, and that of his brother, Mr. S. P. White, as Business Executive, the Penn Bridge Company successfully undertook many important structures; some of them, such as the Anacostia Bridge and the Piney Branch Bridge in the District of Columbia, were largely masonry.

His work in structural engineering was nationally known, and he was highly regarded by the profession of bridge engineers throughout the country. He was a careful, conscientious, and most thorough engineer, and a student in the field to which he devoted his professional life.

Mr. White was a member of the Engineering Society of Western Pennsylvania, the American Society of Social and Political Science, and a Trustee and President of the Young Men's Christian Association at New Brighton. His clubs were the Duquesne Club of Pittsburgh, Pa., and Old Pueblo, of Tucson, Ariz.

---

\* Memoir prepared by Walter J. Douglas, M. Am. Soc. C. E.

He was an ardent Churchman, an active worker in the Protestant Episcopal Church, and prominent in the Diocese of Pittsburgh.

On June 8, 1876, he was married to Annie Augusta Appleton. He is survived by his widow and one son, Samuel A. White, of Beaver Falls, Pa.

Mr. White was elected a Member of the American Society of Civil Engineers on April 3, 1889.

**WILLIAM HALSTED WILEY, M. Am. Soc. C. E.\***

---

**DIED MAY 2, 1925.**

---

William Halsted Wiley, the son of John and Elizabeth B. (Osgood) Wiley, was born on July 10, 1842, in New York, N. Y. In the early Fifties, Mr. Wiley's family moved to East Orange, N. J. Later, he attended the College of the City of New York until just prior to 1861 when the Civil War broke out. He received his Bachelor of Arts degree several years afterward.

He joined the Independent Corps of the New York Volunteer Light Infantry as First Lieutenant, an organization later known as the Seventh Regiment. Many years afterward, he was elected President of the Seventh Regiment War Veterans. In the course of the war, he rose to the command of two companies of artillery, seeing most of his service in South Carolina where he served with distinction in a number of severe engagements. He was given special mention by General Gillmore "for efficient and able services during the siege and bombardment of Fort Sumter and Charleston, S. C." In 1864, he was retired as Brevet Major "for gallant and meritorious services".

After the war, Major Wiley entered Rensselaer Polytechnic Institute and in 1866, was graduated from that institution with the degree of Civil Engineer, following this course with a year of special work at the Columbia School of Mines. For the next nine years he practiced engineering in the East and Middle West, with the Brooklyn, N. Y., Water-Works, the Croton Aqueduct, the Reading Railroad Company, the Riverside Park, of Chicago, Ill., and the Tunnell Hill Coal Company, near Zanesville, Ohio (as Superintendent). In 1876, he entered the publishing business with his father and his older brother, Charles, under the firm name of John Wiley and Sons.

The Wiley publications at that time included books of many sorts, but Major Wiley soon saw a great opportunity to develop the business into one of technical and scientific books. From his service in the war and as an engineer he noticed the great dearth of good American scientific literature. His friendship with officers of both the Army and Navy made it natural that he should be selected both by the West Point and the Annapolis Academies as the publisher of their books.

Major Wiley's wide and varied experience in the engineering field brought him into direct contact with the most prominent engineers of the country and gave him a first-hand knowledge of their needs. This knowledge enabled him to make many suggestions which led to the writing of needed engineering books by well-qualified authors. Thus, the business became definitely one of a scientific nature.

Under his able direction, which continued to the end of his life, the Wiley lists grew to include books in all the branches of engineering, agriculture, chemistry, geology, mathematics, and the biological sciences. In the last few years of his life, realizing the close link between engineering and business, he encouraged his associates to develop a group of books in the latter field.

---

\* Memoir prepared by Calvin W. Rice, Secy., Am. Soc. Mech. Engrs., New York, N. Y.

For many years he was the American correspondent of *Engineering* (London) and published through this paper an account of travels which he wrote with his daughter, Sara King Wiley, entitled "Yosemite, Alaska, and the Yellowstone".

Despite his great activity in the publishing field, Major Wiley found time for many other activities. For three years he was a member of the Township Committee of East Orange, N. J., serving for one year as its Chairman. He served three terms in Congress as a Representative from his district in New Jersey. He was a Commissioner from New Jersey to the St. Louis Exposition in 1904, and was President of one of the International Juries of the Brussels Exposition in 1897, being decorated with the Order of Leopold by the King of Belgium. He was a member of the Executive Committee of the National Security League and, during the World War, was Chairman of the National Preparedness Committee of the American Society of Mechanical Engineers. Major Wiley also was very active in the New York Commandery of the Loyal Legion.

He was a member of the American Society of Mining and Metallurgical Engineers, and the American Institute of Electrical Engineers. He was also a member of the American Society of Mechanical Engineers and served as its Treasurer for forty-one years. Major Wiley was one of the eighty men present at the meeting on March 15, 1880, at which the American Society of Mechanical Engineers was founded. He also belonged to The American Association for the Advancement of Science, and was a member of many clubs, including the University and Engineers' Clubs of New York, and the Cosmos Club, of Washington, D. C.

Major Wiley was one of the very early members of the Theta Xi Fraternity, being the third to be installed by the eight founders of the Fraternity and being in a large measure responsible for the development of its Constitution. He was its President for nearly two score years and was retired as President Emeritus only a few years before his death.

A Congregationalist, he was a member of the Trinity Congregational Church, of East Orange.

Major Wiley was married on June 1, 1870, to Joanna K. Clark, of Zanesville, Ohio. Both his daughter, Sara King, and Mrs. Wiley are deceased.

In all his engineering activities he was ever ready to lend a helping hand. His earnest efforts and foresight contributed much to the upbuilding of the National Societies and he stands out as an example of the type of pioneer who has given freely of his best efforts to make them what they are to-day.

The Major, as he was so kindly called, was most punctilious in all engagements while at the same time tempering his actions by a generous regard for the human relations. He was a past master at story telling. His sense of humor was always keen and, what is quite unique, he never repeated himself.

He was a man of close and strong friendships; a home lover. There was always that chivalry and consideration which bespeaks a true gentleman. Above all, he had the quality that convinced one of absolute truth and frankness which, with his kindly nature, endeared him to all. He was a man of large heart and keen and broad mind. His charity was without regard to

position, creed, or color. For years, after the war, he found employment for men who had served under him. He was greatly loved and admired by his employees, as shown by the fact that many have remained in his employ for periods ranging from fifteen to forty-eight years.

In the death of Major Wiley, the Engineering Profession has lost not only an associate, but a benefactor. In the long period of his professional life, technical books have improved quite as much as has the science and practice of engineering. Major Wiley's name will go down in the annals of the profession, among the revered members, as one who served it well.

Major Wiley was elected a Member of the American Society of Civil Engineers on February 17, 1869, and thus, at the time of his death was one of its oldest members.

## HENRY WILLIAM WILSON, M. Am. Soc. C. E.\*

DIED SEPTEMBER 19, 1928.

Henry William Wilson, the son of William Hasell and Jane (Miller) Wilson, was born at Haverford, Pa., on August 25, 1843. He was tutored privately by Professor B. F. Green for two and one-half years, first at Glenmore and then at Beverwyck, between Albany and Troy, N. Y. He continued his education at Rensselaer Polytechnic Institute, at Troy, where he completed the course in two years and was graduated with the Class of 1864.

Mr. Wilson's professional career began when he entered the service of the Southern Pennsylvania Railroad Company, in 1865, as Rodman on surveys between the Allegheny Mountains and Chambersburg, Pa. In September of the same year he was advanced to the position of Second Assistant Engineer. In January, 1866, he was transferred to the West Pennsylvania Railroad, in charge of surveys in Butler and Allegheny Counties, Pennsylvania, and, in February, was appointed First Assistant Engineer.

During this period, Mr. Wilson was in the office of the Principal Assistant Engineer at Altoona, Pa., which office was transferred to Philadelphia, Pa., in December, 1867. He was also engaged in various kinds of field work, surveying, locating, and superintending construction, etc., all of which was done principally under the direction of his father, the late W. Hasell Wilson, Hon. M. Am. Soc. C. E., who was Chief Engineer. His work in this capacity also included the revision of calculations and plans for the Pennsylvania Railroad Bridge over the Delaware River, at Trenton, N. J., for which he later became Superintendent of Construction.

In 1876, Mr. Wilson entered the office of Wilson Brothers and Company, Engineers and Architects, of Philadelphia, where he was engaged on the design of bridges and other construction work for the firm, under the direction of the late J. M. Wilson, M. Am. Soc. C. E., Engineer of Bridges and Buildings for the Pennsylvania Railroad Company. Mr. Wilson made annual inspections of the bridges of the Railroad System with the Engineer of Bridges and Buildings, who submitted reports to the General Manager. These reports included recommendations as to conditions and the necessary work to be done in bridge construction.

Subsequent to 1885, when the late Mr. J. M. Wilson left the service of the Pennsylvania Railroad Company, Mr. Wilson, as a member of the firm of Wilson Brothers (later, Wilson, Harris, and Richards), attended to all the engineering and structural work until his retirement from active business in 1910. He designed the structural work for the Drexel Building and for the Edison Electric Light Building at Ninth and Sansome Streets, Philadelphia, and made calculations for the bridges on the Atlantic Coast Line Railroad, submitting reports as to their condition and recommending the necessary renewals. He also made examinations and calculations of bridges for the Buffalo, Rochester, and Pittsburgh Railroad Company.

\* Memoir prepared from information on file at the Headquarters of the Society.

Mr. Wilson was a member of the Franklin Society. On October 15, 1874, he was married to Harriet McFarlan Morton, the daughter of the Rev. Henry J. Morton, of Philadelphia. They had one son, Arthur Morton Wilson, who resides in Philadelphia.

Mr. Wilson was elected a Member of the American Society of Civil Engineers on September 6, 1876.

## IRVING MASON WOLVERTON, M. Am. Soc. C. E.\*

DIED JANUARY 6, 1930.

Irving Mason Wolverton was born at Grand Blanc, Mich., on January 29, 1869, and, in 1880, moved with his parents to Flint, Mich. After graduating from the High School at Flint, he entered the Civil Engineering Department of the University of Michigan, from which he was graduated in 1890.

After graduation Mr. Wolverton became associated with the King Bridge Company of Cleveland, Ohio, as an Engineer on structural steel work. After four years with that Company, he was appointed Chief Engineer of The New Columbus Bridge Company, of Columbus, Ohio, with which he remained until 1899.

He was then chosen Chief Engineer of The Mount Vernon Bridge Company of Mount Vernon, Ohio. He successively was made Vice-President and, in 1919, President and Treasurer, which latter position he held until his death. The Mount Vernon Bridge Company has built many notable highway and railroad structures in various parts of the United States, and, under the guidance of Mr. Wolverton, has become one of the leaders in the field of steel construction.

Death came to Mr. Wolverton very suddenly on January 6, 1930. He had gone to Columbus on a business trip and stayed over Sunday in order that he might see a physician who was to be out of town until Monday. It was thought that his trouble was only a cold. Mrs. Wolverton and several of his associates saw him on Sunday, and he seemed to be in very good condition. On Monday morning he was found dead in his bed at the hotel.

Mr. Wolverton had a reputation for loyalty to his friends and for doing well everything that he attempted. He went into all propositions carefully and in detail. His success was due to this painstaking care and to his ability to make and keep a host of friends. He was a member of the Mount Vernon Country Club and The Columbus Club, of Columbus. He was also a member of the Benevolent and Protective Order of Elks and was a Thirty-second Degree Mason.

He was married on September 12, 1893, to Florence Harriet Pope, of Allegan, Mich., and is survived by his widow, three daughters, Carlotta Schafer, of Cleveland, Ohio, Harriet Schelling, of New York, N. Y., and Frances Taylor, of Middletown, Conn., and one son, John P. Wolverton, of Akron, Ohio.

Mr. Wolverton was elected an Associate Member of the American Society of Civil Engineers on December 4, 1895, and a Member on December 1, 1903.

---

\* Memoir prepared by C. G. Conley, M. Am. Soc. C. E.

**IRVING WORTHINGTON, M. Am. Soc. C. E.\***

---

DIED MAY 27, 1928.

---

Irving Worthington was born at Sauk Center, Minn., on June 19, 1868. His mother was Sarah Lewis, of New York State, and his father, Leslie Worthington, was descended from a Connecticut family which claimed a Revolutionary War ancestry on his mother's side. He was related to the late Henry Worthington, M. Am. Soc. C. E., of New York, N. Y.

Irving Worthington's education was begun in the schools of Sauk Center. Later, when the family moved to Barrie, N. Dak., he finished his common school education there and also taught for one year. He moved to Spokane, Wash., in 1889, and was enrolled in the pre-engineering course at Spokane College, where he was a student for two years.

Mr. Worthington's first engineering work in 1891 was on Government surveys under Mr. J. K. Ashley, of Spokane. From 1893 to 1903, he was engaged in the private practice of general engineering and maintained an office in Spokane. During this period, he surveyed much of Chelan and Okanogan Counties, Washington and, as Deputy Mineral Surveyor, the mineral belts and mines of Washington, Oregon, Idaho, and Montana.

In 1903, Mr. Worthington began his long experience in the irrigation field under Ernest McCulloh, M. Am. Soc. C. E., for the Yakima Development Company, of Yakima, Wash. He was active in irrigation investigations for this Company for three years. From 1905 to 1908 he was in charge of important irrigation developments for the Oregon Land and Water Company. During the next five years he was Chief Engineer of the Rogue River Valley Canal Company, Medford, Ore. This project embraced more than 50 000 acres, and included two storage reservoirs, and many miles of canal and laterals, as well as the problems of land settlement. The writer had knowledge of Mr. Worthington's work on this project from personal observation and the results of his labor are now apparent in the productiveness under irrigation in Rogue River Valley.

In 1913, he was called to be Assistant Engineer and Water Superintendent for the Fresno, Calif., Canal and Irrigation Company and continued as such until his appointment as Engineer Appraiser for the Federal Land Bank, at Spokane, which post he held until his death on May 27, 1928.

Mr. Worthington was married to Frances C. Brattain, of Spokane, in March, 1900. Mrs. Worthington, with their three children, Patricia, Hugh, and Jean, survives him.

He was a likeable man, a conscientious and painstaking engineer. Whatever work he undertook, was well done.

Mr. Worthington was elected a Member of the American Society of Civil Engineers on June 24, 1914.

---

\* Memoir prepared by William J. Roberts, M. Am. Soc. C. E.

**ROBERT HARLOW ANDERSON, Assoc. M. Am. Soc. C. E.\***

---

DIED AUGUST 8, 1929.

---

Robert Harlow Anderson was born in North Woburn, Mass., on October 2, 1877. He was educated at Robert College, Constantinople, Turkey, at Williams College, Williamstown, Mass., and at Cornell University, Ithaca, N. Y., receiving the degree of Civil Engineer from the latter institution in 1898.

In June, 1898, Mr. Anderson began his professional career as Rodman and Draftsman on the United States Deep Waterway Survey through New York State. From December to March, 1900, he served as Draftsman for James H. Fuertes, M. Am. Soc. C. E., on an investigation of the city water supply for the Merchants' Association of New York City. In March, 1900, he was engaged as Draftsman and Transitman on surveys for the Nicaragua Canal and, in 1901, became Transitman for the late George S. Morison, Past-President, Am. Soc. C. E., on water power investigations on the Susquehanna River. From 1903 to 1904 he was with the United States Geological Survey and in conjunction with John C. Hoyt, M. Am. Soc. C. E., prepared a report on the hydrography of this river.† After the completion of this report he was appointed Assistant Engineer with the Isthmian Canal Commission. Mr. Anderson was one of the first engineers on the Panama Canal. He was engaged in making investigations and plans, under the Resident Engineer at Bas Obispo, Panama, for the control of the Chagres River.

From 1905 to 1909 he served as Engineer for the McCall's Ferry Power Company on the Holtwood, Pa., Power Dam, and he was also employed on work in connection with an irrigation project at Twin Falls, Idaho, and for a hydro-electric project in Nova Scotia. Mr. Anderson's first connection with the Tennessee Electric Power Company was in 1909 when, as Resident Engineer for the J. G. White Construction Company, he was engaged on the construction of two hydro-electric developments for the Power Company at Parksville and Caney Creek, on the Ocoee River. From 1915 to 1917 he was located at Rock Island, Tenn., in charge of the construction of the Great Falls Hydro-Electric Development for the same Company, and, from 1919 to 1921, he was Engineer for the J. G. White Construction Company, located at Rifton, N. Y., during the building of the dam and power plant on the Wallkill River. He also was engaged on other engineering work for the J. G. White Construction Company at Langley Field, Virginia, and at the U. S. Nitrate Plant at Muscle Shoals, Alabama.

In 1922, Mr. Anderson returned to The Tennessee Electric Power Company as Hydraulic Engineer, which position he held at the time of his death. During 1923 and 1924 he was in charge of the construction of additions to the dam and power-house at the Great Falls Plant. Subsequently, he made surveys and engineering investigations of various projects and was in charge of the construction of an earth storage dam on the Toccoa River, for the Toccoa

\* Memoir prepared by J. A. Longley, Esq., Chattanooga, Tenn.

† Bulletin No. 109, U. S. Geological Survey.

Electric Power Company, a subsidiary of The Tennessee Electric Power Company. This dam is to be 167 ft. high and will contain approximately 1 600 000 cu. ft. of earth, with a power installation of 25 000 h.p. Mr. Anderson was actively in charge of this work until his death.

Mr. Anderson is survived by his widow, Mrs. Elizabeth Fry Anderson, of Sunnyburn, Pa., to whom he was married in 1907. He also leaves one brother, Roger H. Anderson, an Attorney of New York City, and two sisters, Mrs. George Baker, of Altadena, Calif., and Sarah Anderson, of Pasadena, Calif. His father, Charles Anderson, who died in 1928, was Dean of Robert College, Constantinople, until his retirement in 1917, when he returned to the United States.

Mr. Anderson leaves a host of personal friends, both within and without The Tennessee Electric Power Company, who held him in deep admiration for his sterling qualities as a man and a most capable engineer.

Mr. Anderson was elected an Associate Member of the American Society of Civil Engineers on January 8, 1908.

## BERTRAND DON BARKER, Assoc. M. Am. Soc. C. E.\*

DIED NOVEMBER 7, 1929.

Bertrand Don Barker, the son of Don Barker and Adelia Barker, was born on June 17, 1881, at Poultney, Vt. His father was engaged in the operation of State quarries. The boy grew up in New England, attending the local schools. In 1903, he received the degree of Bachelor of Science in Civil Engineering from Norwich University, at Northfield, Vt.

Immediately after his graduation, Mr. Barker entered the service of the United States Coast and Geodetic Survey where his ability and energy brought him advancement. By July, 1905, he was Executive Officer of the U. S. S. *Hydrographer*. He served in this capacity on the *Hydrographer* and the *McArthur* until January, 1907, and in other capacities until May, 1907, when he resigned from the Service.

Mr. Barker next became connected with George W. Jackson, Incorporated, of Chicago, Ill., and New York, N. Y., as Engineer and General Foreman and Superintendent of tunnel construction. From January to August, 1910, he was Superintendent of Shaft No. 1 of the Washington Street Tunnel, Chicago, and from August, 1910, to February, 1912, General Superintendent of Shaft No. 1 of the Yonkers Pressure Tunnel on the Catskill Aqueduct.

In June, 1912, Mr. Barker became associated with George A. Quinlan, M. Am. Soc. C. E., Contracting Engineer of Chicago. Early in 1914, Mr. Quinlan was appointed County Superintendent of Highways of Cook County, Illinois, under the newly enacted Road Law. On assuming this position he took Mr. Barker with him as Chief Engineer.

When the United States entered the World War, Mr. Quinlan went into the Army, and Mr. Barker assumed temporary charge of the County Highway Department. In this capacity, throughout the period of the war, he rendered invaluable, if unrecognized service, to his country by developing and maintaining highway transportation facilities in the great industrial district about Chicago. On the return of Major Quinlan from the Army Mr. Barker was again able to devote his entire time to the engineering work of the Department. With the impetus given to road building by the war, and with funds available from both County and State Highway bond issues, Mr. Barker found plenty to do.

In 1925, with three of his friends, he organized the firm of Barker, Flavin, Sheets, and Wallace, Incorporated, Engineers, with offices in Chicago. Such time as he could spare from his public duties, he devoted to this firm of which he was President at the time of his death.

He was married to Mabel Gibbs, on January 18, 1905, at Chicago. He is survived by his widow and only daughter, Mary Ciel, and by his sisters, Mrs. Alice Jones and Mrs. Allyne Walker.

Despite the strenuous activities of his County Highway Office Mr. Barker always took an active interest in the affairs of the Society. Like many other

\* Memoir prepared by C. C. Wiley, M. Am. Soc. C. E.

men who are busy he postponed filing application for transfer to the grade of Member, although the nature of his work and the part he took in it would undoubtedly have entitled him to this honor.

As an engineer, Mr. Barker was capable, far-seeing, resourceful, energetic, and skillful. The development of the highway system in the metropolitan area around Chicago owes much to him. As a man, he possessed a brusque but delightful personality. His wide interest in things, his keen mind, and his ready-sense of humor, made him liked by all, and he is mourned by his many friends and associates.

On the night of November 7, 1929, Mr. Barker was killed while on his way home from a meeting relating to highway affairs in one of the suburban villages, being struck by a switch engine at the crossing of the Indiana Harbor Belt Railway and West 74th Street, Chicago.

He was particularly active in securing separation of grades between railroads and highways wherever possible in the County. At the time of his death he was presenting the County's case before the State Utilities Commission for separation of grade on the particular crossing at which he was killed.

Mr. Barker was elected an Associate Member of the American Society of Civil Engineers on September 3, 1913.

**JOHN CLARK BENTLEY, Assoc. M. Am. Soc. C. E.\***

DIED SEPTEMBER 24, 1928.

John Clark Bentley was born at Westerly, R. I., on November 17, 1881, the son of Benjamin Courtland Bentley and Henrietta (Clark) Bentley. His father was a leading citizen and prominent builder of Westerly. The boy's preparatory school education was obtained in the public schools of his native town, and he was graduated from Rensselaer Polytechnic Institute at Troy, N. Y., with the degree of Civil Engineer in 1904.

During his summer vacations, Mr. Bentley supplemented his studies by gaining practical experience as Chainman and Transitman on surveys at Plainfield, N. J., and at Westerly. After his graduation he entered the employ of the New York, New Haven, and Hartford Railroad Company, and as Chainman and, subsequently, as Transitman, was engaged on surveys, plans, and estimates, and supervising the removal of bridges and the completion of the elimination of grade crossing at Webster Avenue, New Rochelle, N. Y.

In November, 1905, Mr. Bentley entered the service of the New York, Ontario, and Western Railway Company, at Middletown, N. Y., as Assistant Engineer in charge of preparing plans for maintenance and construction and also of engineering on 240 miles of track, under the Engineer, Maintenance of Way. Among the different projects that he planned and supervised during this time were a retail coal storage plant at Boston, Mass., several bridges, a 980-ft. steel viaduct, the reconstruction of a coal shipping pier at Weehawken, N. J., various grade crossing eliminations, station and shop buildings, yards, etc.

Following a period of several years' service with the Railway Company, and until the latter part of 1917, he was engaged independently in various construction contracts at Elizabeth, N. J., on State road contracts in Maryland, in association with Mr. E. C. Humphry, of Hackensack, N. J., and, again, individually on road contracts at Lakewood and Plainfield, N. J.

After the completion of his road contracts with the City of Plainfield, in the latter part of 1917, Mr. Bentley disbanded his own organization and accepted a position as Superintendent of Road Construction with Snare and Triest, Contractors, on the Raritan Arsenal at Bonhamtown, near New Brunswick, N. J., where he remained until the middle of 1919. During this period, which embraced the extremely cold weather of 1917-18, he forced to completion at record speed, the construction of a large system of main concrete roads and subsidiary gravel roads throughout the Arsenal and also handled the construction of a number of the permanent masonry Administration Buildings.

In 1920, Mr. Bentley decided to re-enter the general construction business on his own account and formed a partnership with Mr. Joseph A. Morrison, of Plainfield, operating under the name of Bentley-Morrison, Engineers and Constructors, with headquarters at Elizabeth. In 1922, this partnership was dissolved and the Bentley-Morrison Corporation was incorporated to carry on

\* Memoir prepared by Joseph A. Morrison, Esq., Plainfield, N. J.

the business of the partnership. Mr. Bentley was made President of the Corporation, which position he held until April, 1927, at which time he disposed of his interest to the other stock holders. During this period, from 1920 to 1927, his organization was engaged on a large variety of contracts in the building and railroad construction field, with such concerns as the Willys Corporation, the Durant Motor Company, the Singer Manufacturing Company, the Standard Oil Company of New Jersey, the Reading Company, the Pennsylvania Railroad Company, the Lehigh Valley Railroad Company, and others.

Mr. Bentley's disposal of his interest in the Corporation of which he was President, was probably somewhat influenced by the condition of his health, which since 1925 had caused him no little concern. He suffered a nervous breakdown in 1926, but after a long vacation in the Adirondacks he returned to the management of his affairs considerably improved in health. In the summer of 1927, he resumed business, as an individual, at Elizabeth, being engaged in building and real estate projects until his sudden death on September 24, 1928.

Mr. Bentley was a man with considerable force of character who brought a keenness of mind and enthusiastic purpose to bear upon the solution of the many problems that presented themselves in the conduct of the affairs with which he was engaged during an active career. He was a member of the Plainfield Lodge of Benevolent and Protective Order of Elks.

He was married, in 1905, to Charlotte Perry, of Troy, whose decease occurred shortly before his own. He is survived by his mother, Mrs. Henrietta Clark Bentley, and one sister, Bertha Bentley, both of Plainfield.

Mr. Bentley was elected an Associate Member of the American Society of Civil Engineers on May 31, 1910.

## ERNEST ARDEN BRUCE, Assoc. M. Am. Soc. C. E.\*

DIED MARCH 8, 1928.

Ernest Arden Bruce, the son of J. A. and E. Lee (Wiseman) Bruce, was born at Ingleside, W. Va., on January 28, 1887. He spent his early life in Bluefield, W. Va., where he fitted himself for college. He entered Concord College in 1904; later, he became a student in West Virginia University from which institution he was graduated in 1908 with the degree of Bachelor of Science in Civil Engineering.

Mr. Bruce began his professional career in Bluefield, where he served as Transitman, and, later, as City Engineer. He also served in the capacity of City Engineer for the Cities of Princeton and Beckley, W. Va. From 1915 to 1917 he was engaged as Assistant City Engineer of Charleston, W. Va., and from 1919 to 1923, he was City Engineer of Charleston, after which he resumed his private practice as Civil and Sanitary Engineer.

He organized the Bruce Construction Company, which Company became extensively engaged in the general contracting business of building roads, streets, and sewers. Mr. Bruce was a member of this Company at the time of his death.

He was a member of the American Association of Engineers, and President of the State Board of Registration of Engineers of West Virginia. He was an engineer of unusual professional attainments, ever active in promoting the increased recognition of Registered Professional Engineers by the public.

Mr. Bruce ably served on many engineering committees appointed to co-operate with various civic bodies in the handling of local public problems. He was considered one of the outstanding leaders in his profession, whose judgment was sound on technical matters.

He possessed a lovable disposition which endeared him to all who were privileged to know him; his untimely passing spread universal sorrow among his friends, and was a distinct loss to his profession.

Mr. Bruce was elected an Associate Member of the American Society of Civil Engineers on April 14, 1919.

\* Memoir prepared by Philip Joseph Walsh, Assoc. M. Am. Soc. C. E.

**THOMAS HIBBEN CLAUSSEN, Assoc. M. Am. Soc. C. E.\***

---

DIED NOVEMBER 9, 1928.

---

Thomas Hibben Claussen, the son of William Dudley and Mary (Hibben) Claussen, was born at Sausalito, Calif., on March 26, 1892. His father was born in Algiers, Africa, and was raised a British subject, whereas his mother was of Canadian birth. Mr. Claussen's boyhood life was spent at Sausalito where his mother still resides. His father died in 1920.

While attending the public schools in his native city Mr. Claussen at one time was a pupil of Kathleen Norris, the novelist. At an early age he entered the Hitchcock Military Academy, at San Rafael, Calif., from which he was graduated in 1910. From 1910 to 1916 he studied civil engineering at Leland Stanford Jr. University at Palo Alto, Calif., with brief intermissions during which time he was in the employ of the City of Sausalito as Draftsman on street work, sewer plans, and construction work. Early in 1917, he entered the employ of the Spring Valley Water Company, of San Francisco, Calif., as Draftsman on general water supply plans.

In September, 1917, Mr. Claussen enlisted in the military service and soon attained the rank of Sergeant in the Intelligence Section of the 363d Infantry. After a period of about one year in this branch, he was commissioned Second Lieutenant of the 50th Field Artillery, 91st Division, and acted as Instructor, training recruits in the military camps in the Eastern and Southeastern parts of the country until the close of the World War. He was honorably discharged from the service on December 26, 1918.

During the first half of 1919 Mr. Claussen served two engagements of about three months each, with the Gorman Engineering Company and Hunter and Hudson, Consulting Engineers, of San Francisco.

August, 1919, brought an important change to Mr. Claussen when he entered the United States Reclamation Service where, for the next six years, he filled several responsible assignments, the first of which was as Assistant Engineer in charge of silt survey, at the Elephant Butte Reservoir. He then, successively, acted as Assistant Engineer and Chief Hydrographer on the Rio Grande Project; made studies of water surface curve, standing wave, and upward pressure, at the Percha Weir; investigated the consumptive use of water on the Rio Grande Project; determined stresses at the Elephant Butte Dam; and studied the effect of back-water from the Elephant Butte Reservoir.

In October, 1922, as Assistant Engineer, he aided in gathering data for a report on flood control for the Lower Rio Grande Valley; subsequently, he assisted on a report on the irrigation of Hope Community from Penasco River, including a reconnaissance survey and office compilations; and assisted on a report for a tri-country project in Nebraska. He was transferred to the Yuma Project in November, 1923, where he held a position as Assistant Engineer until July, 1925, when he retired from the Reclamation Service to enter the service of the State of California.

---

\* Memoir prepared by M. S. Edson, Assoc. M. Am. Soc. C. E.

On August 9, 1925, Mr. Claussen accepted a position with the Division of Engineering and Irrigation of the State of California which Department was then engaged in a comprehensive State-wide water conservation survey. He remained with this Department until February, 1927, when he was forced to give up his position, due to ill health.

On March 7, 1924, he was married to Winifred Dodds, of Beatrice, Nebr., who, with his mother, survives him.

During his short career Mr. Claussen won the admiration of a host of friends due to his unfailing good nature and staunchness of character, and his early demise is keenly felt by all who knew him.

Mr. Claussen was elected a Junior of the American Society of Civil Engineers on November 25, 1919, and an Associate Member on May 19, 1924.

## ADOLPHUS JAMES EDDY, Assoc. M. Am. Soc. C. E.\*

---

DIED JUNE 28, 1929.

---

Adolphus James Eddy, invariably known as "Jim" Eddy, the son of Adolphus Frederick and Mary Ellen (Slover) Eddy, was born at Jacksonville, Ore., on December 25, 1885. He completed his Grammar and High School education in Southern Oregon and moved to San Francisco, Calif., in 1904, where he worked for two years in the shops of the Union Iron Works, earning sufficient money to start his college course.

In 1906, Mr. Eddy entered the University of California and in May, 1910, was graduated with honors in Civil Engineering, Astronomy, and Military Science. He was one of the representatives of the Class selected to speak at the Commencement Exercises. For the following two years, he carried on post-graduate work at the University in Civil Engineering and allied subjects.

He began his professional career as early as 1902, when for eleven months he worked as Chainman and Instrumentman for the Southern Pacific Railroad Company. In June and July, 1908, he acted as Inspector on the construction of a highway in San Mateo County, California. After graduation from college in 1910, until 1917, and again in the early part of 1920, Mr. Eddy was on the Teaching Staff of the College of Civil Engineering at the University of California, as Instructor, Assistant Professor, and, finally, Associate Professor. During this period, he also served as Assistant Instructor in Military Science.

During the same period, Mr. Eddy devoted all his spare time to professional work, including structural designing for John Galen Howard in the summers of 1910 and 1915; for Frederick H. Meyer in 1911; for the Panama-Pacific Exposition Company in 1914; and for Charles Derleth, Jr., M. Am. Soc. C. E., in 1916.

In the fall of 1919, following his military service in the World War, Mr. Eddy was employed for three months by Fred H. Tibbetts, M. Am. Soc. C. E., on field surveys and office investigations of an irrigation project in the Sacramento Valley, involving about 5 600 acres and requiring provision for flood protection and drainage, as well as irrigation service. Commencing in May, 1920, he was employed for about three years by the Standard Oil Company of California on structural engineering work, pertaining largely to the design and construction of the Company's 22-story office building, which was one of the first high buildings constructed on or near the filled-in area of San Francisco. This work involved important and thorough investigations of foundations and complete checking of the steel frame design, special attention being given to possible earthquake effects.

In September, 1923, shortly after the inauguration of the City Manager form of government in Berkeley, Calif., Mr. Eddy was appointed City Engineer and Superintendent of Streets for that city. His work involved a wide variety of engineering problems, including street paving, sewerage systems, storm

---

\* Memoir prepared by the following Committee of the San Francisco Section, Ralph G. Wadsworth, *Chairman*, and C. A. Whitton, *Members*, Am. Soc. C. E., and E. A. Reipke, *Assoc. M. Am. Soc. C. E.*

drainage, garbage disposal, concrete retaining walls, and other structures. Studies and reports were also made on Berkeley's municipal wharf, including plans for extensive repairs and additions, and preliminary studies were made for a municipal airport.

Mr. Eddy always took an extremely active interest in military work of various kinds, beginning with a two-year period of service in the Oregon National Guard in 1902-1903. At the University of California, he completed all the courses in Military Science and was graduated with the commission of Major in the Cadet Corps. Prior to the entrance of the United States into the World War, he was active in organization of citizen-soldier activities at the University, and in the spring of 1917 he entered the first Officers Training Camp at the Presidio of San Francisco, from which he was graduated with a commission as First Lieutenant, Coast Artillery. On November 30, 1917, he was promoted to the rank of Captain, and on November 9, 1918, to that of Major. He took a command of 300 enlisted men and 4 officers, comprising an Army Artillery Park, to France and, while there, attended the Heavy Artillery School at Angers. At the time of the signing of the Armistice, he had just been ordered back to the United States in order to conduct overseas another artillery unit. In January, 1919, at Camp Eustis, Virginia, he had full charge of the test firing of an 8-in. howitzer on a self-propelled mount, and, later in that year, conducted a recruiting party through the Middle Western and Pacific Coast States. He was given an honorable discharge on November 6, 1919.

On May 4, 1921, he was appointed Captain of the 159th Infantry, California National Guard, and was rapidly advanced through the several intervening grades to the rank of Colonel, commanding the regiment, which rank he held from June 29, 1925, until his death. At the time of the disastrous fire, which swept through thirty blocks of high-class residences in Berkeley, in 1923, he risked official censure by ordering out, on his own responsibility, the local National Guard unit, and earned the gratitude of the community for the effective police and relief work accomplished under his direction.

His death, on June 28, 1929, occurred as the direct result of a major operation performed in San Francisco to cure an intestinal disorder, which had given him intermittent trouble subsequent to his service in the war.

Mr. Eddy was a member of Berkeley Lodge No. 363, F. and A. M., the Oakland Scottish Rite Bodies, and Aahmes Temple, A. A. O. N. M. S. He was a Director of the Berkeley Chamber of Commerce, a member of the Rotary Club, the Faculty Club of the University of California, the American Legion, the Association of the Army of the United States, and various other societies. His scholastic honors included membership in Tau Beta Pi, Phi Beta Kappa, and Sigma Xi. His sterling character, charming personality, and boundless good humor won him the friendship and admiration of all who knew him.

He was married at Berkeley, in August, 1916, to Margaret G. Stone. They had three children, Margaret Eleanor, James Stone, and Barbara, all of whom, together with his father and mother, survive him.

Mr. Eddy was elected a Junior of the American Society of Civil Engineers on December 6, 1910, and an Associate Member on July 6, 1920.

## PAUL MAX ENTENMAN, Assoc. M. Am. Soc. C. E.\*

---

DIED MARCH 29, 1929.

---

Paul Max Entenman, the son of Herman and Marie Entenman, was born in New York, N. Y., on January 19, 1887. After graduating from Public School No. 77 in Manhattan in 1900, he was a student at the Morris High School in The Bronx for two years. He attended engineering courses at Cooper Union from 1902 to 1907, and was graduated as the Valedictorian of his Class, with the degree of Bachelor of Science. Among his classmates was Morgan F. Larson, Assoc. M. Am. Soc. C. E., the present Governor of New Jersey. Mr. Entenman continued his studies by taking evening courses at the Polytechnic Institute of Brooklyn from 1907 to 1909, from which he was graduated with the degree of Civil Engineer. Later, he did some post-graduate work in special subjects at Columbia University and at the Brooklyn Institute of Arts and Sciences.

From August, 1904, to June, 1906, Mr. Entenman served as a Rodman and Topographical Draftsman with the Rapid Transit Railroad Commission, New York City, on the construction of subways. He was promoted to the grade of Assistant Engineer, holding that position under the same Commission and its successor, the Public Service Commission for the First District, until November, 1914. He had wide experience in the various types of subway construction, including deep tunnels in rock, cut-and-cover work in rock and in soft ground, and in the underpinning of buildings as well as in the many complicated features incidental to such construction.

He was very much interested in and applied himself zealously to this work, approaching all the problems with a true engineer's mind, taking nothing for granted, but searching out the reasons. He was indefatigable in his attention to his duties. During this time he made the acquaintance of the late Clifford M. Holland, M. Am. Soc. C. E., then a young Assistant Engineer on the same work, who, later, became the Chief Engineer of the Vehicular Tunnel under the Hudson River, which bears his name. The two men became firm friends and this inspiring and unselfish friendship endured until death separated them. Each had a high respect for the other's character and attainments, and each was generous in his praise of the other's accomplishments.

Mr. Entenman's strenuous devotion to his work overtaxed him and his health suffered in consequence, so that in November, 1914, he gave up his position in New York and went to Los Angeles, Calif., where he spent about two years recuperating. He then decided not to return to the East, but to take up work in Southern California.

In October, 1916, he went to Calexico, Calif., on the Mexican border, to work with Joseph C. Allison, M. Am. Soc. C. E., and in April, 1919, they formed a partnership for the general practice of engineering with offices at Calexico and Los Angeles. This partnership continued until March, 1923. Among other activities, Mr. Entenman was engaged on irrigation work in the Imperial Valley, on flood control and irrigation on the Colorado Delta in

---

\* Memoir prepared by Robert Ridgway, Past-President, Am. Soc. C. E.

Lower California, and as Engineer of the Palo Verde Irrigation District at Blythe, Calif. A system of levees was designed and built to protect the Palo Verde Basin from the floods of the Colorado River. From 1919 to 1921 he also served as the City Engineer of Calexico, which then had a population of about 10 000. During this time he designed and built its water-works system as well as other public improvements.

A relapse in 1921 led Mr. Entenman to remove to Banning in the San Gorgonia Pass on the road from Los Angeles to Imperial Valley, where he built the home in which he lived until his death. Although his illness prevented him from traveling about and doing field work he remained active otherwise. From his home he directed in 1923, a ground-water survey in Lower California and Mexico, for the Colorado Land Company, to ascertain the feasibility of obtaining, by pumping, a supply of water for irrigating land too high to be reached by gravity from the Colorado River. In 1926, he designed for Mr. Allison the Bee River Siphon in Lower California. This was a true siphon, consisting of pipes designed to take water from the Colorado River over the levee into the Bee River—an old channel once occupied by the Colorado River—to irrigate delta lands to the west. The siphon was completed in 1928, and has operated very successfully. The design required a careful research into engineering literature relating to the principles of true siphons. It was Mr. Entenman's intention to prepare a paper for the Society describing the unique features of this work, but death intervened before he completed it.

His experience with works in the Colorado River Basin led him to make a broad and careful study of the problems and characteristics of that river and he contributed to the discussions concerning them in the Society's *Transactions* and in the technical press. The Boulder Canyon Project, with its immense dam in Black Canyon, naturally interested him deeply, and he was a strong advocate of it.

In spite of failure of his physical strength, Mr. Entenman retained an undaunted spirit. One can imagine the bitter disappointment of a man, young in years, brought to the realization that all the force and brilliancy of his mind could not release him from the thralldom of ill health and that he must give up his cherished ambition to accomplish great things in his chosen profession; but never losing his courage, he faced the situation squarely, and accepted it as a strong man faces his fate, however hard it may be. The drawings for his Bee River Siphon were made while he was half reclining on his cot, yet the draftsmanship was such as would do credit to any engineering office. From the porch of his home he could see, over the tops of the almond trees, the summit of Mt. San Jacinto, generally snow-capped, and the tree branches were trimmed so that the outlook would be unobstructed. This glorious view of the majestic mountain gave him comfort and satisfaction.

It was an inspiring experience to spend an hour with him. His knowledge of subjects under discussion was so profound and his viewpoint so full of interest that one always came away feeling richer for the contact. He was fond of books and was a discriminating reader, analyzing and digesting what he read. He had a broad vision and his style of writing was clear, forceful

and delightful. Many who knew him, like the writer, found it hard to understand why one gifted with such a wonderful mind, clear vision, natural leadership, and fine personality should be taken away, at such an early age, from the field of action where the qualities he possessed are so much needed. A friend speaking at his funeral services said, in part:

"Paul possessed a brilliant mind and had a great appetite for learning. He was a man of turbulent interests and subtle perceptions. He himself was brutally direct and liked others to be so. One had to brace one's feet to meet him. There was no chance to shirk or hide behind a graceful pose or a cultivated one, or any other kind of barrier between yourself and him.

"That was his genius—people became closer knit and more self-contained when he was around. He enjoyed life and had no listless pleasures. His mind was always active and this indefatigable creative energy sustained him through years of ill health, nor did it subside until the end.

"He felt the enthusiasm of discovery; he felt that existence was inspiring; he endeavored to extract the intrinsic from the accidental in love and beauty—in life and death.

"He stood his fate—racked in body, his soul was never sick.

"I who have felt pain's tireless cohorts tread  
Their wild reverberant march throughout my form,  
Have learned to treasure torment and to dread  
The childish instability, the warm  
Futility of pleasure. None can know  
Full ecstasy unless from pain and woe!"

He was married on June 27, 1921, to Edith Burnette, of San Diego, Calif., who survives him. Through her wonderfully sympathetic understanding of him and his needs she was of great assistance to him in his illness, collecting information and making observations for him when they were required.

Mr. Entenman was elected a Junior of the American Society of Civil Engineers on March 1, 1910, and an Associate Member on February 4, 1913.

**CHARLES CLARENCE FOSTER, Assoc. M. Am. Soc. C. E.\***

---

DIED DECEMBER 27, 1928.

---

Charles Clarence Foster, the son of William E. C. and Laura Elisabeth (Miller) Foster, was born in Iowa City, Iowa, on December 23, 1880. He was graduated from the Iowa City High School in 1901 and from the State University of Iowa in 1904, with the degree of Bachelor of Science in Civil Engineering.

Soon after his graduation from the State University of Iowa, Mr. Foster entered the employ of the Chicago, Burlington and Quincy Railway Company, as Assistant Engineer, at Burlington, Iowa, where he accumulated valuable experience in maintenance-of-way and engineering practice. He left this position in 1907 to accept service as Resident Engineer with the Kansas City, Mexico and Orient Railway Company, on its Pacific Division, his headquarters being El Fuerto, Sinaloa, and, later, at Chihuahua, Chihuahua, Mexico. During this period he had charge of several miles of heavy railroad construction.

On his return to the United States in 1908, Mr. Foster was successively employed with the U. S. Drainage Investigation Survey; the W. J. Hoy Construction Company on building construction at St. Paul, Minn.; and the Great Northern Railway Company, in the capacity of Resident Engineer on construction. In 1911, he entered the service of the George J. Grant Construction Company, at St. Paul. He remained with this firm seven years, acting as Engineer and Estimator; he was also in charge of varied types of field and office work in connection with reinforced concrete buildings and structures.

During the World War, Mr. Foster acted as Assistant Engineer at the Army Supply Base, at Norfolk, Va., on the construction of Government buildings and warehouses. In 1920, he again returned to railroad work, entering the employ of the Pittsburgh and West Virginia Railway Company. He was in charge, as Resident Engineer, of the building of a branch line of that carrier into virgin coal fields of Pennsylvania and West Virginia, after which he devoted about two years to the engineering features in connection with opening a modern type of coal mine for the Cleveland and Western Coal Company, at Powhatan, Ohio.

In 1925, he moved to Pittsburgh, Pa., where he became associated with Messrs. John F. Casey and Company, General Contractors, in whose employ he continued until his death.

On December 25, 1909, Mr. Foster was married to Antoinette May Thompson, at St. Paul, who survives him.

He was a member of the First Presbyterian Church in Iowa City, and was also prominent in fraternal circles, as a member of the Phi Kappa Psi Fraternity, Iowa City Lodge No. 4, A. F. and A. M., Iowa City Chapter No. 2, Royal Arch Masons, Palestine Commandery No. 2, Knights Templars, and Osborne Shrine, St. Paul.

---

\* Memoir prepared by Hugh B. Holmes, M. Am. Soc. C. E.

Mr. Foster was of a modest and unassuming disposition—a most lovable and agreeable companion. He was exceedingly popular with all who came in contact with him, and to his friends and associates his death came as a surprise and severe shock. He died of double pneumonia on December 27, 1928, at his home in Bellvue, a suburb of Pittsburgh. Interment was made in the family plot at Iowa City, Iowa, on December 30, 1928.

For his co-workers, fellow members in the Society, and a host of others who knew and liked him, there is much sadness in the thought that so good a friend has departed. Mr. Foster was one who went about his work in a conscientious manner, giving much attention to his profession and but little to the gratitude, or the rewards, that might be due him. Those who came in close contact with him feel his loss keenly.

Mr. Foster was elected an Associate Member of the American Society of Civil Engineers on March 7, 1921.

## EDWIN PHILIP FOX, Assoc. M. Am. Soc. C. E.\*

DIED APRIL 18, 1929.

Edwin Philip Fox, the son of Mr. and Mrs. F. W. Fox, was born in Philadelphia, Pa., on March 19, 1881. Mr. Fox's educational training was received in the schools of Philadelphia.

His first position was that of Mechanical Draftsman with the Chicago Pneumatic Tool Company, which covered the period from March, 1900, to January, 1901. Mr. Fox then acted successively in the following capacities: From January, 1901, to February, 1902, as Structural Draftsman for the McClintic-Marshall Construction Company at Pottstown, Pa.; from February to September, 1902, as Structural Draftsman with Steel and Wike, at Philadelphia; from September, 1902, to July, 1904, as Structural Draftsman and Squad Leader for L. F. Shoemaker and Company, of Philadelphia; from July, 1904, to January, 1905, as Structural Draftsman for the American Bridge Company, at Pencoyd, Pa.; from January, 1905, to August, 1907, as Squad Leader for the McClintic-Marshall Construction Company, at Pottstown; from August, 1907, to March, 1908, as Squad Leader for the American Bridge Company, at Pencoyd; and from March to June, 1908, in a temporary engagement to look after drawing-room work on the Reventzen Bridge in Costa Rica for the Baltimore Bridge Company, of Baltimore, Md.

In June, 1908, Mr. Fox again entered the employ of the McClintic-Marshall Construction Company, in charge of structural detailing, estimating, and designing, standardizing of shop drawings, and, in addition, acting as Designing Engineer on general plant layout. He also had charge of detail design and of inspection of the structural work for the operating shields for tunnels under the East River, at New York, N. Y.

In all, Mr. Fox remained with the McClintic-Marshall Construction Company for a period of about twenty years, and it was on the recommendation of this Company that he went with the Wheeling Steel Corporation, at Wheeling, W. Va., to take charge of its structural work.

In April, 1924, Mr. Fox went to Cleveland, Ohio, with the Forrest City Structural Steel Company, as Chief Engineer and Vice-President of the Company. He remained with this Company until January, 1928, when he was made Assistant General Manager of the Petroleum Iron Works Company, at Beaumont, Tex., which office he held at the time of his death on April 18, 1929.

Mr. Fox was widely known as an authority on structural work. He was one of the founders of The Builders Exchange of Beaumont, Vice-President of the Gulf States Erection Company of Beaumont, as well as a member of the Chamber of Commerce and of the Rotary Club and the Beaumont Club. He was also a member of Centennial Lodge No. 544, A. F. and A. M., of Carnegie, Pa., and of the Lutheran Church.

Mr. Fox was married in 1903 to Annie B. Auchenbach, who, with one son and two daughters, survives him.

Mr. Fox was elected an Associate Member of the American Society of Civil Engineers on September 9, 1919.

\* Memoir prepared from information on file at the Headquarters of the Society.

## GARRETT ALEXANDER FRASER, Assoc. M. Am. Soc. C. E.\*

---

DIED APRIL 10, 1929.

---

Garrett Alexander Fraser was born on February 24, 1895, in Spokane, Wash.; his boyhood home, however, was in Butte, Mont., where he lived until he was seventeen years of age and had completed high school. His mother died in his late boyhood and a loving aunt, Margaret C. Gillette, gave him a mother's care and in return received his sincere and constant affection.

Mr. Fraser's schooling was practically completed at the outbreak of the World War in 1917, and the University of Washington at Seattle granted him a Bachelor of Science in Civil Engineering degree early in that year in order to permit him to prepare to enter the Army. His service record as prepared by the War Department the day following his death may well be quoted, as follows:

"Garrett Alexander Fraser was admitted to the first Reserve Officers' Training Camp, Vancouver Barracks, Washington, May 15, 1917, organized under the provisions of Section 54, National Defense Act, where he trained, as a civilian candidate for a commission, until the close of the camp August 14, 1917, when honorably discharged.

"He enlisted on August 15, 1917, at Vancouver Barracks, Washington, as a private in the Engineers; was assigned serial number 2 439 404, and joined Headquarters, 316th Engineers, 91st Division, at Camp Lewis, Washington. He was appointed Battalion Sergeant-Major, September 13, 1917. He was in training at the Engineers Training Camp, Camp Lee, Virginia, December 28, 1917, to March 17, 1918, for a commission and was commissioned a Second Lieutenant, Engineers, March 18, 1918. He continued in training at Camp Lee, Virginia, until transferred in April, 1918, to Camp Dodge, Iowa, where he joined Company B, 528th Engineers, Service Battalion; sailed with it from the United States July 9, 1918, and served with this regiment in France, participating in the St. Mihiel offensive, September 12-16, 1918. He was promoted to First Lieutenant, Engineers, March 26, 1919. He returned to the United States May 30, 1919, and was honorably discharged at Hoboken, New Jersey, June 6, 1919, by reason of the demobilization of the emergency forces."

On his return home after demobilization Mr. Fraser attended the Butte School of Mines for a few months, later actually working in the Butte mines in the vicinity of the School. In January, 1921, and for the next eight years, he served on the staff of the Puget Sound Bridge and Dredging Company of Seattle, becoming a Vice-President in 1928. In these years, he was instrumental in bringing to a successful conclusion many engineering works of a general nature such as bridges, dredging, subaqueous tunnel, and a large multiple-arch dam, located in different parts of the United States, Canada, and Mexico. At the time of his death he had but recently moved to New York City and had become Assistant Secretary and Treasurer of the Metals Mining Shares, Incorporated, and of the Minerals Research Corporation. He is known best for having built the International Bridge across the Rio Grande between Brownsville, Tex., and Matamoros, Tamaulipas, Mexico, which was

---

\* Memoir prepared by Roy E. Miller, M. Am. Soc. C. E.

completed and opened for traffic for the Gateway Bridge Company on July 4, 1928.

Mr. Fraser passed through his thirty-four years of life with all the loyalty, courage, and zest, and with all the joy and laughter that can come to healthy, clean-minded men of his day and generation, which is to say that none was more blessed. He was saved from bodily and mental injury in two years of service in France during the World War, only to be brought down to a death as sudden and dramatic as war itself: and yet it was a death that one who knew him intimately realized he would accept as wholly fitting to his life and thoughts—a death by an instrumentality of this new world in which he lived.

Mr. Fraser was killed when the airplane in which he was a passenger crashed in taking off at Tampico, Tamps., Mexico, on April 10, 1929. He was en route from the City of Mexico to Brownsville, Tex., and was one of five in the plane, all of whom were killed, so that none was left to tell the true cause of the crash. It is said, however, that planes were changed at Tampico, the change being hurriedly made and insufficient time being taken to properly warm up the engine, so that after making a height of perhaps 300 ft., the engine failed. Thereupon the pilot attempted to volplane back to the aviation field and in banking for the turn without power lost complete control of the plane. As in all other new lines of human endeavor, sacrifices seem necessary as a corollary to the advancement of the art of flying. It is difficult to take a philosophical point of view of this cost in human lives to accomplish progress in the development of the world's new machines when one loses a companion and a devoted friend.

Of the things that Mr. Fraser accomplished, none was so outstanding as the promise of future deeds. His life had been so largely one of preparation—his talents so versatile. His day had but just arrived.

His dominant traits were loyalty to his associates and friends; an abiding interest in all who came within his circle of acquaintanceship; and the ability to make himself understood and sincerely liked by every one. His mind was active and quick, and he had a full measure of initiative and energy. Because of natural modesty and because his main interests were in another direction, only a few of his companions knew that Mr. Fraser had rare mathematical ability which amounted to almost that of a genius. He belonged in that branch of the Engineering Profession from which business executives are raised.

Mr. Fraser was elected an Associate Member of the American Society of Civil Engineers on March 15, 1926.

**EDWARD CHARLES GERSBACH, Assoc. M. Am. Soc. C. E.\***

---

DIED MARCH 3, 1929.

---

Edward Charles Gersbach was born in Montezuma, Iowa, on July 4, 1880, the son of Frank and Emma (Schell) Gersbach. His father was born in Germany, but came to the United States at an early age. His mother was a native of Iowa, although of German extraction. He received his primary education in the town of his birth, and went from there to Iowa State College, Iowa City, Iowa, from which he was graduated in 1904 with the degree of Bachelor of Science in Civil Engineering.

After completing his High School course, Mr. Gersbach commenced work in engineering lines as Chainman and Rodman, first for the Iowa Central Railway Company, and, later, for the Chicago, Rock Island, and Pacific Railway Company. While he was in college, he spent his vacation in 1901 as Instrumentman for the Chicago Union Transfer Company, and the following summer as Inspector on sewer construction for the same Company. During the summer of 1903 he was Transitman for the Logansport, Hammond, and Chicago Traction Company, and following his graduation in 1904 was employed with the Marshalltown Interurban Railway Company as Transitman. He then served as Draftsman for the American Bridge Company, at Ambridge, Pa., for several months and, later, as Instrumentman with the Indiana Harbor Railroad Company.

In the meantime, Mr. Gersbach had taken a Government Civil Service examination. He passed this and accordingly was appointed to the U. S. Reclamation Service in May, 1905. During the next three years, he served in various capacities as Engineering Aid, Instrumentman, and Assistant Engineer. In January, 1907, he was in direct charge of the location and construction of 110 miles of lateral and waste ditches on the Huntley Project, in Idaho.

On being transferred to the Sun River Project, Montana, as Assistant Engineer, he had charge of the design and construction of concrete structures. In March, 1908, he was transferred to the Blackfoot Project, Montana, as Division Engineer.

In July, 1911, Mr. Gersbach entered the U. S. Indian Irrigation Service, where he was placed in charge of the construction of, and, later, the operation of, the Hogback Project on the Navajo Indian Reservation in Northwestern New Mexico. He retained this position until 1924, when he was transferred to work among the Rio Grande Indian Pueblos, with headquarters in Albuquerque, N. Mex., where he remained until his death.

His illness, which terminated fatally, was incurred in the line of duty. While he was engaged on instrumental work beside an open cut, he slipped, and, being a large man, injured one of the ligaments in his hip. Although he had the best of medical and surgical care, complications followed, resulting in his death on March 3, 1929. His body was taken to his old home in Montezuma for interment.

---

\* Memoir prepared by H. F. Robinson, Esq., Albuquerque, N. Mex.

During Mr. Gersbach's engagement on the Hogback Project, in New Mexico, he met Olive Johnston, who at that time was a missionary nurse at an Indian school, and they were married on April 3, 1912. They had one son, Frank. In addition to his widow and son, his surviving relatives are his father, a brother, Otto Gersbach, of Chicago, Ill., and a sister, Mrs. Nellie Barteld.

Mr. Gersbach was a careful and skillful engineer, respected and liked by his associates—a man with a host of friends. He was a Mason, with his affiliations in Montezuma. His death is a distinct loss to his community and the Department of the Government in the employ of which he had served so many years.

Mr. Gersbach was elected an Associate Member of the American Society of Civil Engineers on June 1, 1909.

**WILLIAM CARY HATTAN, Assoc. M. Am. Soc. C. E.\***

---

DIED MARCH 25, 1929.

---

William Cary Hattan, the son of Mark and Jennie E. (Siler) Hattan, was born at Kerrs Creek, Va., on December 15, 1875, of English (paternal) and German (maternal) ancestry. He was educated in the public schools and, later, attended Washington and Lee University, at Lexington, Va., from which he was graduated in 1899, receiving the degree of Bachelor of Science in Civil Engineering.

Mr. Hattan began his engineering work immediately after graduation, accepting his first position with the West Virginia Short Line Railroad Company as Rodman, Inspector of Materials, and Masonry Inspector. He was with this Company until March, 1901. From this date until August of the same year he was Masonry Inspector and Estimator for the Pennsylvania Railroad Company on the Wolf Creek Branch. From August, 1901, to January, 1902, he was in charge of a party doing general engineering work for J. H. Nichols, Civil and Mining Engineer, of Sharon, Pa. In January, 1902, Mr. Hattan accepted the position of Resident Engineer on construction with the Ozark and Cherokee Central Railway Company in Indian Territory. He was with this Company until January, 1903, at which time he returned to the East. From March to June, 1903, he was Assistant Resident Engineer on the Piney Extension for the Chesapeake and Ohio Railway Company, at Beckley, W. Va.

From June, 1903, until May, 1904, Mr. Hattan was associated with Vandevanter and Hood, Civil Engineers, of Baltimore, Md., in general engineering work, and as Assistant Engineer in charge of location and construction of the Baltimore and Belair Electric Railway. In May, 1904, he entered the employ of the Western Maryland Railroad Company as Resident Engineer on the construction of the Cumberland Extension improvement work. While in the service of this Company he had charge of the erection of several large bridges, concrete arches, station buildings, and water tank and pumping station.

In the fall of 1905, Mr. Hattan accepted a position as Resident Engineer with the Carolina, Clinchfield and Ohio Railway Company and was given charge of a residency at the summit of the Blue Ridge Mountain where the construction work was very heavy. Although this residency was only 4.4 miles long, it included six tunnels which required three years to complete. His services on this work were very satisfactory, and at its conclusion he was transferred to the south end of the Carolina, Clinchfield and Ohio Railway where he had charge of the erection of one of the largest bridges built by this Company. He remained with this railroad until the construction work was completed and the road put into operation in September, 1909.

In April, 1910, he returned to the Western Maryland Railroad Company as Resident Engineer on construction. His ability was noted by the contractors on this work and in July, 1910, the Carter Construction Company appointed

---

\* Memoir prepared by C. K. Lucas, Esq., Erwin, Tenn.

him Division Engineer in charge of sub-contract work on the road. He held this position until December, 1911.

When the Carolina, Clinchfield and Ohio Railway Company decided to build its Elkhorn Extension Mr. Hattan was made Division Engineer and placed in charge of the construction work on this 32-mile branch which, on account of the topography of the country and its inaccessibility, presented some very difficult engineering problems. On this extension there were eight steel and concrete bridges and twenty tunnels with an aggregate length of 20 786 ft., one of which, Sandy Ridge, was 7 854 ft. long, and lined throughout with concrete. This extension cost approximately \$5 500 000, and upon its completion in June, 1915, Mr. Hattan accepted a position with the Kingsport Improvement Corporation. While with this Company he had charge of the municipal development and laid out the larger part of the present city of Kingsport, Tenn.

In June, 1916, Mr. Hattan entered the service of Thomas and Jones, Contractors, as General Superintendent in charge of construction work on the Missouri, Kansas and Texas Railroad Belt Line and its terminals at San Antonio, Tex. Upon the completion of this work in September, 1917, he took charge of the construction of Park Aviation Field, near Memphis, Tenn., where he was General Superintendent for the contractors, Thomas-Harmon Company. From February until November, 1918, he was Area Superintendent in charge of Area "C", U. S. Government Explosives Plant, at Nitro, W. Va., Thompson-Starrett Company, Contractors.

In December, 1918, he moved to Meyersdale, Pa., where he was engaged in private practice as Engineer and Contractor until July, 1920, when he accepted the position of Chief Engineer for the Carolina, Clinchfield and Ohio Railway Company (now the Clinchfield Railroad Company), with headquarters at Erwin, Tenn. This Company was very fortunate in securing the services of Mr. Hattan, as he proved to be a most efficient and accurate engineer with varied experience in both construction and maintenance work. He remained with this Company as Chief Engineer until his death which was caused by complications following an operation for appendicitis.

Mr. Hattan was a modest, unassuming, Christian gentleman who commanded the admiration, respect, and friendship of all who came in contact with him. He was an Elder of the Presbyterian Church; Assistant Teacher of the Brotherhood Bible Class; President of the Kiwanis Club of Erwin; and a member of the City School Board. He was also a member of the Tennessee Society, Sons of American Revolution, and of the American Railway Engineering Association.

He was married at Meyersdale, Pa., on April 12, 1912, to Sara Stein who, with a son and daughter, survives him.

Mr. Hattan was elected an Associate Member of the American Society of Civil Engineers on November 6, 1907.

## JOHN LUCEY, Assoc. M. Am. Soc. C. E.\*

---

DIED SEPTEMBER 16, 1929.

---

John Lucey was born in Little Falls, N. Y., on June 24, 1886, the son of the late Cornelius D. and Bridget (Lynch) Lucey.

Mr. Lucey received his early education at the public schools of Little Falls and was graduated from St. Mary's Academy, Little Falls, N. Y., in 1898. He attended Union College at Schenectady, N. Y., for a time and, later, the Engineering School of New York University from which he was graduated in 1908 with the degree of Bachelor of Science in Civil Engineering.

He began his engineering career in the Construction Department of the New York Central Railroad Company as Rodman and Transitman, making surveys and plans for the track changes in connection with the Barge Canal crossings, in September, 1908. In 1914, he was made Assistant Engineer in charge of construction of concrete arches and Office Assistant in charge of plans and final estimates of this work.

Mr. Lucey was employed by the Rockwood Sprinkler Company of New York City from May, 1914, to September, 1916, in making estimates and designing automatic sprinkler equipment.

He then returned to the New York Central Railroad Company as Assistant Engineer and, in 1916, and 1917, was in charge of the construction of a 250-ft. span, double-track, steel, truss bridge over the Barge Canal at Brewerton, N. Y., including track changes and water supply facilities.

In May, 1917, Mr. Lucey left the United States for the Dominican Republic, West Indies, to take charge as Resident Engineer, under the direction of the Department of Public Works, of harbor improvements in the Port of Puerto Plata. This work included the dredging of the harbor and the construction of a reinforced concrete pier on concrete piling with a custom house of similar material and a steel warehouse built on the pier.

For the next three years he was District Engineer, in general charge of all Departmental work in the District of the Cibao. This work consisted principally of the construction of about 200 km. of macadam highway; the surfacing and graveling of 90 km. of old dirt road; and the location, grading, and surfacing of 110 km. of new road. The greater part of this work was done by force account, Mr. Lucey being directly responsible for the organization, the direction of the work, and the handling of the funds for the payment of all labor and materials. All this was done to the entire satisfaction of the Dominican Government officials.

From 1921 to 1923 he was in the City of Mexico, Mexico, as Superintendent on the completion of a three-story concrete and steel building for the Compania Importadora del Auto Universal and on a hydro-electric survey for the Real del Monte Mining Company. From 1924 to 1926, he was with the Mexican Railroad Company as Chief of Party, under Mr. O. G. Bunsen, on the location of the proposed line between Pachuca and Tampico.

---

\* Memoir prepared by John T. Collins, Assoc. M. Am. Soc. C. E.

Mr. Lucey then went with the International Railways Company of Central America in Salvador, and for two years, until the end of 1928, was in charge of the location and construction of the railroad for the Polichic Banana Company and as Supervising Engineer of the line between Zacapa and Ostua for the section being built under contract by Keilhaue and Rodezno.

Outside his professional life John Lucey turned to literature for his real recreation. From his childhood until his death he explored the realm of books. The telling of what he had discovered, leavened with his keen sense of humor, made of him a very enjoyable and entertaining associate. Besides his companionship, he was a true friend, always doing thoughtful things for those whom he liked. His death was a great loss to his many friends, his engineering associates, and to his family.

He never married. He is survived by five sisters: Mrs. Mary Stewart, of Hollywood, Calif., and the Misses Katherine, Anna, Julia, and Theresa Lucey, of Yonkers, N. Y.; and one brother, Jeremiah Lucey, of Pittsfield, Mass.

Mr. Lucey was elected an Associate Member of the American Society of Civil Engineers on January 13, 1919.

**CLIFFORD LYNDE, Assoc. M. Am. Soc. C. E.\***

---

DIED MAY 21, 1929.

---

Clifford Lynde, the son of James and Lizzie E. (Clifford) Lynde, was born at Chelsea, Mass., on November 16, 1884.

After graduating from the Massachusetts Institute of Technology in 1906, Mr. Lynde was located in Oil City, Pa., for a year. From there he went to the New York Board of Water Supply as Assistant Engineer, with headquarters in Walden, N. Y. He was employed on the construction of the Catskill Aqueduct until 1914, when he moved to Brooklyn, N. Y., where he was engaged on subway construction by the Cranford Company. At the completion of this work, he was employed for a short time by Prentice Sanger, Architect, returning to Walden in 1918 to make special studies for proposed new equipment for the Walden Knife Company.

During this period, Mr. Lynde suffered an attack of influenza and, later, rheumatic fever with resultant heart trouble, from which he never completely recovered. For many months he made a brave struggle to regain his health and, in an effort to obtain strength, he moved to Miami, Fla., where he resided from 1923 to 1928. He established himself in business as a Manufacturer's Agent and was very successful in this venture, surviving the boom and deflation times as well as the great hurricane. Because of failing health, he again returned north to spend six months in a Montclair, N. J., Sanitarium. He survived until May 21, 1929, when he passed away in Walden, N. Y.

Mr. Lynde was married to Mildred Fowler, in Walden, on June 11, 1912. He is survived by his widow, his mother, and two children, Elizabeth A. and Fairfield F. Lynde.

"Cliff" will long be remembered by his many friends for his genial and happy disposition, his unflinching optimism, and his ability to surmount cheerfully for years the greatest of obstacles—ill health. In his passing, those who counted themselves among his friends have sustained a real and genuine loss.

Mr. Lynde was elected a Junior of the American Society of Civil Engineers on December 1, 1908, and an Associate Member on November 28, 1916.

---

\* Memoir prepared by Dean G. Edwards, M. Am. Soc. C. E.

## CHARLES DIX McARTHUR, Assoc. M. Am. Soc. C. E.\*

DIED NOVEMBER 28, 1929.

Charles Dix McArthur was born in Plattsburgh, a small town near Springfield, Ohio, on August 23, 1870. His father, Smith McArthur, of Scotch ancestry, was a grandson of Duncan McArthur, Governor of Ohio. His mother, Phoebe (Judy) McArthur, was of Swiss lineage. His early education was in the public schools in Plattsburgh and New Carlisle, Ohio, and, later, he had an opportunity to attend Antioch College for two years, but the necessity of earning his own living prevented his graduation.

In 1896, while working for the Eastman Kodak Company of Rochester, N. Y., Mr. McArthur took advantage of the night course in machine design at the Mechanics Institute in that city from which he received a diploma in June, 1900. From 1897 until 1901 he was also Instructor in Mechanical Drawing at the Institute. In August, 1899, and during the year following, he was engaged in designing metal working machinery for the Gleason Tool Company. He resigned this position, however, to enter the employ of the Buffalo, Rochester, and Pittsburgh Railway Company, for which he designed the mechanical equipment of the locomotive repair shops at Dubois, Pa., and also superintended the erection of the equipment of these shops. In 1903, Mr. McArthur went as Master Mechanic to the Adrian Blast Furnace, at Dubois, removing to New York City in September, 1903, to become City Manager of the heating and plumbing business of Howe and Bassett. He spent several years in the heating business, during which he both designed and installed heating equipment in various buildings, notably the Stuyvesant High School.

In January, 1908, Mr. McArthur designed and applied for a patent on a steel form for use in the construction of the Catskill Aqueduct. This led to his employment as Chief Engineer by the Blaw Collapsible Steel Centering Company of Pittsburgh, Pa., which, later, became the Blaw-Knox Company. He remained with this company for many years, except for a brief interlude during 1913 and 1914 when he was employed by Stewart and Fauguier in the construction, in from 30 to 70 ft. of water, of the quay walls of the first unit of the Halifax Ocean Terminals for the Intercolonial Railway Company of Canada; he designed the forms for this construction work. While he was with the Blaw-Knox Company, Mr. McArthur took out more than twenty patents relating to steel forms for the construction of aqueducts, railway, and other tunnels, subways, retaining walls, and similar structures. He was a familiar and highly regarded figure wherever important concrete works were being designed or constructed. During most of these years Mr. McArthur lived in Pittsburgh, but he represented the Company for a time in London, England, and also in California.

In 1928, he resigned from the Blaw-Knox Company for the purpose of devoting his entire time to the development and introduction of new wood-working machines which he had invented, and on January 2, 1929, the Mc-

Arthur Company was incorporated with its office in Dayton, Ohio, for the purpose of manufacturing "undercut" boring machines, "metal dows", and other patented specialties. This Company had just been brought to a profitable status when on Thanksgiving Day, November 28, 1929, while on a pleasure drive to dine in the country, he died quite suddenly and unexpectedly.

Mr. McArthur was always greatly interested in new engineering ventures and kept himself informed as to the latest developments in the Engineering Profession. He possessed a strong and forceful character, and his work in his chosen profession was well done. He was loved and respected for his faithfulness, loyalty, and honesty by all with whom he came in contact. He loved music, books, flowers, and little children, the simple life, and the beauty of Nature. He liked to shape things with his own hands, was a finished workman in wood and metal, and adorned his home with cabinet work and carvings of his own making.

He is survived by his widow (*née* Therese M. Ridenour) and a son, Arthur, as well as a son, Duncan, by his first wife (*née* Louise Middledorf), of California. He is also survived by five sisters and two brothers.

He was a member of the Protestant Episcopal Church of the Redeemer in Pittsburgh, Davage Lodge (Masonic), Pittsburgh, the American Association for the Advancement of Science, the American Association of Engineers, and the Engineers' Club of Dayton.

Mr. McArthur was elected an Associate Member of the American Society of Civil Engineers on January 17, 1916.

## FRANK HILL MCGUFFIE, Assoc. M. Am. Soc. C. E.\*

DIED OCTOBER 17, 1928.

Frank Hill McGuffie, the son of Matthew and Martha (Morgan) McGuffie, was born at Waverly, N. Y., on August 27, 1887. His early life was spent in his native village. He attended St. John's College, Manlius, N. Y., from 1903 to 1906, and for several months in 1913 was a student at Cornell University, Ithaca, N. Y., in special engineering work.

During the summer months, while he was at college, Mr. McGuffie worked as Chainman and Rodman for the Lehigh Valley Railroad Company, and continued in that employ as Rodman and Levelman from 1906 until 1908. In July, 1908, he accepted a position as Engineer in charge of construction on the estate of Mr. B. L. Winters, at Smithboro, N. Y. His work there which continued until October, 1910, consisted of the design and construction of roads, small bridges, and a water supply system. He then spent several months as Draftsman and Transitman on base line surveys for the Riordan Company, of London, Ont., at St. Jovite, Que., Canada.

In May, 1911, Mr. McGuffie entered the service of the New York State Department of Highways and for more than six years was engaged as a Levelman in charge of contracts and survey parties on location. From 1918 to July, 1924, inclusive, he served as Assistant Engineer with the same Department in responsible charge of the design of pavements and bridges. His duties included supervision of village and county paving, highway construction work, and the maintenance of 150 miles of highways. Coincident with this engagement, Mr. McGuffie was County Engineer of Sullivan County, New York, for three years. He also did a certain amount of private work, including the design of a sewerage system for the Village of Waverly, bridge work for the Delaware and Northern Railroad Company, and the design of a dam for the Callicoon Electric Company.

From August, 1924, until his death, he was employed by the National Surety Company of New York as Field Engineer, with headquarters at Denver, Colo. He was sent West by the Surety Company to supervise the completion of a large paving job for the Colorado State Highway Department on which the contractor had defaulted. His work for this company included the making of cost estimates, preparation of plans and specifications, acting in an advisory capacity to contractors, and the compiling of contract data for underwriters. His territory included Colorado and the adjacent States, where he was well and favorably known by both contractors and engineers.

Mr. McGuffie died at Denver on October 17, 1928, and was buried at Sayre, Pa., which is near his old home. Although troubled with pernicious anemia to some extent, he was apparently in good health and was active in his duties up to a day or two before his death, which came as a distinct shock to his family and friends.

Because of his genial disposition and pleasing personality he was popular among his friends and business associates. He was generous and, with a

\* Memoir prepared by William B. Freeman, M. Am. Soc. C. E.

natural inclination to be accommodating, was willing at all times to take endless trouble in order to be of service to a friend. Gifted with much ability and energy he gave promise of attaining a considerable degree of success in his profession, had not death terminated his career at a relatively early age.

Immediately on his election to the Society, less than a year before his death, Mr. McGuffie became actively interested in the affairs of the Colorado Section and had demonstrated that he was a valuable addition to the membership. He was also a regular attendant at the meetings of the Cornell Club of Colorado. He was a member of the Masonic Fraternity, a Thirty-second Degree Mason, and a Shriner.

On May 24, 1928, he was married to Reba Burrus, at Denver, Colo. In addition to his widow, he is survived by a sister, Mrs. Lois C. Davenport, of Sayre, and a brother, Dr. Robert N. McGuffie, of Passaic, N. J.

Mr. McGuffie was elected an Associate Member of the American Society of Civil Engineers on December 5, 1927.

## THOMAS MCKENZIE, Assoc. M. Am. Soc. C. E.\*

DIED JULY 25, 1929.

Thomas McKenzie, the son of Andrew and Martha (Cook) McKenzie, was born in Providence, R. I., on September 10, 1867. His parents were of Scottish and English ancestry, his father's family having come to the United States in their youth. His mother died in his childhood and he went to live with his uncle and aunt, Mr. and Mrs. John McCulloch, of Providence, R. I.

While Mr. McKenzie was still a young man his uncle and aunt removed to Westerly, R. I., where he attended the local public schools and, later, learned the moulder's trade in the shops of the C. B. Cottrell and Sons Press Works, in Pawcatuck, Conn., situated across the river from Westerly. His uncle, who also was employed there as a Master Moulder, later, decided to enter the business field in Westerly for himself, taking his young nephew with him. Mr. McKenzie continued in business with his uncle until 1889, when he determined to abandon foundry work and enter the engineering and building profession by means of which he might work his way upward in life to a more satisfactory and lucrative career.

In January, 1889, he went to Providence, and entered the office of the late J. Herbert Shedd, M. Am. Soc. C. E., as a student in civil engineering. He remained with Mr. Shedd for three years, acting as Rodman, Chainman, and Office Draftsman. During his studentship he attended the night schools in Providence, employing his spare time improving his natural talents as a Draftsman, in which work he later became very proficient.

While Mr. McKenzie was with Mr. Shedd, from 1889 to 1892, he was engaged on the encroachment line surveys on the Pawcatuck River at Westerly, and Stonington, Conn., as well as on other engineering work in connection with Mr. Shedd's general practice.

After completing his three years' apprenticeship, he found it necessary to make a change of employment, owing to Mr. Shedd's connection with the City Engineer's Office in Providence. Consequently, early in 1892, he entered the office of the late Samuel M. Gray, M. Am. Soc. C. E., as a Construction Engineer. Mr. McKenzie remained with Mr. Gray for five years as an Assistant Engineer. During this time he was in charge of construction at Bradford, Vt., Chautauqua, N. Y., Meredith, N. H., Gallipolis, Ohio, and at Rockville, Conn.

His work at Bradford consisted of a small water-works system, including a storage and distributing reservoir. At Chautauqua, he completed the sewer system already well under way at the time of his arrival on the ground. This work included the building of a Chemical Precipitation Disposal Plant, which kept him busily engaged all of one winter. This was followed by the building of a water-works system, including a small storage and distributing reservoir, with its earth work dam and masonry spillway, at Meredith. At Gallipolis, he constructed the water-works plant, including a system of pipes and hydrants, reservoir, pumping station, and a unique source of supply. This consisted of

\* Memoir prepared by George H. Leland, M. Am. Soc. C. E.

sinking four 4-ft., cast-iron pipe wells on an island in the Ohio River. These wells were connected with the pumps by a long line of suction pipe located on the high banks of the river. Considerable difficulty was experienced in the construction of these works, but they were finally completed in a satisfactory manner. His work at Rockville was the building of a sewer system in 1895 and 1896. This construction required considerable rock excavation in the streets and an inverted siphon under the Hockanum River.

In the construction of these various undertakings, Mr. McKenzie was very careful and conscientious to see that all parts of the work were done in accordance with the contracts and specifications.

In 1897, the Town of Westerly, after considerable litigation in the Courts, acquired the rights, franchises, good-will, and title to all the property held by the Westerly Water Company, including the right to use the waters of Shunoc Brook in Connecticut as a source of water supply and the privilege of furnishing water to the Village of Pawcatuck, Conn.

Under the direction of Mr. Gray, Consulting Engineer, plans were made to install a system of small wells driven in the Pawcatuck Valley. These plans involved the abandonment of Shunoc Brook as a water supply, and necessitated a new pumping station and new mains. Mr. McKenzie was selected to take charge of the reconstruction of the new and improved system. After completing the improvements and additions, the system was given a thorough test, found to be satisfactory, and the works were then turned over to the Town. The Board of Water Commissioners immediately appointed Mr. McKenzie to be Superintendent and General Manager for the Westerly Water-Works which position, extending over a period of more than thirty-two years, he held at the time of his death.

During his early connection with the water-works, or in 1902, the pipe system was extended to the Watch Hill District and along the South Shore, supplying the summer population with good water and fire protection. The extension of the distribution with the ever-increasing consumption of water on both sides of the river required more storage capacity than was available from the one small iron stand-pipe, built in 1888 by the Water Company. As a result, one of the most important improvements in the system was the building of a reinforced concrete stand-pipe under the supervision of Mr. McKenzie, with Mr. Gray as Consulting Engineer. The plan was successfully completed by the Aberthaw Construction Company, of Boston, Mass., and was put into service in connection with the iron stand-pipe then in use.

In 1914 the Town decided to install a sewer system for the Westerly Fire District and Mr. McKenzie was instructed to take charge of the surveys for this work in connection with his other duties as Superintendent of the Water-Works. The sewer system as finally planned for the District included in addition to the pipe system, two pumping stations, an Imhoff tank, and two filter beds, costing approximately \$600 000. These works were built largely by contract under the supervision of Mr. McKenzie as Engineer in Charge.

In connection with his duties attending the water-works and sewer system of Westerly, he found time to rebuild some of the streets and highways for

the town, also, to assist in an advisory capacity some of the near-by towns and villages with their water problems. He was an indefatigable worker, and was always willing to serve in the interests of the town's affairs, and, later, in the building of the new Memorial Hospital in Westerly, for which he served on the Building Committee.

Mr. McKenzie was prominent in Masonic circles, having reached the Thirty-second Degree several years previous to his death. He was Grand Master of the Connecticut Grand Lodge. In 1916, he was Connecticut State Chairman of the George Washington National Memorial Association, besides holding many other important offices in Rhode Island and Connecticut. He was a member of the New England Water Works Association and the Providence Engineering Society. He was a communicant of Christ Protestant Episcopal Church, of Westerly, a member of the Vestry, Junior Warden, and Treasurer of the Church organization.

In 1892, while working on his first construction job with Mr. Gray at Bradford, Vt., he met Gertrude F. Jones, daughter of the late Dr. Julian F. Jones. They were married in Bradford, Vt., in January, 1896, and made their home in Providence until Mr. McKenzie went to Westerly in 1897. His wife died at her home in Westerly on September 28, 1928, leaving one son, Julian L., 22 years of age.

Mr. McKenzie felt the loss of his companion very keenly, but bore up bravely and plunged into his work far beyond his strength, which over-activity brought on a severe attack of heart trouble terminating in his death after four days' illness. He always had been of robust health and unusually well and strong, but he over-taxed himself.

He was very systematic in all his work; careful statistics and records were kept of the operation of both the water and sewer plants, carefully indexed, and put on file, together with the plans of all the works. He always managed to surround himself with a corps of faithful assistants and co-laborers, who at all times were willing and ready to perform the tasks he gave them. Many of these assistants and laborers remained with him for several years. Mr. McKenzie was greatly respected and admired as a faithful and loyal servant of the community in which he served, was popular as a speaker at public meetings, and an able executive and presiding officer. His loss will be greatly felt in the town in which he spent the best part of his life.

In closing, it may be well to remark that Mr. McKenzie owed a large measure of his success and formation of character to his Aunt Mary who cared for him in his early life in place of his mother and of whom he was very fond. His own mother could not have done more for him. Later, he repaid his debt of gratitude and love to her by taking her into his own home in her declining years.

Mr. McKenzie was elected an Associate Member of the American Society of Civil Engineers on November 6, 1895.

**FREDERICK MEISTER, Assoc. M. Am. Soc. C. E.\***

---

**DIED APRIL 1, 1928.**

---

Frederick Meister was born in Jersey City, N. J., on July 5, 1881, the son of Frederick and Anna Meister (*née* Memple). His father was one of the earliest settlers in the Heights Section of Jersey City and one of its pioneer builders. In his son's boyhood recollections, building operations and developments incident thereto (in the course of which an almost suburban community became an important section of a growing city) played a major part, so that one might say that in his youth he was dedicated to the profession which was to have such great import in his life.

His father often spoke of the intense interest the lad displayed in everything that pertained to building and decided that should this inclination persist, he would have him educated as an Architect. A marked talent in drawing further emphasized the advisability of a pursuit along these lines, and, at the age of nine, the boy began the study of drawing and artcraft under private masters. Previously, he had been enrolled as a pupil in the then flourishing private school in Jersey City Heights known as "The Academy", where he acquired his scholarly perfection of the German language, an invaluable asset in later years when the study of engineering became paramount, for it gave him the advantage of access to the best that the German schools of technology afforded. He was an earnest student of the piano and after several commendable attempts at composition, almost decided upon music as his career. After graduating from the public and High Schools of his native city, however, he was admitted to Pratt Institute, at Brooklyn, N. Y., two years in advance of the prescribed age on the merit of his drawing skill and advanced knowledge of mathematics.

In 1898, Mr. Meister received a degree in Architecture from Pratt Institute and thereupon became apprenticed to Emil Guhl, pre-eminent as an Architect at that time in Jersey City. Here was a master of the old school, whose disciplining was more that of the schoolmaster than of the employer. Mr. Meister regarded this particular period of association as one of the happiest of his life, with so much of mischief and recreation included in the day's routine.

His work consisted in surveying and laying out many of the North Hudson towns, and this outdoor occupation was more pleasant than lucrative, however little one relished dragging about the necessary equipment. Back at the drawing board in Mr. Guhl's office, the prospect of practicing architecture in a small community, with the work shorn of its beauty and much of the vision so necessarily a part of this fine profession, became irksome indeed. Consequently, with the introduction of steel which was destined to play such a large part in the building industry in New York, Mr. Meister turned to the study of structural engineering and found his first engagement in this field with Messrs. Levering and Garrigues, by which firm he was employed

---

\* Memoir prepared by Edward J. Spoerer, Assoc. M. Am. Soc. C. E.

for seven years. He severed his connection with this Company to take up the duties of Chief Draftsman, and, subsequently, Chief Engineer, with the Hinkle Iron Company, of New York, N. Y., with which he was associated for more than twenty-two years, or until the Company retired from active business. From the former employees of this latter concern sprang the present Hinkle Steel Construction Company, of which organization Mr. Meister was Vice-President and Engineer at the time of his death.

For many years preceding his death his services as Consulting Engineer were sought by the leading architects and builders of his vicinity, among them being Thomas Lamb, Townsend, Steinle and Haskell, Eugene DeRosa, Incorporated, Jacobs and Youngs, Shapiro and Sons, H. B. Moss, Richard Carvel, the Cova Realty Company, Kenlon and Michels, C. H. Horn Sons, George Kiester, and Cohn Brothers, of New York. He also worked with William Neumann, J. Welitoff, and Flagg and Stades, of Jersey City (all architects), serving as Engineer of Record on all their projects.

In the construction of theatres and auditoriums in which he specialized and in which he earned a reputation second to none, his services were sought throughout the United States, and many aspiring engineers were glad of the opportunity to work with him on any project, for the knowledge they gained by such an association. His adeptness in structural problems was almost uncanny; nothing baffled him and no problem failed to meet defeat at his hands. His opinion in matters of arbitration were accepted as conclusive and beyond question. In the building departments he was affectionately known as "The Meister". The name was not inaptly applied, for he gave of his knowledge and services without stint, a real example of a "Master" and a Christian gentleman. Great in body, great in soul, and great in mind, he did much to help others find themselves, and felt well repaid in the pleasure of being of service. It was this bigness of nature, this uncomplaining acceptance of the burdens of others, to which may be attributed the heart attack which caused his sudden death. So rugged was his constitution that he never feared for himself, and practically his last act was a needless sacrifice of himself for the benefit of his associates.

Mr. Meister's interest in theatre construction was so engrossing that he turned his efforts to the abolishment of the disturbing posts which supported the balconies of all theatres and large auditoriums. On November 25, 1913, he received Letters Patent on "Floor Supporting Structure of Theatres and the Like" which eliminated for all time the necessity of unsightly posts to support balconies. He allowed this fine innovation to be used by architects throughout the United States for no other consideration than the asking. In fact, he had gained such prominence as an authority on theatre construction that at the time of the tragic collapse of the roof of one of the largest theatres in Washington, D. C., he was the one first selected by the authorities to conduct an investigation into the cause of the catastrophe. Unfortunately, the serious illness of his father, to whom he was deeply devoted, would not permit of his protracted absence and he was obliged to refuse the commission. Thereafter, many municipal authorities throughout the country sought his opinion and guidance in an inspection of their theatres and auditoriums.

Quiet, unassuming, modest to a fault, Mr. Meister often allowed the credit of a worthwhile feat to accrue to some one to whom it might prove a stepping stone to higher things. It is rarely that at a man's bier men of high and lowly station meet on common ground to weep openly for a loved associate and friend. These stepping stones should oftentimes bring to mind a most lovable character and distinguished gentleman, whose untimely demise is a real loss to the Engineering Profession, for it is problematical to what exceptional attainments his genius might have led had life been spared to him.

Among Mr. Meister's engineering works might be mentioned the following: Hammerstein's former Lexington Avenue Opera House and his personal services to Oscar Hammerstein during the erection of the Manhattan Opera House; the O'Shea Theatre, Toronto, Ont., Canada; the Harrisburg and the State Theatres, Harrisburg, Pa.; the Strand and Capitol Theatres, New Britain, Conn.; the Danbury Theatre, Danbury, Conn.; the Waterbury Theatre, Waterbury, Conn.; the Strand and York Theatres, York, Pa.; the Ritz Theatre, National Theatre, and Capitol Theatre, Jersey City, N. J.; several theatres for B. S. Moss, New York City; the Colonial Theatre, Bethlehem, Pa.; the Audubon Theatre, New York City; the Hyde Park Theatre, Hyde Park, Pa.; New York Public School No. 178; the Chamber of Commerce, Spingarn Building, Lerner Building, and Richards Chemical Building, Jersey City, N. J.; the Elks' Clubhouse, Asbury Park, N. J.; the Cova Office Building, 60th Street and Broadway, New York City; a Roman Catholic school, Mariners' Harbor, Staten Island; Park Avenue Hotel, 38th Street and Park Avenue, New York City; the Borden Plant and the Griffith Piano Building, Newark, N. J.; and the New Bank Building, Hackensack, N. J.

In addition, work on which he was engaged as both architect and engineer also may be mentioned: the Rockaway Hotel and Park Inn Baths, Rockaway, N. Y.; the Service Station of the Glidden Motor Company, New York City; the Distributing Station, Lotus Oil Corporation, New York City; the garage for the Automobile Club of America; the service station for the Stewart Distributing Company, New York City; and numerous apartment houses and office buildings in New York City and Jersey City. His last and perhaps most representative work is the present additions to the Cathedral of St. John the Divine, New York City, a task to which he devoted four years, surmounting many problems which will attest through the ages to his splendid ability.

The following are excerpts from many beautiful expressions of sorrow on Mr. Meister's passing:

Joseph F. Dujat, Sculptor:

"Had I command of all the words in every language they would still be inadequate to express my sorrow. It is impossible to express in words the extraordinary high esteem in which I held the friendship of Frederick Meister, whose superb character made one better for having known him, and his spirit will continue to permeate the actions of those with whom he came in contact".

The Rev. Father A. J. Molinelle:

"It was a blow to me to learn of his sudden passing, so much so that it did not seem true. When I saw him last he appeared to be strong and healthy and full of vigor and ambition. I had occasion to meet him off and on and consulted him on construction in general, and have always found him faithful

and true to me and right and proper in everything which he undertook. I feel his loss more than I can tell."

James E. Geissberger, Civil Engineer:

"He will live in my memory always. I have lost a loyal, a noble friend, the community a citizen of sterling character, and the profession a brilliant mind, so he has not lived in vain! His motto, which he religiously lived up to was, 'Helpful, honorable, and true be man's purpose.'"

M. Shapiro and Sons, Engineers and Contractors, New York City:

"We have all worked with Mr. Meister these many years on many of the theatres in New York, and during this period we have found our association with him one of the greatest pleasures of our work. To him we owe a great deal. He was generous in his advice because it seemed to give him joy to be of service. He will be mourned by nearly every Engineer in New York who is connected with theatre construction."

The late Canon Robert Ellis Jones, of the Cathedral of St. John the Divine, New York City:

"I admired him greatly for his professional attainments and his fine character. His deep interest in our Cathedral was a special assistance to me personally. When our building is finally complete it will owe much of its individuality and majesty to Mr. Meister's guidance—a relation that I will not allow to be forgotten".

In conclusion, his widow, the former Ottillie C. Kerner, of Jersey City, N. J., to whom he was married in 1907, and who survives him, feelingly eulogizes him in the following lines:

#### "REQUIEM: FREDERICK MEISTER

"What I am now is Mortal's Fate:  
Life's purpose ended: Naught to make  
My presence felt in your dear midst—  
Unless it be, a thought of me  
Vibrant and eager to give my best  
To help and serve: That is the test  
Of Man's short sojourn: Have I won  
That recognition, now that I am done?  
Full well content with Life am I  
This priceless bond which shall not die!  
Your kindly thought shall be to me  
The shroud of Love in which I sleep;  
Oblivion shall not penetrate  
This gossamer veil whose watch you keep:  
Until that Hour, when you, dear Friend,  
Shall with me in God's realm attend!  
Until that day, fast be the tie  
By which no Man can really die;  
For Death is conquered so combined:  
In Memory's Stronghold fast enshrined."

With many engineering feats as living memorials to his genius, his finest monument will ever be in the hearts of those who called him "friend".

Mr. Meister was elected an Associate Member of the American Society of Civil Engineers on June 23, 1916.

**EMIT COIN NICKEY, Assoc. M. Am. Soc. C. E.\***

---

DIED MAY 5, 1929.

---

Emit Coin Nickey, the son of L. F. and Addie M. Nickey, was born near Trafalgar, Ind., on March 14, 1882. He was educated at Ohio Northern University where he completed a partial course in 1904.

After leaving the University Mr. Nickey's first work was with the St. Louis-San Francisco Railroad Company as Rodman and Instrumentman until June, 1905. He then accepted a position with the County of Butler, Missouri, as County Surveyor, and was also engaged on townsite subdivision work in Southeast Missouri.

From June, 1905, until May, 1928, Mr. Nickey served as County Highway Engineer of Butler County, Missouri, having charge of all highway and bridge improvement work of that county and the financing of the same. In August, 1919, he successfully waged a campaign for a \$500 000 county bond issue for roads and bridges, to meet Federal and State Aid funds for the 100-mile road system in Butler County completed at a total cost of approximately \$1 000 000. In addition, he financed general county funds for road and bridge improvements each year approximated at \$100 000 and prepared plans, estimate of cost, and made location surveys for all this work.

From August, 1913, until September, 1915, he served as Drainage Engineer in charge of surveys. He prepared plans and estimates of cost for Drainage Districts Nos. 10 and 11 in Butler County, and also for more than 40 miles of ditches. The cost of this undertaking was approximately \$130 000.

From May, 1905 to June, 1909, Mr. Nickey served as City Engineer at Poplar Bluff, Mo. Again, from January, 1927, until September, 1928, when he resigned, due to ill health, he was City Engineer of Poplar Bluff, in charge of all the engineering work within the city, including a street paving program estimated at \$400 000. He also was engaged on sewerage and other drainage work. From 1905 until his death in 1929 he served as County Surveyor of Butler County.

Mr. Nickey was a man of high ideals, of sterling character and of the highest ability. Of pleasing personality, he possessed a genial disposition, endearing himself to all who knew him. He was a member of the American Association of Engineers, and a member of Lodge No. 209, A. F. and A. M., of Poplar Bluff. He was also a member of the Benevolent and Protective Order of Elks, Poplar Bluff Lodge No. 589.

Mr. Nickey moved from Missouri in October, 1928, to Colorado where he died on May 5, 1929, of cerebral hemorrhage. The funeral rites were held under the auspices of the Colorado Springs Lodge No. 76, A. F. and A. M., and Colorado Springs Commandery, Knights Templars; interment was in Evergreen Cemetery, Colorado Springs, Colo.

He was married in Poplar Bluff, on February 14, 1905, to Bessie Flanigan, who survives him.

Mr. Nickey was elected an Associate Member of the American Society of Civil Engineers on November 25, 1919.

---

\* Memoir prepared by E. C. Thomes, Esq., Poplar Bluff, Mo.

## ALBERT EDWARD PADDOCK, Assoc. M. Am. Soc. C. E.\*

DIED APRIL 20, 1929.

Albert Edward Paddock was born at Malone, N. Y., on April 15, 1884. After completing a public school education he entered Syracuse University, at Syracuse, N. Y. He was registered in the Engineering Department, where he completed the first two years of a four years' course. Owing to the death of his father before the completion of his second year at college, he left school, with characteristic unselfishness, to assume the responsibilities of an oldest son of a large family. While at Syracuse he had taken an active part in athletics as Captain of the Freshman Crew and as a member of the University football team. Actuated by a determination to be self-supporting, he accepted in 1906 an assignment as Foreman of Construction and Operation of Water-Works in Dawson, Yukon Territory, where he remained for two years. On returning to the United States, he was employed as a Mechanical Operator for the Northwestern Improvement Company at Cle Elum, Wash.

In November, 1911, Mr. Paddock joined the U. S. Reclamation Service and was assigned as Surveyman and as a Foreman of construction work on the Tieton Project in the State of Washington. He was soon advanced to Chief of Party and then to Engineer in Charge of Engineering and Construction on a Division of this Project.

His next assignment in the Reclamation Service was as Engineer in Charge of Construction on a Division of the Sunnyside Project in Washington, on the completion of which he was assigned to the position of Locating Engineer on the Okanogan Project. Subsequently, he became Assistant Tunnel Superintendent on one of the features of the Yakima Storage Project.

When the Yakima work was completed in August, 1913, Mr. Paddock was employed by the Southern Alberta Land Company as Superintendent of Construction on a large concrete diversion dam and canal head-works on the Bow River, in Alberta, Canada. He transferred from this work in September, 1914, to the U. S. Reclamation Service, North Division, and was assigned as Foreman in charge of concrete conduit, outlet tower, and spillway excavation and construction on the Sherburne Lakes Reservoir Dam of the Milk River Project, in Montana.

Mr. Paddock then was assigned to the Shoshone Project, Wyoming, as Assistant Tunnel Superintendent. In this capacity he was engaged on the enlargement of the outlet tunnel and installation of balanced gates outletting from the Shoshone Reservoir. On the completion of this tunnel he was again assigned to the work on the Sherburne Lakes Reservoir Dam, from which he resigned in 1916 to accept a position as Superintendent of Construction for H. G. Fenton, Contractor, on the repair and extensions of the Sweetwater Dam, near San Diego, Calif.

On July 3, 1917, Mr. Paddock entered the employ of the City of San Diego and was assigned as Field Engineer on the construction of the Lower Otay Dam, which work was being carried on by contract. When the project was

\* Memoir prepared by H. N. Savage, M. Am. Soc. C. E.

taken over by the City of San Diego in November, 1918, for construction by municipal forces, Mr. Paddock was advanced to the position of Superintendent of Construction. On the completion of the Lower Otay Dam in 1919, he was transferred in the same capacity to the Barrett Dam, which was also being constructed with municipal forces by the City of San Diego.

Mr. Paddock's outstanding success as a superintendent on heavy construction brought him to the attention of the Utah Construction Company to the service of which he transferred in August, 1920, as Resident Construction Engineer and Superintendent of the Hetch Hetchy Dam which the Company had under contract.

He continued in the employ of the Utah Construction Company continuously from that time until his fatal accident, with the following principal assignments of contract work: Construction Engineer on the Freeman Masonry Weir across the Sacramento River, about 25 miles above Woodland, Calif.; from December, 1923, to February, 1924, Superintendent of Construction on excavation and embankment for roadbed, incident to double-tracking the main line of the Southern Pacific System in the vicinity of Truckee, Nev.; from February to December 1924, Superintendent of roadbed construction on the Natrone Cut-Off in Oregon-California, for the Southern Pacific System; from February, 1925, to October, 1926, Superintendent of Construction of the American Falls Dam across the Snake River in Idaho, an important feature of the Minnedoka Project of the U. S. Reclamation Service.

Before the completion of this work Mr. Paddock was also assigned, in October, 1926, as Superintendent of Construction for the Contractor on the Gibson Masonry Dam of the U. S. Reclamation Service, about 70 miles west of Great Falls, Mont. He also continued to direct the building of the American Falls Dam until its completion early in 1927. At the same time he carried on the construction of the Gibson Dam and continued in charge to the time of his death which occurred on April 20, 1929, while in the performance of his duties as he, with customary aggressive responsibility, considered them to be.

The construction riggers at the Gibson Dam, in moving the concrete-carrying chutes, fouled them against the high concrete hoist towers. Mr. Paddock, arriving on the scene and sensing the conditions and consequent delay, characteristically jumped on top of the concrete bucket then at the base of the tower, and signaled the engine-man to hoist him to where the chute was caught, about 100 ft. above the base of the tower. One of the riggers who had been fixing lines higher up in the tower also had noticed that the chute was caught, and without signaling for the bucket, and unknown to the hoisting engineer on the ground, came down the hoist cable hand over hand to where the chute was caught. Thus, he was inside the tower with his hand presumably on the hoist cable when the concrete bucket, with Mr. Paddock standing on top of it, was being hoisted. The rigger lost his hold on the hoist rope and inside tower frame and fell down inside the tower, a distance of about 60 ft., landing on Mr. Paddock. Mr. Paddock was fatally injured and died within a few hours; the rigger, however, escaped with only a few broken bones.

Throughout Mr. Paddock's professional work he had exemplified executive qualifications of a very prominent type. He was outstanding among the multitude of construction foremen in the loyalty he displayed toward, and received from, his associates and subordinates. This was primarily in evidence in his aggressiveness in automatically responding personally to every apparent requirement to do whatever appeared to him necessary without waiting for others, thereby materially advancing the progress of all types of work under his responsible supervision, although he never discounted or interfered with the duty or work of his subordinates who were effectively carrying on.

Mr. W. H. Mattis, President and General Manager of the Utah Construction Company, writes of the loss sustained by his Company as:

"\* \* \* immeasurable, as he was a vital part of the Company, and an exponent of its policies. \* \* \* his unusually high place in our organization was due to his outstanding personal ability and character. He seemed to exemplify all the ideals of high-minded men; he had the confidence of his superiors, the affection of his men, and the respect of all with whom he dealt."

On September 14, 1920, Mr. Paddock was married to Mary G. Riveroll, in Los Angeles, Calif., who survives him. He is also survived by his mother, two brothers, and a sister. He was a member of Delta Upsilon Fraternity, a Scottish Rite Mason, and a member of Al Bahr Temple, A. A. O. N. M. S. He was buried in San Diego, Calif.

Mr. Paddock was elected an Associate Member of the American Society of Civil Engineers on November 26, 1918.

## CHARLES HENRY REYNOLDS, Assoc. M. Am. Soc. C. E.\*

---

DIED NOVEMBER 1, 1929.

---

Charles Henry Reynolds, the son of Mr. and Mrs. Aldrich J. Reynolds, was born in Forestville, near Manchester, Iowa, on December 3, 1874. At the age of two he moved to Fort Dodge, Iowa, where he resided until his death.

Mr. Reynolds received his education in the public schools of Fort Dodge and was graduated from the High School. After his graduation, he was Assistant to the City Engineer at Fort Dodge for five years, during which time the first pavement was laid in that city. As to his additional education, he studied under Mr. Easley when he was his Assistant City Engineer, and, later, took a correspondence course in Engineering, which he completed with a very high standing.

His entire professional ambitions were wrapped up in the growth of his city. During his long career of thirty-one years as City Engineer, Mr. Reynolds saw the city emerge from its first permanent sidewalk, which he constructed of brick, to the many miles of paving it now possesses. In addition, many beautiful bridges in Fort Dodge are also monuments to his activities. Another improvement which took place under his direction and of which he was exceptionally proud, was the selection of numbers for city streets in place of the names which they formerly had. This change took place about 1900.

Mr. Reynolds was probably more closely identified with the growth of Fort Dodge than any other one person. He took much pride in his native city and was always ambitious for its improvement. The last photograph he had taken was on the site of the new City Water-Works, on North First Street, where he was present to witness the turning of the first shovelful of earth.

In addition to his duties as City Engineer, he was for twelve years County Surveyor of Webster County, and for sixteen years Principal Drainage Engineer in Webster and near-by counties. He also did some general engineering practice for surrounding municipalities for sewers, bridge, and street work.

He was a member and active worker in many lodges and fraternal organizations of the city. Among them were the Elks Lodge, of which he was Past Exalted Ruler and Past District Deputy Grand Exalted Ruler. He was also very active in the Masonic Lodge, having been Past Commander of Calvary Commandery, Knights Templars, Past Patron of the Eastern Star, Past Watchman of Shepherds in the White Shrine, and a member of Za-Ga-Zig Shrine, Des Moines, Iowa.

Mr. Reynolds was a member of the National Arbitration Commission. He was also a member of St. Mark's Protestant Episcopal Church, of Fort Dodge, and, for nine years, was Secretary of the Oakland Cemetery Association, in which office he was responsible for the adoption of the perpetual-care plan, which has been one of the outstanding improvements in the city.

---

\* Memoir prepared by C. H. Currie, M. Am. Soc. C. E.

A lasting tribute to Mr. Reynolds may well be summed up in the fact that his appointment and re-appointment as City Engineer over a period of thirty-one years were never questioned; and this occurred in a city where politics and officers changed frequently.

Mr. Reynolds was very highly respected among engineers throughout the State and by every one who knew him. He was married in 1898 to Laura Ellen Beresford, of Fort Dodge. Besides his widow, he is survived by his son, Jack, and two daughters, Myriam and Helen.

Mr. Reynolds was elected an Associate Member of the American Society of Civil Engineers on November 25, 1919.

## HARRY CHARLES SANFORD, Assoc. M. Am. Soc. C. E.\*

---

DIED APRIL 22, 1928.

---

Harry Charles Sanford, the son of Sylvan and Julia (Sanford) Sanford, was born at Mantua, Ohio, on December 29, 1869. His father, who was of English descent, was a highly respected doctor of medicine.

Mr. Sanford received his early education in the schools of his native town, later attending the Grand River Institute at Austinburg, Ohio, for two years, and completing his education at Valparaiso University, Valparaiso, Ind., from which he was graduated in 1889 with the degree of Bachelor of Science.

His first work was in Cleveland, Ohio, where for several months, beginning in August, 1889, he was engaged as Draftsman on decennial maps of that city. From May, 1890, for a year, he was Rodman, Transitman, and Assistant to the Division Engineer, on the Akron and Chicago Junction Railroad (now a part of the Baltimore and Ohio System). From 1891 to 1895, Mr. Sanford was Assistant Engineer to Ryan and McDonald, Contractors for the construction of the Baltimore Belt Line Tunnel, which is used by all passenger trains on the Baltimore and Ohio Railroad passing through the City of Baltimore, Md. On this, his first experience with contractors, he found the work so congenial that it determined his life career.

During 1895, Mr. John B. McDonald was awarded the contract for the construction of the Jerome Park Reservoir, the large storage reservoir for the Croton Water System located in the Borough of The Bronx, New York, N. Y.; it was to occupy the site of the Jerome Park Race Track. Mr. Sanford transferred to this work and remained on it for approximately two years, in charge of plant layout and construction plans. In 1897, although the contract was far from completion, Mr. Sanford resigned his position and took another with Rodgers, Farrell and Hegeman, Contractors for the construction of twelve miles of the Pittsburgh, Bessemer and Lake Erie Railroad, a subsidiary of the United States Steel Corporation. In less than a year he was made Resident Engineer on the same railroad, in charge of the construction of a steel viaduct, 4000 ft. long, and of 3 miles of heavy grade work. For about one year he was Division Engineer with the Buffalo, Rochester, and Pittsburgh Railroad Company during which time 10 miles of construction were completed between Craigsville and Butler, Pa.

Early in 1899 Mr. Sanford joined the forces of the Degnon Contracting Company. In December of that year the contract for the construction of the first Rapid Transit Railroad (underground) in New York City was awarded to Mr. John B. McDonald. This work, involving twenty-one miles of structure, was divided into "sections" which were carried on by sub-contractors, of which three sections in Manhattan were awarded to the Degnon Contracting Company. Two of these were contiguous from City Hall to Bond Street, and the third was along 42d Street and Broadway to 50th Street. Mr. Sanford

\* Memoir prepared by William J. Boucher, M. Am. Soc. C. E. Mr. Boucher died on September 14, 1929.

was placed in charge of the latter section, which was without doubt the most difficult piece of city construction ever undertaken. On both 42d Street and Broadway heavy street cars were in operation, supplied by underground trolley current; large water and gas mains had to be maintained in service; many high-tension and telephone wires and cables were in conduit which had to be broken away; the wires and cables were carried on the street timbering and the sewers in flumes.

The underlying material everywhere was rock, which had been excavated only sufficiently to permit the placing of these utilities. Therefore, all the space required for the four-track railroad and stations had to be excavated in rock below all these services. Practically all the buildings alongside the railroad had vaults under the sidewalks, in which were heating or electric plants or storage space; taking over the space occupied by these vaults involved bulkheading, re-arranging, etc., all a very tedious operation. At Park (Fourth) Avenue and 42d Street, and at 42d Street and Broadway, the railroad curved under private property (obtained under easement). At the former of these locations the construction of the Belmont Hotel was carried on simultaneously with the construction of the railroad; similarly, at the latter location, the construction of the New York Times Building was proceeding; in both buildings the columns were ingeniously placed between the subway tracks.

When it is realized that there were no precedents to guide the engineers or contractors in this undertaking, and that the work was done in rock and under city streets with heavy continuous traffic, and with only negligible delays or incidents, its magnitude grows more and more and reflects great credit upon all concerned and particularly upon Mr. Sanford. On the completion of this work, in 1904, the Degnon Company was re-organized and Mr. Sanford was made Chief Engineer; he retained this position as long as the Company remained active (until 1921). He also filled the office of Treasurer of the Company from 1904 to 1917.

During 1904, 1905, and 1906, the construction of the subway was carried on under Broadway (Manhattan), from St. Paul's Church to Bowling Green. This work, the first under a wood deck street carrying traffic (a system originated, and here first applied, by him) was Mr. Sanford's responsibility.

From 1906 to 1909 the Degnon Company was engaged, under the direction of Mr. Sanford, in constructing a section of the Center Street Subway, which is now operated by the Brooklyn-Manhattan Transit Company, and the Sixth Avenue Subway from 12th Street to 33d Street, which is operated by the Hudson-Manhattan Railroad Company. This latter was excavated entirely in rock, the elevated railroad columns being supported along the entire distance and, later, their load being transferred to the roof of the reinforced concrete subway structure.

From 1909 to 1912, Mr. Sanford was in charge of the construction of that section of the Catskill Aqueduct known as "Contract No. 47", in Ulster County, New York. This covered the south half of the Bonticou Grade Tunnel, 0.65 mile; 3.8 miles of cut-and-cover aqueduct; the short Mohonk Grade Tunnel; and the Wallkill Pressure Tunnel, 4.5 miles long—a total of 9.25 miles. The work, as the names indicate, was varied in character, with heavy earth

and rock cuts and much deep tunneling. Six working shafts were required varying in depth from 348 to 482 ft. The equipment was composed of two compressed air plants, one electric power plant, and a rock-crushing plant. A 36-in. gauge railroad, crossing a special steel truss bridge, served the various sections of the contract. The shafts were electrically operated. The work was carried on expeditiously and efficiently and at what is believed to be the record speed in America to that time for hard rock tunnels of this size; 523 ft. were excavated in one month, the dimensions of the rock cut being 17 ft. high and 13 ft. 4 in. wide.

In the summer of 1912, the Degnon Company began its work on the enlarged subway system of New York City by being awarded a contract for building a section on Broadway, from City Hall to White Street. This was rapidly followed by two sections under Fourth Avenue, Brooklyn; and, somewhat later, two sections under West Broadway and Varick Street, of the "West Side Line"; then a combined subway and elevated link (Route 50) in Long Island City; next, a section along 59th Street and 60th Street, crossing under Fifth Avenue; then a mile in Brooklyn known as the Flatbush Avenue Tunnel, a two-track line built through sandy ground entirely by tunneling methods for which a specially designed roof shield was used, concrete being placed by pneumatic pressure. Another difficult section was under St. Felix Street, and the Long Island Railroad Station, in Brooklyn; and, finally, a section was constructed under 14th Street, extending east from Union Square, Manhattan, which made a total of ten sections in a period of somewhat more than five years—a record equalled by no other single subway contractor. All this work, aggregating in cost more than \$20 000 000, came under the direct supervision of Mr. Sanford, who had the responsibility for making the estimates and bids in obtaining the work, and, later, in carrying on the construction.

During 1914, the Public Service Commission announced its plans of extending the 59th Street line to join the Boroughs of Manhattan and Queens by laying two additional tracks on the lower or roadway level of Queensborough Bridge. The Degnon Company had large real estate interests in Queens and one of the attractive features of the property was its close proximity to Manhattan markets, which could easily be reached by means of motor-truck distribution—then rapidly becoming popular. The plan to place two additional tracks on the bridge would, of course, necessitate taking about 30 ft. from the roadway, thus seriously reducing the capacity, which, even then, was very undesirable. The Degnon Company, on Mr. Sanford's initiative, made protest against this taking of part of the roadway, and Mr. Sanford, assisted by the late William J. Boucher, M. Am. Soc. C. E., made a complete investigation of the possibility of a tunnel under the East River at the extension of 60th Street.

As a result, the Degnon Company made a proposition to the Public Service Commission offering to build the tunnel for a definite fixed lump sum of money and to accept a substantial reduction on its 59th Street Subway section. The plans were changed accordingly and bids were asked for the construction of two single-track tunnels. The Degnon Company's figures were made public and were recognized as the maximum that could be asked and when the bids

were opened it was found that another contractor had made an offer about \$26 000 lower. As is known, the tunnels were built, thus saving the full roadway of the bridge for vehicular traffic, which now has reached such tremendous volume that plans are under way (1929) to increase its capacity by re-locating the elevated tracks and trains on the upper level.

During 1914 and 1915, Mr. Sanford, as Vice-President of the New York and New Jersey Construction Company, a subsidiary of the Degnon Company, supervised the construction of the two-mile rock tunnel of the Passaic Valley Sewer, built at a depth of about 250 ft. below the surface of Newark Bay, New Jersey. This work, with Reginald H. Keays, M. Am. Soc. C. E., in immediate charge, was excavated through rock and lined with concrete; the rate of excavation per month set a new record for rock tunnels.

When the United States entered the World War in 1917, the Degnon Company offered the services of its organization to the United States Government for the construction of a portion of the many projects which were undertaken. Contracts for demolition and excavation in the Brooklyn Navy Yard and for the construction of warehouses and other buildings, were finished in 1917. Several months were occupied in constructing the launching ways for fabricated steel vessels at the yards of the Submarine Boat Company on the west shore of Newark Bay. Here, thousands of wooden piles were placed in the extremely cold winter of 1917-18, and a record for pile-driving was established when 82 were driven by one crew in one working day. To all this work Mr. Sanford gave his attention and earnest thought.

In May, 1918, the Degnon Company, as co-contractor with Mason and Hanger, was awarded the dock and inland warehouses of the Charleston, S. C., Port Terminal—a rail and water project for the receipt, storage, and embarkation of supplies of all kinds to the war front in Europe. The two organizations labored side by side from May to December and, after the Armistice had been signed, the small part remaining unfinished was completed by the Mason and Hanger Company. Throughout the seven months of activity, Mr. Sanford, known as General Manager of the enterprise, and his wife, made Charleston their residence. Every day, many times long into the night, Sundays included, he devoted his full time and energies to the work, and by his untiring devotion he inspired all who were with him to give their best efforts to the success of the project.

On returning to New York, in 1919, Mr. Sanford was kept busy straightening out some of the tangles which were inevitable, due to the demands of the war. In June of that year he resumed work on an uncompleted sewage treatment contract in Philadelphia, Pa., on which construction had been started in 1917, but had been discontinued at the request, or demand, of the United States Government. Two highway contracts, also in Pennsylvania, were undertaken and carried out between 1919 and 1921.

On the completion of these latter contracts, Mr. Sanford took a much needed rest. For two years he devoted the greater part of his time to a project very dear to his heart—commercial apple orchard work in Ulster County, New York. There, several years before, he had planted hundreds of choice

varieties of fruit, which were just then coming into bearing. He maintained a home in Englewood, N. J., but he and his wife spent a large part of their time at the orchards, although he was also frequently called in consultation of engineering matters.

In November, 1923, Mr. Sanford was engaged by Gibbs and Hill, Consulting Engineers, as Engineer-in-Charge of the construction of the power house at Narrows, Va., and of the pole line for the electrification of 134 miles of the Virginian Railway. This work occupied about one and one-half years and was not an easy task, for the foundation conditions proved very troublesome, requiring considerable ingenuity and ability in its execution to completion.

During March, 1925, Mr. Sanford began the work which was destined to be his last engagement. The Rosoff Subway Construction Company made him its Chief Engineer and Vice-President on the first contract it obtained on the Eighth Avenue Subway in New York; this contract covered the section extending from 122d Street to 132d Street on St. Nicholas Avenue. Somewhat later three other contracts on this same line were awarded that Company, making a total of two miles of subway. In this capacity, Mr. Sanford was again on work with which he was thoroughly familiar and the progress was extremely rapid; as was to be expected, he gave the best that was in him. His duties were many, his responsibilities great, his working hours long, and his recreation periods far apart. The result of this overwork was inevitable—he was stricken with a cold in April, 1928, which quickly developed into pneumonia, from which he failed to rally. The end came on the 22d of that month. He had made many plans intending to retire from active work in a comparatively short time.

Mr. Sanford was a quiet man—he preferred to listen to what others had to say. When he came to a conclusion, it was a sound one. Slow to admit any to his friendship, he was apparently weighing those whom he met; but when he knew his friends and had tried them, he opened wide his heart and his home to them. His acquaintances were legion, those who were privileged to call him their friend were comparatively few. It was indeed a privilege to know him; all feel his loss keenly. He was essentially a "home man", and he and Mrs. Sanford were generally to be found there, where a cheery welcome always awaited the caller.

Mr. Sanford was for many years a member of the Methodist Episcopal Church and for some time had been on the Official Board of St. James Church, New York City. On February 27, 1901, he was married to Helen Kurtz, of Cleveland, Ohio, who survives him. They had no children.

Mr. Sanford was elected an Associate Member of the American Society of Civil Engineers on October 5, 1898.

## ERICH GEORGE SCHROEDER, Assoc. M. Am. Soc. C. E.\*

DIED SEPTEMBER 24, 1928.

Erich George Schroeder was born on September 15, 1886, in Templin, near Berlin, Germany. The youngest of ten children he was only four and one-half years of age when his family emigrated to the United States, their destination being Milwaukee, Wis., where two older brothers, William R. and Paul, already had settled.

Mr. Schroeder's early boyhood was spent in Milwaukee, where he went to school and, later, was employed as a steam-fitter and plumber with Schroeder and Suelflow. After a year or more he entered Marquette University and, subsequently, the University of Wisconsin, at Madison, Wis., from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1914.

Immediately after his graduation, he was appointed Chief Estimator and Designer of Paul Riesen's Sons, Contractors, with which Company he remained until March, 1915, when he resigned to go to Clarksburg, W. Va., in charge of the Design and Construction Department of the Concrete Steel Bridge Company. In October, 1915, he and his friend, Abbey, opened offices, under the name of Schroeder and Abbey, in Philadelphia, Pa., as Contractors, Designers, and Architectural Engineers. This business association, however, did not seem to prosper and, in consequence, they dissolved partnership and Mr. Schroeder returned to the West.

In February, 1916, he again located in Milwaukee and opened offices for the Portland Cement Association, of Chicago, Ill., as Division Engineer for Wisconsin. In this position he traveled over the entire United States engaged in general promotion work for cement, especially its use in road building. He addressed public meetings and acquired by experience an excellent knowledge of salesmanship and the ability to deal with public officials and contractors. In December, 1916, the Paul J. Kalman Company, of St. Paul, Minn., sent Mr. Schroeder to Omaha, Nebr., as Manager of a branch there, in which capacity he designed and estimated reinforced concrete buildings. In August, 1917, he was taken ill in St. Paul and was forced to return to Milwaukee where he remained for a time, gradually recuperating until March, 1918, when he accepted a position with the Truscon Steel Company, of Milwaukee, to design and estimate concrete structures.

In July of the same year, however, Mr. Schroeder was on his way across the "great pond" to serve his country, with the 26th Engineer Regiment, in France, but he did not see much active service, as the Armistice was signed on November 11, 1918. He attended the field university in L'Ans where he took a course in Architecture, and made a few trips to Paris and to Southern France, Nice, and the Riviera.

On his return from overseas in July, 1919, he was appointed by the Concrete Engineering Company, of Omaha, as Manager of its Milwaukee Office.

\* Memoir prepared by William R. Schroeder, Esq., Milwaukee, Wis.

From July, 1920, until March, 1922, he was associated with the Robert Reisinger Company as Estimator, Designer, and Superintendent of Construction and, in 1922, he re-opened his own offices in Milwaukee as President of the Erich G. Schroeder Company. He designed buildings, bridges, etc., doing special work in the erection and design of apartment houses. Relative to this subject one of his friends remarked at his death: "He is no more, but his buildings will be his monuments". Among them are the Ellison Apartment, the Miramar, Seville, Sereno, Wesco, Alberta, Riviera, Oak Crest, Oak Park, Oak Manor, Sheldon, and Miami Apartments, and his own—the last—the Bellevue Manor Apartment.

This latter building was just completed when Mr. Schroeder became ill on September 18, 1928. He was taken to the hospital on September 19, where he underwent an unsuccessful operation for appendicitis. He died on September 24, 1928, when only 42 years of age. He is survived by his widow, Marie J. Schroeder, four sisters, Rosalie M., Lydia P., Ella L., and Elizabeth H. Schroeder; one brother, William R. Schroeder, all of Milwaukee, a nephew, William F. Schroeder, of Evansville, Ind., and two children whom he had adopted on Mother's Day, 1928, at the ages of one year, Nancy R. and Erich George Schroeder.

Mr. Schroeder was well liked by his friends, his contractors, his employees, and his old college and university chums. They always will remember him for his happy disposition, his good humor, his jokes at the opportune moment, and last, but not least, his great skill on the football field. As his father died in 1897, and his mother in 1902, his older brothers and sisters were father and mother to him, taking care of his education which involved sacrifices he never forgot nor failed to increasingly appreciate.

He was a member of the Alpha Gamma Phi Fraternity, the Milwaukee Athletic Club, the Elks Club, and the American Legion.

Mr. Schroeder was elected an Associate Member of the American Society of Civil Engineers on August 28, 1922.

## THOMAS PATTON STEVENSON, Assoc. M. Am. Soc. C. E.\*

DIED NOVEMBER 8, 1928.

Thomas Patton Stevenson was born in Philadelphia, Pa., on May 6, 1876. In 1897, he matriculated at the University of Pennsylvania where he studied Civil Engineering for two years.

In May, 1900, Mr. Stevenson went to Cuba as Assistant with the Engineer Corps of the Cuban Steel Ore Company on the construction of ten miles of railroad; from August, 1900, to February, 1902, he was engaged with the Engineering Department of Santiago, Cuba, (under Capt. S. D. Rockenbach, U. S. Corps of Engineers, Engineer Officer, and the late A. S. Hobby, Jr., M. Am. Soc. C. E., Principal Assistant Engineer) in surveying, road and culvert construction, and sewer work.

In 1902, he organized the firm of Stevenson and Headman, Engineers and Contractors, of Philadelphia, Pa., and Rio de Janeiro, Brazil. In March, 1902, the firm laid by contract 4 000 m. of pipe and connection with stand-pipe in the City of Paramaribo, Dutch Guiana; in 1905, it built by contract 6 km. of railroad embankments, 100 km. in the interior of Dutch Guiana on a system known as "Suriname Koloniale Spoorwegen", and also signed a contract with the "Koloniale Spoorwegen" for railroad ties (native wood).

Having liquidated his firm, Mr. Stevenson went to Para, Brazil, in 1906, as the Construction Representative of an American Syndicate holding concessions there. In this same year, he went to Rio de Janeiro where he held a position as Assistant Engineer in the Rio de Janeiro Tramway, Light, and Power Company, which had just been organized with the object of supplying electric tramway power and light service to that city. He remained in this position until 1912 when he founded the Federal Express Company in Rio de Janeiro, of which Company he served as President until his death.

During the last sixteen years of his life, Mr. Stevenson demonstrated an extraordinary capacity for work and organization. He led the Federal Express Company which he formed with American and Brazilian elements and capital to sound prosperity, thus giving an example worth imitating, with respect to efficient co-operation of American interests in the development of Brazil.

The Federal Express Company, which continues its successful operation under the administration of his remaining associates, enjoys a very high standing in business circles and is the Agent in Brazil of the Munson Steamship Line, the American Express Company, the White Company, the Marine Office of America, and many other important American firms. In addition to representing American interests, the Company conducts on its own account a general express, transportation, storage, insurance, tourist, and banking business.

Mr. Stevenson was very active and had an extraordinary amount of executive ability which he utilized in his social as well as in his business relations. He was not only one of the founder members of the American Chamber of Commerce for Brazil, but was also its first Secretary. He served continuously

\* Memoir prepared by A. Lund, Director, The Federal Express Co., Rio de Janeiro, Brazil.

and tirelessly in this capacity until after many years he was induced to accept the Presidency. He was also one of the founders of the Rio de Janeiro Country Club of which he served as Director and he was a member of the Jockey and Golf Clubs. His vision and initiative in establishing the Country Club made evident only one of the many ways in which he used his great ability for the pleasure as well as the profit of the entire community. He was deeply interested in furthering good relations between Brazilians and Americans, and he worked to this end with great success.

Mr. Stevenson died of heart disease, from which he had been suffering for a long time, at his home in Rio de Janeiro on November 8, 1928. His burial was attended by practically the entire American colony and by the most prominent members of Brazilian society and of business firms of Rio de Janeiro. He is survived by his widow, Esther S. Stevenson, of Philadelphia, Pa.

His success in Brazil was due, to a great extent, to the fact that he made Rio de Janeiro his permanent home, took pains to study and understand the psychology of Brazilians, and to follow the Republic both in its material and intellectual aspect. He associated freely with Brazilians and, consequently, was able to promote the American business interests with which his Company was connected in a most efficient manner and without the friction which develops when there is lack of mutual understanding.

Mr. Stevenson was elected a Junior of the American Society of Civil Engineers on April 4, 1905, and an Associate Member on November 6, 1907.

## HARRISON STIDHAM, Assoc. M. Am. Soc. C. E.\*

DIED JULY 9, 1927.

Harrison Stidham, the son of Alfred D. and Martha J. (Gorham) Stidham, was born on April 6, 1869, in Washington, D. C. He attended the public schools of Washington and was graduated from the Central High School in 1887. He entered Cornell University at Ithaca, N. Y., in 1887 and was graduated with the Class of 1891, receiving the degree of Civil Engineer.

Following his graduation from the University, Mr. Stidham was employed from 1891 to 1894, with the United States Coast and Geodetic Survey in connection with the primary triangulation along the 39th Parallel, Kansas and Colorado, and the survey of Pensacola Bay, Florida. In June, 1894, he was employed by the late George E. Waring, Sanitary Engineer, in the construction of sewers and sewage disposal systems. In 1895, he went with Colonel Waring as District Superintendent, in the Department of Street Cleaning, New York City; later, he became Superintendent of Snow Removal and Assistant General Superintendent, and was detailed by Colonel Waring to investigate new appliances and methods.

In April, 1898, Mr. Stidham was appointed General Superintendent of The Tubular Dispatch Company of New York. This Company operated an 8-in. tube system carrying United States mail in New York. During the period of Mr. Stidham's connection with the service the extension of the system was made across Brooklyn Bridge.

In January, 1900, he entered consulting practice as a Sanitary Engineer in New York City in partnership with Mr. George L. Walker. During the period, 1901 to 1905, he was with the American Bridge Company, in the Division Engineer's Office, New York, associated with the Department of Estimates and Costs.

In January, 1905, Mr. Stidham returned to Washington as Superintendent of the Street Cleaning Department. During the following year he re-organized the Department and placed it on a highly efficient basis. At that time the Washington Fertilizer Company held the contract for the disposal of garbage in the District. Its service was unsatisfactory and wholly inadequate for the standards of the Street Cleaning Department, as set by Mr. Stidham, and, during 1905, the Company was heavily penalized for failure to meet requirements. In January, 1906, the Company retained Mr. Stidham as General Manager, and under his efficient direction it was re-organized on a basis that afforded satisfactory service and a profitable return. Mr. Stidham continued as General Manager until January, 1918, when the Company was taken over by the United States Government.

During the World War, Mr. Stidham was a Captain in the Construction Division, stationed in Washington. Following the war he became Secretary-Treasurer of the Wilkins Security Company and thereafter devoted himself to business affairs. His faculty for organization and business management

\* Memoir prepared by James H. Edwards and John C. Hoyt, Members, Am. Soc. C. E. Mr. Edwards died on August 14, 1930.

combined with his technical ability, brought marked success to his various activities. He had a lively interest in club work and public affairs and left a host of friends in the numerous organizations with which he was connected.

Mr. Stidham was the author of "Problems of Snow Removal" (1896), and "Pneumatic Tubes" (1900). He was a member of the Delta Upsilon Fraternity; the Cosmos Club of Washington; the Chevy Chase Club of Maryland; the Kirkside Club of Washington; and the Washington Society of Engineers.

He was married to Clara Kerr, of Collins, N. Y., on September 7, 1901. Mrs. Stidham, with two sons, Alfred and Shaler, and one daughter, Sara, survives him.

Mr. Stidham was elected an Associate Member of the American Society of Civil Engineers on April 4, 1900.

## DAVID THOMPSON, Assoc. M. Am. Soc. C. E.\*

DIED APRIL 29, 1929.

David Thompson was born in Philadelphia, Pa., on March 17, 1887. He was the son of David S. Thompson, a member of the Philadelphia Stock Exchange, and Mary (Taylor) Thompson, the daughter of John M. Taylor, a wholesale dry goods merchant of Philadelphia.

Mr. Thompson's early education was acquired in the public schools and High School of his native city, after which at the age of 17, he entered the University of Pennsylvania. He was graduated therefrom in June, 1908, with the degree of Bachelor of Science in Civil Engineering, and the marked distinction of being the youngest member in his class.

His first professional engagement was from 1908 to March, 1910, as Draftsman on the design of track elevation, etc., in the Grade Crossing Division of the Bureau of Surveys of Philadelphia. During March of the same year, he served as Rodman with the New York Division of the Pennsylvania Railroad Company, at Jersey City, N. J.

Attracted by a higher salary, he accepted in April, 1910, a position with the Isthmian Canal Commission at Culebra, Canal Zone, Panama. He was assigned to the Construction Department and served as Inspector of Dredging, with the Division of Lock Design, and Draftsman on machinery equipment, until October, 1912.

Subsequently, Mr. Thompson was engaged in the following positions: From March to September, 1914, on inspection, construction, and installation of ice-making equipment and refrigeration for the Railway and Stationary Refrigerating Company (The Clothel Company), of New York, N. Y.; from April to October, 1915, on steel inspection under Mr. Lyddon, of the Inspection Office of the English Army, at Pittsburgh, Pa.; from January to March, 1916, with the R. H. Beaumont Company, of Philadelphia, as Draftsman on the design of elevating and conveying equipment; from March, 1916, to July, 1917, in the offices of the Chief Engineer and Assistant Engineer of the Pennsylvania Railroad Company, at Philadelphia, as Draftsman on design and track work; from August, 1917, to September, 1918, during the World War, with the Bureau of Yards and Docks of the United States Navy Department, at Washington, D. C., as Inspector on construction of armor plate and ordnance and projectile plants at Charleston, W. Va., and at the League Island Navy Yard in Philadelphia; and from September to December, 1918, with the Emergency Fleet Corporation of the United States Shipping Board, Department of Shipyard Plants, at Philadelphia, as Draftsman on the design of water pipe lines for fire protection. At this time, Mr. Thompson was compelled to give up active work on account of ill health from which he had suffered ever since his residence in the Canal Zone. By January, 1925, he had recovered sufficiently to continue his professional career, and he accordingly accepted a position in the U. S. Engineer Office at Wilmington, Del., as Inspector on dredging work, where he continued until April.

\* Memoir prepared from information on file at the Headquarters of the Society.

The West seemed to attract Mr. Thompson and in May, 1925, he went to Los Angeles, Calif., where he was active in the City Engineering Department, as Junior Civil Engineer, on street improvements, paving, etc. At intervals, dating from 1912, Mr. Thompson was also engaged in private work.

At the time of his death he was again employed in Government work and was located at Hawthorne, Nev., as Associate Engineer with the U. S. Naval Ammunition Depot at that place. His death occurred, after a short illness, from pneumonia. He is survived by his mother, Mrs. Mary Taylor Thompson, and two sisters.

A gentleman of staunch character and high principles which were the outward expression of an intrinsic fineness of nature, and intensely interested in his profession during his entire career, Mr. Thompson was conscientious, capable, and dependable. He was an affectionate and devoted son, and was highly regarded by his teachers and loved by his classmates. The following tells but slightly of an affection for him which lasted through the years:

"I remember him as if it were yesterday, as we sat together our four years in college. During our association I became very fond of David, as he was a man of upright character and fine bearing and I feel it was a privilege to have been so close to him during that time."

He was a member of the Methodist Episcopal Church. He had joined that church when he was 12 years of age and had remained active in its affairs throughout his life.

Mr. Thompson was elected an Associate Member of the American Society of Civil Engineers on June 6, 1927.

## BOYD FREEZE WALKER, Assoc. M. Am. Soc. C. E.\*

DIED DECEMBER 16, 1929.

Boyd Freeze Walker was born in Des Moines, Iowa, on February 3, 1888. He attended the public schools and was graduated from the Des Moines High School. He then entered the Civil Engineering Department of Iowa State College, at Ames, from which he was graduated in 1912 with the degree of Bachelor of Science in Civil Engineering. He was an enthusiastic participant in athletics in High School, and remained interested in them throughout his life. He held the championship in hurdling and running at Iowa State College and also was considered one of the best "high jumpers".

Mr. Walker's first engagement was as Road Engineer for the Chicago, Rock Island and Pacific Railway Company, which position he soon resigned to go to Great Falls, Mont., where he was employed by the Ambursen Company as Construction Engineer on the Great Falls Dam. On its completion he was sent to Prince Albert, Ont., Canada, as Assistant Engineer on the construction of a large dam. From May, 1913, to May, 1914, he served as Deputy County Surveyor at Fort Benton, Mont., on office and field work on road construction.

In April, 1915, he went to Council Bluffs, Iowa, where he secured a position as Assistant to the County Engineer of Pottawattamie County, on road and bridge work. At this time he also undertook his first drainage project in this County. Mr. Walker served as County Engineer of Pottawattamie County for three years, at the expiration of which time he entered private practice, specializing in county drainage work, special investigations, and reports for corporations and individuals, etc., in his own and the surrounding counties, and establishing himself as one of the most capable engineers in that part of Iowa.

In the fall of 1925, a delegation of business men of Council Bluffs called on Mr. Walker asking him to consider the nomination for City Engineer. After debating the question for some time, he accepted the proposal and in March, 1926, he was elected to that office by a large majority. This position he held until his death from anemia after an illness of two months.

Mr. Walker's memory is perpetuated in Council Bluffs by many city improvements which he forwarded. He kept himself well informed on all technical and other subjects, and having been called on repeatedly to serve as Consulting Engineer by various railroad companies in their respective lawsuits, he was studying law at the time of his death.

He was a man of few words, but when he chose to speak his word was one on which to depend. He was kind to and considerate of his fellow workers and there was no undertaking too insignificant for his personal attention. He was an active worker in the various civic organizations of Council Bluffs and was always glad to give his time for any plan that would improve or better his city or State. A warm-hearted, law-abiding citizen, he occupied a most difficult position, but never at any time did he usurp his power or do that which could cause him to be criticized as unfair or unjust.

Mr. Walker was a Thirty-second Degree Mason, member of the Shrine and of the Eastern Star, as well as of the Benevolent and Protective Order of Elks and the Beta Theta Pi Fraternity. He was also affiliated with the Iowa Engineering Society, of which he was a Director at the time of his death, and the Engineers' Club of Omaha, Nebr. He was a member of the First Presbyterian Church of Council Bluffs.

On December 20, 1916, he was married to Marigold C. Robey, of Omaha, Nebr. He is survived by his widow, three children, George, Boyd, Jr., and Marigold B.; his mother, Mrs. A. H. Walker, and a brother, George L. Walker, of Des Moines; and three sisters, Mrs. J. S. Brisco, of Arroyo Grande, Calif., Mrs. D. E. Nichols, of Livingston, Mont., and Mrs. A. H. Hinkley, of Puunene, Maui, Hawaii.

As a sincere appreciation of Mr. Walker, the following may be quoted:

"A man who is faithful to family, country, God, and fellow men and efficient in the discharge of duties and obligations, is a loss to the country when he departs. The loss is greater when death comes in the prime of life as it did in the case of Mr. Walker. Not half of his normal expectancy in years had been lived, and had he been permitted he would have given good service to his country and his family and community for many years. \* \* \* As the record stands, Mr. Walker's family and friends \* \* \* may well feel pride in his accomplishments for they, like his character, were clean and sound and good."

Mr. Walker was elected an Associate Member of the American Society of Civil Engineers on June 10, 1929.

**JAMES JOSEPH WALL, JR., Assoc. M. Am. Soc. C. E.\***

---

DIED AUGUST 16, 1929.

---

James Joseph Wall, Jr., the son of James Joseph Wall and Amelia Mary (Jones) Wall, was born on February 24, 1892, at Saginaw, Mich.

After graduating from the Central High School at Duluth, Minn., Mr. Wall entered Cornell University and was graduated from the College of Civil Engineering in 1916. During vacations previous to his graduation, he served as Chainman and Rodman for the Canadian Northern Railways and as Concrete Road Inspector at Superior, Wis., for the Portland Cement Association of Philadelphia, Pa. While at Cornell, Mr. Wall was active as a member of the Sigma Nu Fraternity, Manager of Fencing, and Advertising Manager of the "Cornell Civil Engineer".

In April, 1917, Mr. Wall entered the First Officers' Training Camp, at Plattsburg, N. Y., and served during the World War as First Lieutenant, Officers' Reserve Corps, 6th U. S. Engineers, and as a Captain of Engineers, U. S. Army, in command of A Company, 2d Engineers, Second Division, American Expeditionary Forces. He was cited by General Pershing and Major General Lejeune, of the U. S. Marine Corps, and also by General Buat, of the French Army, for bravery and gallantry, particularly in the rapid launching (in 7 min.) of bridges, under heavy fire, by his Company over the Meuse River during the night of November 10, 1918. These footbridges were completed ahead of schedule and resulted in the elimination of enemy machine gun nests with small losses for the Allies.

After his discharge from the Army, Mr. Wall was employed, successively, in the Sales Department of the Lakewood Engineering Company, Cleveland, Ohio, and as Engineer in charge of road grading on Route No. 3, Whitehorse Pike, New Jersey. From February to June, 1920, he was Assistant Field Engineer on Irrigation Construction for the Barahona Sugar Company, Santo Domingo, and on highway location and construction for the Dominican Republic. Following employment on valuation work by the Savage Arms Plant, Utica, N. Y., and as Engineer on concrete road construction at Freehold and Spring Lake, N. J., in 1921, Mr. Wall became Sales Representative for the Holt Manufacturing Company, which position he held until September, 1923. After being connected with the Portland Cement Association, Pittsburgh, Pa., in concrete products promotion in 1924, he became Sales Representative for the Crescent Portland Cement Company, with headquarters at Dayton, Ohio, which position he held until shortly before his death.

---

\* Memoir prepared by William L. Havens, M. Am. Soc. C. E.

His health failing, Mr. Wall went to Texas, where he was engaged for a short time on work for the Atchison, Topeka and Santa Fé Railway Company at San Angelo, Tex. He was obliged, however, to give up his work and enter the United States Veterans Hospital at Legion, Tex., where he died of tuberculosis on August 16, 1929.

He had an exceptionally pleasing personality which not only made him popular among his fellow students during his college days, but also served him well in his later employment in sales work. His success as an engineer salesman was no less marked than his bravery as a soldier.

Mr. Wall was elected an Associate Member of the American Society of Civil Engineers on December 14, 1925.

**ROBERT BROWN MURPHY WILSON, Assoc. M. Am. Soc. C. E.\***

DIED DECEMBER 15, 1928.

Robert Brown Murphy Wilson was born at Chatsworth, Ill., on January 2, 1883, the son of Charles A. and Amelia D. (Levering) Wilson. His father was, for many years, a banker in Chatsworth and was largely interested in real estate in that section of Illinois. He subsequently removed to Chicago, Ill., where he engaged in the stock brokerage business.

His grandfather, Dr. R. B. M. Wilson, was a native of Island Magee, near Belfast, Ireland. He was graduated in medicine from the University of Edinburgh, and directly thereafter came to America. Dr. Wilson settled in Washington, Ill., and was prominent in the practice of his profession throughout that section of the State until his death in 1879. Dr. Wilson's wife was Jane Anthony, of Sherburne, Vt., who when a child moved with her father to Illinois and through her, Robert Brown Murphy Wilson was descended from Josiah Wood, of Middleboro, Mass., who was a soldier in the Revolutionary Army.

On his mother's side, he traced his descent from Wiggard Levering who came to America from Leyden, Holland, in 1685, settling near Philadelphia, Pa., where he purchased land between the Schuylkill River and Wissahickon Creek. A portion of this land is now included in Fairmount Park, Philadelphia, and the Levering family has been continuously represented in this section of the latter city for nearly 250 years.

Mr. Wilson was graduated from the Chicago Manual Training School in 1900, and immediately entered the Engineering School of the University of Chicago with advanced standing; but, at the close of his Junior year, owing to various circumstances, he decided to enter the practical work of his profession and to qualify for his degree by outside study. He subsequently completed all his college requirements, except one subject, and was much commended for his proficient work in Spanish.

Mr. Wilson's first engagement was as Rodman on the construction of the Mobile, Jackson, and Kansas City Railroad in Mississippi, during 1902 and a part of 1903. During the latter year he secured an appointment as Surveyman in the United States Engineer District at Mobile, Ala., and was engaged on hydrographic work in that vicinity for two years or more, except for a period of several months, when owing to the failure of Federal appropriations he was temporarily furloughed and accepted a position as Instrumentman with the Florida East Coast Railway Company. During the latter engagement he was occupied with reconnaissance work through the Everglades and from Key Largo to Key West, Fla.

For the next eight years, until 1913, he followed railroad work in Mexico. His first work there was in connection with the construction of the Colima Extension of the Mexican Central Railway, on which he served as Assistant to the Division Engineer. This Division represented very heavy construction and included both tunnel and bridge work. Subsequently, he was placed in

\* Memoir prepared by David G. Anderson, M. Am. Soc. C. E.

charge of the extension of the Mexican Central Railway from Paredon to Saltillo, in the State of Coahuila, and, still later, of another extension from Marfil to Guanajuato, Mexico.

In 1909, Mr. Wilson became connected with the Southern Pacific Railway Company of Mexico, and served as Chief of Party on exploration work on the Yaqui River; Roadmaster on the Sinaloa Division; Assistant Superintendent, Maintenance of Way, on the Sinaloa and Sonora Divisions; and Engineer, Maintenance of Way, for all the Southern Pacific Lines in Mexico. His railroad work in Mexico was of the pioneering type and was attended with many difficulties.

For a time in 1913, he was interested in land development in Mexico, but in the following year he became connected with the Union Carbide Sales Company, as traveling representative, promoting the use of carbide in connection with the oxy-acetylene process.

Shortly after the entrance of the United States into the World War, Mr. Wilson entered the first Officers' Training Camp, at Fort Sheridan, Illinois, on May 13, 1917. He accepted a commission as Captain in the Engineer Officers' Reserve Corps on August 15, 1917, and was assigned to active duty the same day; he sailed for foreign service, September 9, accepted a commission as Major of Engineers on November 12, 1918, returned to the United States, June 27, 1919, and was honorably discharged on July 24, 1919, at Camp Grant, Illinois, while serving with the 311th Engineers.

On the completion of his war service Major Wilson resumed his connection with the Union Carbide Sales Company until 1921, when he became associated with the American Steam Conveyor Corporation, in Chicago. In 1923, he returned to Mexico and to the time of his death was General Manager of the Mina La Prinesa, a silver mine in Chilpancingo, Guerrero, Mexico. His death, which was the result of several severe attacks of inflammatory rheumatism affecting the heart, occurred while he was a patient at the Evanston, Ill., Hospital, on December 15, 1928.

Major Wilson was a member of the Wilmette (Ill.), Presbyterian Church and took a deep and sincere interest in its work. During the periods when his professional duties permitted him to reside at home, he devoted himself to a boys' Sunday School class. He was conscientious in all his work, considerate and thoughtful toward others, and always to be remembered for his cheery greetings and for the smiles that brought happiness to those with whom he came in contact. He never married, but was always a devoted son. He represented the finest type of a Christian gentleman, and was a worthy member of his chosen profession.

Major Wilson was elected an Associate Member of the American Society of Civil Engineers on June 30, 1911.

## FRANCIS HERBERT WRIGHT, Assoc. M. Am. Soc. C. E.\*

DIED MAY 29, 1928.

Francis Herbert Wright was born in Memphis, Tenn., on December 8, 1874, the second son of Col. A. D. Wright, formerly a Confederate Officer, and Mary Ellen (Farrell) Wright. Colonel Wright was a lineal descendant of a titled English officer of high rank, who married a daughter of a Spanish Grandee, Gen. Manuel Cardenas, and established his residence on a Spanish grant owned by his distinguished father-in-law—the present site of San Antonio, Tex. Mary Ellen Farrell was the grand-daughter of Capt. John Sappington, an early Mayor of St. Louis, Mo. John Sappington, the third of his line and name in America, served seven years in the American Army during the Revolutionary War. He was a member of the personal bodyguard of General Washington, at Valley Forge, and when the war ended was a Captain on the Staff of General Lafayette. With Daniel Boone and a company of pioneers he was one of the founders of Boonesboro, Ky., and served a term in the Kentucky Legislature before going to St. Louis where he died in 1807, a man of property.

Mr. Wright was educated in private schools, where he was distinguished because of his proficiency in, and liking for, mathematics. He began his engineering career at a very early age on levee surveys and construction along the Mississippi River. In 1891, he was a Rodman and Inspector for the Board of State Engineers, at New Orleans, La., and also for the United States Engineer Office in that city. Then followed work for various railway companies and two years in Oregon, Washington, and Montana, on railway location and construction.

Mr. Wright was employed at the World's Fair, Chicago, Ill., in 1893, and from 1896 to 1899 was an Inspector, Corps of Engineers, U. S. Army, under Capt. (now Maj.-Gen., *Retired*), Mason M. Patrick. While on furlough, in 1898, he was employed for a time as an Assistant Engineer in the office of the City Engineer of Memphis, Tenn. In 1899, he became an Inspector of dredging at Port Royal, S. C., for the Bureau of Yards and Docks, United States Navy, and also engaged on levee construction at Bird Point, Mo., for the Corps of Engineers, U. S. Army. This work ended in 1900. During 1901, he was employed as a Concrete and Masonry Inspector for the Illinois Central Railway Company, entering private practice when that work was completed. In 1902-1903, he served as Assistant City Engineer of Little Rock, Ark., and Assistant Engineer in charge of sewer construction in Helena, Ark. After a short period as Draftsman on location for the St. Louis-San Francisco Railroad Company, he became, in 1903, City Engineer of Helena, Ark., where he remained until late in 1907.

In 1908, Mr. Wright went to Chicago, Ill., where he served as Sales Engineer for about a year for the Northwestern Expanded Metal Company. In 1909 he was employed as Chief Designing Engineer for Mr. Carl Weber, who was engaged in the construction of reinforced concrete chimneys. He left

Mr. Weber in 1910 to become Chief Engineer for and, later, a partner in, the Julian S. Nolan Company, designers and builders of two-way reinforced concrete and tile slabs. Mr. Wright patented an L-shaped closer for the open ends of tiles used in the Nolan-Wright System and the Company was very successful until the beginning of the World War in 1914, which caused a slowing down of the building industry. With the entry of the United States into the war, in 1917, the Company suspended operations entirely.

Mr. Wright volunteered immediately for service and was recommended for the rank of Captain in the Engineer Officers Reserve Corps, by the Army and Navy officers under whom he had served as a young man. The physical examination revealed a faulty heart, hitherto unsuspected, and he was not accepted. During the war he worked, in the vicinity of New Orleans, in charge of the construction of wharves and warehouses, as an Assistant Engineer for Ford, Bacon and Davis, later doing considerable appraisal work for the same Company, principally for the valuation of alien property. After the Armistice was signed, he served as a Construction Engineer for Dwight P. Robinson and Company, Incorporated, later leaving that Company to become Engineer and Eastern Representative in the New York District for the Hay-Walker Brick Company. He remained in this position for several years until the firm went into the hands of a receiver. During the period he was associated with the Hay-Walker Brick Company, he invented several types of wall tile, the patents being taken out in the names of other men. He was an Estimator for the Longacre Engineering and Construction Company, Incorporated, for a time, and then became New York Representative for a patented door, on which work he was engaged at the time of his death.

Mr. Wright was a man of very friendly disposition, one intensely interested in everything that tended toward improvement in the working conditions, remuneration, and treatment of engineers. He had a warm heart and made friends easily. In 1924, he purchased an apartment in a co-operative apartment house in Sunnyside Gardens, Long Island City, N. Y., where he served for a time as an officer of the Co-operative Corporation as well as being active for several terms as an officer of local property owners associations. Nothing was too difficult or disagreeable for him to undertake for the general good of the community, and his death was sincerely regretted by a large circle of friends.

In politics, he was a Democrat and a member of the Anaroc Democratic Club. He had a deeply religious nature and was a faithful and devout member of the Roman Catholic Church.

In 1900, he was married to Mary Alice Smith, in Arkansas. They had two children, Mary Frances, one of the prize winners in the International Turnverein Convention swimming contests in Berlin, Germany, in the summer of 1928, and James Mayo, who is in business in New York, N. Y. Mrs. Wright died shortly after the war and, in 1923, Mr. Wright was married to Sarah Leion, of Norwich, Conn., who survives him.

Mr. Wright was elected an Associate Member of the American Society of Civil Engineers on November 4, 1914.

**JOSEPH LLOYD CAGNANI, Jun. Am. Soc. C. E.\***

DIED AUGUST 2, 1929.

Joseph Lloyd Cagnani, the second son of Enrico and Palmira Zavatoni Cagnani, was born in New York, N. Y., on July 15, 1904. He was educated in that city and was graduated in 1928 from Cooper Union, with the degree of Bachelor of Science in Civil Engineering.

It was during this schooling period in 1922, which consisted mainly of evening-session study, that Mr. Cagnani entered the service of the Cutler-Hammer Manufacturing Company of New York, in the capacity of Draftsman on conveyor layouts. Later, in 1923, he became Estimator, Draftsman, and Designer for the Harris Structural Steel Company. His unusual ability and persevering efforts were quickly recognized and won for him the appointment of Assistant to the Chief Engineer.

Mr. Cagnani was intensely interested in mechanics, and, with the development of the airplane and aeronautics, he was eager to enter that field. Imbued with this one idea, he matriculated for post-graduate work in aeronautics at the Guggenheim School at New York University. His inclination and his conscientious application to this branch made him an excellent student, and, convinced of his physical and mental eligibility, he decided to enter the field.

In October, 1928, he became a commercial pilot for the Barrett Airways, Incorporated, at Armonk, N. Y. As he possessed a pedagogical turn of mind and an entertaining personality, and was also equipped with concrete facts and principles, he succeeded, in the spring of 1929, to the position of Director of the Ground School—a position that he filled with remarkable aptitude and understanding.

Subsequently, on August 2, 1929, Mr. Cagnani passed the examination for Transport Flier, attaining the highest average ever given for that test. Rejoicing in his new achievement, later on the same day he was flying a "joy plane" with two young friends, when motor and wing defects and disabilities caused him to fall 2 500 ft. It later appeared that he had fought death calmly and coolly every foot of the way down, as the inspectors found him with one hand on the ignition switch, to prevent fire, and the other on the controls.

He died as he had lived, a gentleman unafraid. "Big Joe", they called him, and he was big in heart and soul as well as in body. Four qualities go to make a man—courage, strength, loyalty, and intelligence—and all four Mr. Cagnani had in abundance. His death was a loss not only to his friends, but to all who knew him.

Mr. Cagnani was elected a Junior of the American Society of Civil Engineers on October 1, 1927.

\* Memoir prepared by Mrs. Arthur Levin, Lazar Levin, and Charles W. E. Schroeder, Jun. Am. Soc. C. E.

**FREDERICK OLIVER MACY, Jun. Am. Soc. C. E.\***

---

**DIED DECEMBER 6, 1928.**

---

Frederick Oliver Macy was born on May 10, 1905, at St. Croix Falls, Wis., the son of Elbert Clyde Macy, M. Am. Soc. C. E., and Minta (Tilden) Macy. Owing to the character of his father's business, that of a Construction Engineer, the boy's grade school education was obtained in the States of Washington, New York, and Iowa. A full four-year High School course was completed, however, in Ames, Iowa, at the home of his grandfather, Mr. Fred C. Tilden.

During this time, Mr. Macy showed the same devotion to study and the disposition to think clearly and accurately that characterized his later work in the university and in business. He took an active part in athletics while in High School and twice won the tennis medal. He played each year in the class basketball teams. He was a member of the track relay team in 1923 that took the National High School Medal. He was Athletic Editor of the High School paper during 1922-23, was Advertising Manager during his Senior year, and Manager for the Class Annual for his Class of 1924.

While attending the Ames schools he worked during the summer vacations of 1918 and 1919 as Transportation and Material Yard Clerk in the Hog Island Ship Building Yards near Philadelphia, Pa., and although young, thus served his country during the World War. In the summer of 1919 he worked as a Machinist Helper for the Great Western Power Company, in connection with the building of a power plant in the mountains of California.

From September, 1921, to July, 1922, Mr. Macy accompanied his family to Japan, China, and the Philippine Islands and worked with his father on proposed power developments. He thus began with practical experience a profession that he had chosen to be his life's work.

After finishing High School Mr. Macy entered Leland Stanford University at Palo Alto, Calif., where he took the civil engineering course and was graduated, with honors, in the Class of 1928. During vacations he was, in 1926, again employed at the scene of his earlier work, the enlargement of the Big Meadows Dam of the Great Western Power Company. In the summer of 1927, he was engaged on building construction in Los Angeles, Calif., and won the high esteem of his employers. His work at the University was of the highest order, which, together with his practical experience, gained in vacation periods both while in high school and in the University, won for him the opportunity to serve as Instructor in Surveying while still finishing his own course. During his Senior Year he was elected President of the Student Chapter of the Society and was chosen by his Class to represent it in presenting the bronze plate for the Class of 1928 to be placed in the Memorial Chapel.

Before his graduation, Mr. Macy was offered a responsible position in connection with making surveys and plans for a large water system to supply a group of cities in the neighborhood of San Francisco, Calif. His previous experience with a number of important engineering projects during his vaca-

---

\* Memoir prepared by Charles B. Wing and F. M. Thebo, Members, Am. Soc. C. E.

tions was a guaranty of success here. He continued in this work until late in November, 1928, when he resigned to accept a position in connection with power plant work in Europe. While en route from San Francisco he was stricken with pneumonia and became very ill before reaching his grandfather's home in Ames. He was immediately removed to the Mary Greeley Hospital where every possible effort was made to meet the crisis, but on December 6, with his family about him, he slipped away just before noon.

Few young men have been privileged to look forward to a more promising place of service in his chosen profession and none enjoyed a more complete respect and love than "Ted" Macy. He had a genius for friendship, born of a native grace of manner which was a fit expression for the kindly consideration that he cherished for all his companions.

To know him was to be charmed and won by his frank friendliness and generous thoughtfulness. To share his life was to be stimulated. Had he lived he would have gone far in his profession. He had already advanced far in the high adventure of unselfish friendship.

Mr. Macy was elected a Junior of the American Society of Civil Engineers on October 1, 1928.

**LOUIS ALFONZO PEDERSON, Jun. Am. Soc. C. E.\***

---

**DIED APRIL 5, 1929.**

---

Louis Alfonzo Pederson, the only son of Mr. and Mrs. H. A. Pederson of Tucson, Ariz., was born at Saint David, Ariz., on June 6, 1903. He was educated in the public schools of Saint David and Bisbee, Ariz., and was graduated from the Saint David High School in 1922 with the highest honors of his class. Through his efforts in his High School career, he earned a scholarship at the University of Arizona.

Mr. Pederson began his engineering career in September, 1922, working as a Chainman for P. E. Fernald, U. S. Mineral Surveyor at Tucson, in which capacity he was engaged until April, 1923. From May to August, 1923, he was employed as Head Chainman for Mr. Fernald.

Mr. Pederson's parents moved to Tucson in the spring of 1923, and Mr. Pederson then attended the University of Arizona from September, 1923, to May, 1924, as a student in Civil Engineering.

In June, 1924, he accepted a position with W. R. Elliott, Consulting Engineer, of Phoenix, Ariz., and was employed by Mr. Elliott until February, 1925, in the capacities of Head Chainman, Rodman, and Draftsman, successively.

From March to June, 1925, Mr. Pederson was with the Beardsley Land and Investment Company, of Phoenix, as Rodman, Instrumentman, Calculator, and Draftsman on irrigation and power investigations in the vicinity of Phoenix, under the direction of A. F. Harter, Assoc. M. Am. Soc. C. E., being in charge of a party on topographic surveys for storage reservoirs on the Agua Fria River. From July, 1925, to June, 1926, he was in the employ of the City of Tucson, as Head Chainman, Instrumentman, and Sand Inspector. He was also employed on city sub-division work and on paving and sewer construction.

In June, 1926, he accepted a position with the Griggs Engineering Company, of Phoenix, assuming charge of all field work on the San Pedro Irrigation Project on the San Pedro River, at Benson, Ariz., under the direction of Mr. Harter. This consisted of all the preliminary surveys on this project, including re-establishment of section corners, topography over the entire area of about 40 000 acres of land, preliminary canal location, location of diversion dam and storage reservoir, bed-rock investigations at the storage dam and diversion dam, and the running of exclusion areas within the limits of the project. Mr. Pederson showed marked ability and was placed in charge of two parties. The field work was completed in April, 1927, at which time he was transferred to Phoenix, where he was employed by the Maricopa County Municipal Water Conservation District No. 1 on canal location and construction connected with the Lake Pleasant Dam on the Agua Fria River. He remained throughout the entire construction period, at all times in direct charge of important work which was completed in March, 1928.

---

\* Memoir prepared by A. F. Harter, Assoc. M. Am. Soc. C. E.

Mr. Pederson's achievements during the construction period were appreciated to such an extent that on the completion of the undertaking he was retained in the Operating Department as Water Master in charge of the delivery of water to the irrigated areas and, after the irrigating season, he was transferred to the Phoenix Office as Computer and Draftsman. He was employed in this capacity at the time of his death.

His tasks always were carefully and accurately undertaken. Mr. Pederson was one of a group of young, far-sighted engineers who never slighted the work at hand; he was definitely aware and certain of the nature of each problem he attacked before plunging into it, regardless of its difficulty or intricacy. His field and office work stand as a fine tribute not only to himself but to the organization as well.

He was an ardent student at all times, having been enrolled with the Wilson Engineering Corporation, of Cambridge, Mass., and he was well advanced in this correspondence course at the time of his death.

He was unmarried and was affiliated with the Church of Jesus Christ of Latter Day Saints, of which he was a regular attendant.

Mr. Pederson was elected a Junior of the American Society of Civil Engineers on March 5, 1928.

**ROBERT BRUETTE POWELL, Jun. Am. Soc. C. E.\***

---

DIED MARCH 11, 1929.

---

Robert Bruette Powell, the oldest son of Mr. and Mrs. F. J. Powell, of Wausau, Wis., was born at Fort Atkinson, Wis., on May 23, 1900. He was educated at the University of Wisconsin where he received the degree of Bachelor of Science in Civil Engineering in 1923.

During the summers of Mr. Powell's college work he endeavored to gain as much practical experience in his profession as possible. From June to September, 1920, he was employed as Instrumentman with the Wisconsin Valley Electric Company, and in the summers of 1921 and 1922 he served as Inspector and Surveyor on waterway dredging with the Wisconsin Valley Improvement Company. The following year, from March to May, he was engaged in basin and dam site surveys on the Chippewa River for L. A. DeGuerre, Consulting Engineer, Wisconsin Rapids, Wis. At the termination of this short connection, Mr. Powell accepted a position with the Dixie Construction Company, of the Alabama Power Company, and from May, 1923, to February, 1924, he served as Chief of Party on the location of transmission lines and basin surveys.

In April, 1924, Mr. Powell established a connection with the Electric Bond and Share Company, of New York, N. Y., as Designer in the Hydraulic Division. While in this employ he received excellent training and experience in various kinds of work, such as preliminary studies, license drawings, investigation of old structures, substructures, power house and switchyard, penstocks, spillway gate and bulkhead sections, surge tank foundations, and economic studies.

After three years with the Electric Bond and Share Company he was employed by Murray and Flood, Engineers, New York City, and sent to Columbia, S. C., for assignment on the Saluda River Hydro-Electric Development in making hydraulic investigations and other preliminary engineering studies. When the actual construction work began, Mr. Powell was promoted to the position of Supervising Structural Engineer and his main assignment was the supervision of the erection of the penstocks and the intakes. These structures were practically completed before his sudden death in an automobile accident, and now stand as monuments to him.

After his death, letters were received from men with whom "Bob" Powell had worked, and from men who had worked under him, which told frankly of the high esteem in which he was held by those who knew him. One man wrote, "I never worked with one more sincere, more exacting, and more faithful to any trust"; and to those who knew Mr. Powell best these were surely his outstanding characteristics.

---

\* Memoir prepared by A. R. Wellwood, Res. Engr., Saluda River Hydro-Elec. Development, Columbia, S. C.

T. C. Williams, Vice-President of the Lexington Water Power Company, the owners of the Saluda River Hydro-Electric Development, stated:

"He had such a pleasing personality and was so well liked by every one. I was especially impressed with his cheerful willingness to work just as many hours as necessary, and when there was a peak load, he was always ready to go the limit".

Arthur R. Wellwood, Resident Engineer on the Saluda Development for Murray and Flood, and Mr. Powell's immediate superior, said:

"I feel that I have lost a friend as well as a valued co-worker. He had a very bright engineering mind and I considered him an A-1 Engineer. He was due to go a long way in his chosen field. He had been entrusted with very important features of the construction of the Saluda Dam and had done efficiently each task assigned".

William S. Murray, of Murray and Flood, Engineers, wrote:

"Powell had a compelling personality and I have a very difficult time reconciling the passing out of a man who seemed to have laid all the foundations for an interesting and constructive career".

Mr. Powell was elected a Junior of the American Society of Civil Engineers on April 12, 1926.

**CARL SPEER, Jr., Jun. Am. Soc. C. E.\***

---

**DIED JANUARY 18, 1929.**

---

Carl Speer, Jr., the son of Carl and Anna Speer, was born in Baltimore, Md., on December 21, 1901. His preliminary education was received in the public schools of Baltimore. He studied Civil and Sanitary Engineering at the Johns Hopkins University, obtaining the degrees of Bachelor of Science in 1923 and Master of Science in Sanitary Engineering in 1926.

From 1921 to 1922, Mr. Speer was employed as Inspector on construction with the Maryland State Roads Commission. During 1923 and 1924, he served as Junior Engineer with the New York Transit Commission on traffic engineering of subways and elevated lines. From June, 1925, to February, 1926, he was engaged in shellfish investigations for the Maryland State Department of Health. Beginning in July, 1926, and until his death, he was carrying out, as Junior Sanitary Engineer in the Division of Water Safety Control of the City of Chicago, Ill., experimental studies in the treatment of the public water supply.

The writer, as teacher, employer, and friend of Mr. Speer, realizes too well the inadequacy of the foregoing chronological account as a description of an individual of more than usual charm and intelligence. Scientific curiosity and enthusiasm, those rare characteristics of productive men, were possessed by Mr. Speer in an unusual degree. That they would have led him upward to important engineering contributions, his friends and his associates have little reason to doubt. These attributes, coupled with a keen and delightful personality, make his death at the beginning of his career most tragic. The world has lost a promising aide. In all his work, energy and ability were dominant. Ever on the alert for new concepts, he carried on his work with freshness and pleasure. His ideal was to create a value to his fellow man.

On June 26, 1926, he was married to Charlotte A. Stout, of Baltimore. He is survived by his widow, his father, and one sister.

Mr. Speer was elected a Junior of the American Society of Civil Engineers on March 14, 1927.

---

\* Memoir prepared by Abel Wolman, M. Am. Soc. C. E.

## LEWIS IRVING FLETCHER, Affiliate, Am. Soc. C. E.\*

---

DIED AUGUST 12, 1929.

---

Lewis Irving Fletcher, the son of Lewis E. and Lucy Ellen (McCracken) Fletcher, was born in Marlborough, Mass., on December 7, 1865. He was educated in the schools of his native town and, later, attended a business college in Boston, Mass.

At the beginning of his professional career, Mr. Fletcher was engaged in construction for the New England Telephone and Telegraph Company, after which he built and operated the lighting plant for the Nashua, N. H., Electric Light Company. In 1889, he again built and operated an electric light and power plant for the Lowell, Mass., Electric Light Corporation.

For a time thereafter, he was engaged in the machinery business in Boston, subsequent to which he went to Easton, Pa., where as Chief Engineer he constructed a hydro-electric plant on the Delaware River for the Easton and Lehigh Power Companies. In 1902 and 1903 he was located at Bulls Bridge, Conn., in connection with the power development on the Housatonic River at that place, and in 1904 he served as Consulting Engineer for the Town of Easton. From 1905 to 1907 he was engaged as Engineer on Dam Construction for the American Pipe and Construction Company of Philadelphia, Pa. During this period he built twenty-two reservoirs and dams along the main line of the Pennsylvania Railroad, in Pennsylvania.

During 1909 and 1910, Mr. Fletcher was employed with the Ambursen Company at Rapidan, Minn., on the construction of a dam and power plant, and with H. M. Byllesby and Company, of Chicago, Ill. Later, he went to Estacada, Ore., where he finished the construction of a dam and hydro-electric plant on the Clackamas River. In 1912, he completed dams and paper mills for the Cornell Wood Products Company, in Cornell, Wis.

He went to Kent, Ohio, in 1913, where he was engaged in general contracting business, building roads and bridges in Northeastern Ohio. From 1921 to 1924, he served as Hydraulic Engineer and Resident Manager for J. Livingston and Company, Inc., of New York, N. Y., at Judsonia, Ark. In 1926 he was engaged on work for the United Gas Improvement Company, at New Milford, Conn., and at the time of his death, he was with the Davey Compressor Company, of Kent, Ohio.

Mr. Fletcher's sudden death at his home in Kent was a shock to the entire community. He became ill as he was preparing to retire for the night and died in less than an hour from an internal hemorrhage. His was a kind and lovable personality, a man who held the marked esteem of scores of friends and associates.

Mr. Fletcher was a member of the Masonic Blue Lodge, at Nashua, N. H.; of the Knights Templars and Consistory, at Lowell, Mass.; of the Shrine, at Boston, and of the Order of the Eastern Star and the Benevolent and Protective Order of Elks, at Kent. He was an attendant at the Christian Science Church.

He was married at Lowell, Mass., on October 14, 1890, to Annie A. Shedd, who, with their daughter, Mona, survives him. He is also survived by four brothers, Howard, of Detroit, Mich., Fred, of Marlborough, Mass., Percy, of Fairhaven, Mass., and George, of Newark, N. J.

Mr. Fletcher was elected an Affiliate of the American Society of Civil Engineers on February 6, 1912.

## JOHN ROBERT STANTON, F. Am. Soc. C. E.\*

---

DIED APRIL 28, 1927.

---

John Robert Stanton, the son of John and Elizabeth R. Stanton, was born in New York, N. Y., on September 25, 1857. He was educated in the public schools of New York and was graduated from the School of Mines at Columbia University.

Mr. Stanton's career as a Mining Engineer was begun in 1879, in connection with the Atlantic Mining Company and the Central Mining Company of Michigan. In 1890, he became Secretary-Treasurer and Director of the Wolverine Copper Mining Company, and eight years later he was elected Treasurer of the Mohawk Mining Company, of which Company he afterward became President. He also acted as President and Director of the Fort Mountain Talc Company and the White Pine Extension Copper Company of Michigan. His further associations in the field of copper mining were with the Winona Copper Company and the Michigan Copper Company, during which period he was engaged in the active management of eight Lake Superior mines.

Having come from a family of noted metallurgists, Mr. Stanton was especially well posted on the Lake Superior Copper Region. His father had been rated as one of the best informed men on copper in America, and it was estimated in 1905 that the output of the copper mines in which he was interested reached 90 000 000 lb. per year. This fact may account somewhat for Mr. Stanton's interest and accurate knowledge of the business in which he remained active until 1918 when he retired on account of poor health. He left New York to live at his country home at Galesville, Wis., where he died April 28, 1927.

From 1876 to 1887, he was a member of the old Seventh Regiment, N. G. N. Y., later serving six years as Lieutenant and four years as Captain. He was a life member of Company A, Seventh Regiment Veterans Association.

Mr. Stanton was a member of the following societies: The American Institute of Electrical Engineers; the Lake Superior Mining Institution; the Franklin Institute of Philadelphia; the American Association for the Advancement of Science; the National Geographic Society of America; the American Forestry Association; the New York Botanical Gardens Society; the New York Zoological Society; the Horticultural Society; St. George's, St. Andrew's, and the Robert Burns Societies; the Huguenot Society; Sons of the Revolution; the Municipal Art Society; the Thomas Hunter Association; the Society for the Prevention of Cruelty to Children; and the Society for the Prevention of Cruelty to Animals.

He was also active in the following clubs: The New York Yacht Club; the Columbia Yacht Club; the Onigoaming Yacht Club; the Union League Club; the Lotus Club; the Engineers Club; the Republican Club; the Twi-

---

\* Memoir prepared from information on file at the Headquarters of the Society.

light and Dunwoody Country Club; the Chicago Athletic Club; and the Nisewandic Club.

Mr. Stanton was married on September 4, 1899, to Helen Maud Kilmer who, with a sister, Mrs. J. W. Moore, of Haughton, Mich., survives him.

Mr. Stanton was elected a Fellow of the American Society of Civil Engineers on April 4, 1899.

John and George Washington, the first President and Vice President of the United States, were born in 1732 and 1731 respectively. They were both of the same family, the Washingtons, and were both of the same generation. They were both of the same family, the Washingtons, and were both of the same generation. They were both of the same family, the Washingtons, and were both of the same generation.

The first President of the United States, George Washington, was born in 1732. He was a member of the Continental Congress and was elected President in 1789. He served two terms and died in 1799. He was the first President of the United States and was a member of the Continental Congress.

The second President of the United States, John Adams, was born in 1735. He was a member of the Continental Congress and was elected President in 1797. He served two terms and died in 1800. He was the second President of the United States and was a member of the Continental Congress.

The third President of the United States, Thomas Jefferson, was born in 1743. He was a member of the Continental Congress and was elected President in 1801. He served two terms and died in 1826. He was the third President of the United States and was a member of the Continental Congress.

The fourth President of the United States, James Madison, was born in 1751. He was a member of the Continental Congress and was elected President in 1809. He served two terms and died in 1836. He was the fourth President of the United States and was a member of the Continental Congress.

The fifth President of the United States, James Monroe, was born in 1758. He was a member of the Continental Congress and was elected President in 1817. He served two terms and died in 1831. He was the fifth President of the United States and was a member of the Continental Congress.

The sixth President of the United States, James Monroe, was born in 1758. He was a member of the Continental Congress and was elected President in 1817. He served two terms and died in 1831. He was the fifth President of the United States and was a member of the Continental Congress.

#### METERS.

- "Experiments on Discharge Over Spillways and Models, Keokuk Dam." Floyd A. Nagler and Albion Davis. (With Discussion.) 777.

#### MODELS.

- "Experiments on Discharge Over Spillways and —, Keokuk Dam." Floyd A. Nagler and Albion Davis. (With Discussion.) 777.  
— to illustrate crown stresses in a skew arch. 139.

#### PARKS AND PARKWAYS.

- "Engineering Applied to National Parks." Stephen T. Mather. 1181. Discussion: H. K. Bishop, and W. W. Crosby. 1193.

#### PAVEMENT.

- "Foundations and Drainage of Highways." Albert C. Rose. (With Discussion.) 62.

#### PIPE LINES.

- in use in Atacama Desert, Chile. 609.

#### POWER PLANTS.

- "Pumped-Storage Hydro-Electric Plants." William W. K. Freeman. 884. Discussion: John R. Freeman, H. Alden Foster, Oren Reed, Paul L. Heslop, and A. H. Markwart. 903.

#### PUMPS.

- "Characteristics of Centrifugal Oil Pump." Michael D. Aisenstein. 425. Discussion: Morrough P. O'Brien. 440.

**RAINFALL.**

"Water Supply from — on Valley Floors." A. L. Sonderegger. 1242. Discussion: Harold C. Troxell, Harry F. Blaney, C. W. Sopp, W. P. Rowe, Ivan E. Houk, and Charles H. Lee. 1269.

**REINFORCED CONCRETE.**

"Studies of Shear in — Beams." T. D. Mylrea. (With Discussion.) 734.

**REPORTS OF COMMITTEES.**

"Consumptive Use of Water in Irrigation." Progress Report of the Duty of Water Committee of the Irrigation Division. S. T. Harding, Harry Barnes, Lynn Crandall, Augustus Griffin, Charles R. Hedke, O. W. Israelson, R. I. Meeker, H. M. Murdock, R. L. Parshall, W. L. Powers, G. E. P. Smith, and O. L. Waller. 1349. Discussion: Harold Conkling, Charles H. Lee, and M. R. Lewis. 1378.

"Drainage of Irrigated Lands." Report of the Committee of the Irrigation Division. Thomas H. Means, J. L. Burkholder, L. M. Holt, H. S. Kleinschmidt, and L. M. Lawson. 1425. Discussion: M. R. Lewis. 1448.

"Interstate Water Matters." Progress Report of the Committee of the Irrigation Division. M. C. Hinderlider, George M. Bacon, Frank C. Emerson, A. L. Fellows, C. E. Grunsky, C. S. Heidel, R. I. Meeker, and J. C. Stevens. 1400. Discussion: R. I. Meeker. 1422.

**RESERVOIRS.**

"Pumped-Storage Hydro-Electric Plants." William W. K. Freeman. (With Discussion.) 884.

Transmission and delivery of reservoir water. G. Clyde Baldwin. 296.

**RIVERS.**

"Flood Control on the River Po in Italy." John R. Freeman. 161. Discussion: C. McD. Townsend, Oren Reed, John P. Hogan, William B. Gregory, John R. Slattery, Arthur P. Davis, G. de Thierry, M. Giandotti, R. D. Goodrich, and C. E. Grunsky. 197.

"Interstate Water Matters." Progress Report of the Committee of the Irrigation Division. (With Discussion.) 1400.

"Silt Transportation by Sacramento and Colorado — and by the Imperial Canal." C. E. Grunsky. (With Discussion.) 1104.

**ROADS.**

"Engineering Applied to National Parks." Stephen T. Mather. (With Discussion.) 1181.

"Foundations and Drainage of Highways." Albert C. Rose. (With Discussion.) 62.

"The Engineer's Part in Making the Highway Safe." A. H. Hinkle. (With Discussion.) 522.

**RUN-OFF.**

"Water Supply from Rainfall on Valley Floors." A. L. Sonderegger. (With Discussion.) 1242.

**SAFETY DEVICES AND MEASURES.**

- "The Engineer's Part in Making the Highway Safe." A. H. Hinkle. (With Discussion.) 522.

**SAND.**

- "Experiments to Determine Rate of Evaporation from Saturated Soils and River-Bed Sands." Ralph L. Parshall. (With Discussion.) 961.  
"Measuring Materials for Concrete." William Mayo Venable. 1082.

**SEA WATER.**

- "Pre-Determining the Extent of a Sewage Field in —." A. M. Rawn and H. K. Palmer. (With Discussion.) 1036.

**SEEPAGE.**

- Canal — as contributing to the drainage problem. 1431.  
"Water Supply from Rainfall on Valley Floors." A. L. Sonderegger. (With Discussion.) 1242.

**SEPTIC TANKS.**

- "Comments on the Design of Sludge Digestion Tanks." Richard H. Gould. (With Discussion.) 704.  
"The Sewage Disposal Works of Decatur, Illinois." Samuel A. Greeley and William D. Hatfield. (With Discussion.) 544.

**SEWAGE DISPOSAL.**

- "Comments on the Design of Sludge Digestion Tanks." Richard H. Gould. 704. Discussion: Harrison P. Eddy, John R. Downes, Willem Rudolfs, Edmund B. Besselievre, Jerry Donohue, and Kenneth Allen. 715.  
"Pre-Determining the Extent of a Sewage Field in Sea Water." A. M. Rawn and H. K. Palmer. 1036. Discussion: George W. Fuller, Kenneth Allen, R. F. Goudey, Warren E. Howland, and Harrison P. Eddy. 1061.  
"The — Works of Decatur, Illinois." Samuel A. Greeley and William D. Hatfield. 544. Discussion: George W. Fuller, and John F. Skinner. 594.

**SEWAGE TREATMENT.**

See **SEWAGE DISPOSAL.**

**SEWERAGE.**

- "County Sewer District Work in Ohio and Assessment of Cost According to Benefits." E. G. Bradbury. 445. Discussion: O. Bonney, R. F. MacDowell, F. D. Stewart, W. M. Olson, and Frank C. Tolles. 457.

**SILT.**

- " — Transportation by Sacramento and Colorado Rivers and by the Imperial Canal." C. E. Grunsky. 1104. Discussion: C. S. Howard, Harry F. Blaney, E. S. Lindley, Thaddeus Merriman, and Ivan E. Houk. 1134.

**SIPHONS.**

- "Stream Flow in General Terms." Melvin D. Casler. (With Discussion.) 1.

**SOILS.**

- "Drainage of Irrigated Lands." Report of the Committee of the Irrigation Division. (With Discussion.) 1425.
- "Experiments to Determine Rate of Evaporation from Saturated — and River-Bed Sands." Ralph L. Parshall. (With Discussion.) 961.
- "Foundations and Drainage of Highways." Albert C. Rose. 62. Discussion: Harry Tucker, Winslow H. Herschel, Charles Terzaghi, and D. P. Krynine. 85.

**SPILLWAYS.**

- "Experiments on Discharge Over — and Models, Keokuk Dam." Floyd A. Nagler and Albion Davis. (With Discussion.) 777.

**STRAIN.**

- "One Hundred Fifty Years Advance in Structural Analysis." H. M. Westergaard. (With Discussion.) 226.
